MORRIS'S

TREATISE ON ANATOMY

FIFTH EDITION

CONTRIBUTORS TO FIFTH EDITION

CHARLES R. BARDEEN, University of Wisconsin.

ELIOT R. CLARK, Johns Hopkins University.

IRVING HARDESTY, Tulane University of Louisiana.

C. M. JACKSON, University of Minnesota.

F. W. JONES, London School of Medicine for Women.

ABRAM T. KERR, Cornell University.

J. PLAYFAIR McMURRICH, University of Toronto.

JOHN MORLEY, Manchester University.

H. D. SENIOR, University and Bellevue Hospital Medical College., N. Y.

R. J. TERRY, Washington University, St. Louis.

PETER THOMPSON, University of Birmingham.

DAVID WATERSTON, King's College, London.

For arrangement of subjects and authors see page v.

THIS WORK IS ALSO PUBLISHED IN FIVE PARTS AS FOLLOWS:

PART I. Morphogenesis. Osteology. Articulations. Index. $1.50.
PART II. Muscles. Blood-Vascular System. Lymphatic System. Index. $2.50.
PART III. Nervous System. Special Sense Organs. Index. $2.00.
PART IV. Digestive System. Respiratory System. Skin, Mammary and Ductless Glands. Urogenital System. Index. $1.50.
PART V. Clinical and Topographical Anatomy. Index. $1.50.

MORRIS'S
HUMAN ANATOMY

A COMPLETE SYSTEMATIC TREATISE
BY ENGLISH AND AMERICAN AUTHORS

EDITED BY
C. M. JACKSON, M. S., M. D.
PROFESSOR AND DIRECTOR OF THE DEPARTMENT OF ANATOMY,
UNIVERSITY OF MINNESOTA

ELEVEN HUNDRED AND EIGHTY TWO ILLUSTRATIONS
THREE HUNDRED AND FIFTY EIGHT PRINTED IN COLOURS

FIFTH EDITION, REVISED AND LARGELY REWRITTEN

PHILADELPHIA

ARRANGEMENT OF SUBJECTS AND AUTHORS

The names of the more recent of those who wrote or revised articles for previous editions have been retained in the following list in order that due credit should be given them for the work done and for their share in the great success which Morris's "Anatomy" has achieved.

MORPHOGENESIS. Revised and largely rewritten for the fifth edition by C. M. Jackson, M.S., M.D., Professor of Anatomy in the University of Minnesota. Originally written by J. Playfair McMurrich, A.M., Ph.D., Professor of Anatomy, University of Toronto.

OSTEOLOGY. Revised for the third, fourth and fifth editions by Peter Thompson, M.D., Professor of Anatomy, University of Birmingham; Member of Anatomical Society of Great Britain. This article was originally written by Sir John Bland Sutton, F.R.C.S.

ARTICULATIONS. Revised for the fifth edition by Frederic Wood Jones, D.Sc., M.B., B.S. (Lond.), M.R.C.S., L.R.C.P., Head of the Department of Anatomy and Lecturer in the London School of Medicine for Women. Originally written by Sir Henry Morris, A.M., M.B.

MUSCLES. Rewritten and revised for the fourth and fifth editions by Charles R. Bardeen, A.B., M.D., Professor of Anatomy in the University of Wisconsin; Member Association of American Anatomists; Member of Editorial Board of "American Journal of Anatomy."

BLOOD-VASCULAR SYSTEM. Revised and in part rewritten by Harold D. Senior, M.B., F.R.C.S., Professor of Anatomy, University and Bellevue Hospital Medical College. The section on Blood-vessels was formerly revised by Florence R. Sabin, B.S., M.D., Associate Professor of Anatomy, Johns Hopkins University.

LYMPHATIC SYSTEM. Revised and partly rewritten for the fifth edition by Eliot R. Clark, A.B., M.D., Associate in Anatomy, Johns Hopkins University. Revised for previous edition by Florence R. Sabin, B.S., M.D.

NERVOUS SYSTEM. Revised and largely rewritten for the fourth and fifth editions by Irving Hardesty, A.B., Ph.D., Professor of Anatomy, Tulane University, Louisiana; Member Association of American Anatomists.

SPECIAL SENSE ORGANS. Revised for the fifth edition by David Waterston, M.A., M.D., F.R.C.S., Professor of Anatomy in the University of London. In the earlier edition, the Ear, Nose, Tongue were revised by Abram T. Kerr, B.S., M.D.

DIGESTIVE SYSTEM. Revised and largely rewritten for the fifth edition by C. M. Jackson, M.S., M.D., Professor of Anatomy, University of Minnesota. Revised for the fourth edition by G. Carl Huber, M.D.

RESPIRATORY SYSTEM. Revised for the fourth and fifth editions by R. J. Terry, A.B., M.D., Professor of Anatomy, Washington University, St. Louis; Member Association of American Anatomists.

UROGENITAL SYSTEM. Revised for the fourth and fifth editions by J. Playfair McMurrich, A.M., Ph.D., Professor of Anatomy, University of Toronto; Member Association of American Anatomists.

THE SKIN AND MAMMARY GLAND; THE DUCTLESS GLANDS. By Abram T. Kerr, B.S., M.D., Professor of Anatomy, Cornell University; Member Association of American Anatomists, etc. The article on the Ductless Glands was originally written by G. Carl Huber, M.D.

CLINICAL AND TOPOGRAPHICAL ANATOMY. By John Morley, Ch.M., F.R.C.S., Honorary Surgeon, Ancoats Hospital, Manchester, and Lecturer in Clinical Anatomy, Manchester University. Originally written by W. H. A. Jacobson, F.R.C.S.

EDITOR'S PREFACE TO THE FIFTH EDITION

One criticism upon most of the current text-books of human anatomy is that they are too extensive for the beginner. Much precious time is wasted by him in floundering through a mass of details which obscure the fundamental facts. And yet it is important to have these details conveniently accessible for both present and future reference. To meet this difficulty, the attempt is made in this edition to discriminate systematically in the use of sizes of type. The larger type is used for the more fundamental facts, which should be mastered first, and the smaller type for details. While it has been found difficult to apply this principle uniformly through the various sections, it is hoped that the plan, even though but imperfectly realized, will prove useful to the beginner.

In the illustrations of the bones, as heretofore, the origins of muscles are indicated by red lines, the insertions by blue lines, and the attachments of ligaments by dotted black lines.

While the authors of the present edition are for the most part the same as in the previous edition, a few changes have been made as noted under the preceding section, "Arrangement of Subjects and Authors." Owing to the retirement of the distinguished originator and former editor of this work, Sir Henry Morris, and of Professor McMurrich as co-editor, the responsibility for the general supervision of the fifth revision has fallen to the present editor.

Each author is alone responsible for the subject-matter of the article following his name. Care has been exercised on the part of the editor, however, to make the whole uniform, complete and systematic.

As to nomenclature, the Anglicised form of the BNA has been continued, excepting those cases where the Latin form is adopted into English (e. g., most of the muscles), and rare cases where the BNA term seems undesirable. As a rule, the Anglicised form where first used is followed by the BNA Latin term *in brackets*, except where the two are practically identical. For convenience of reference, some of the commoner synonyms of the old nomenclature are also added in parenthesis.

The previous edition of Morris's Anatomy was the first general text-book of anatomy in English to adopt the BNA. During the past few years the merit of this system of nomenclature has become so widely recognized that it is now very generally accepted among the English-speaking nations. Lack of space forbids the enumeration here of the many advantages of this system, not the least of which is the reduction of some 30,000 anatomical terms (including synonyms) to 5000. The comparatively few defects of the BNA will doubtless be remedied by revision (preferably through the International Anatomical Congress). For a full discussion of the BNA system, with complete list of the Latin terms and English equivalents, the reader is referred to the excellent work on the BNA by Professor L. F. Barker, of Johns Hopkins University.

In addition to the bibliographical references scattered throughout the text, a brief list is given at the close of each section. These brief lists of carefully selected references are intended merely as a guide to put the student "on track" of the original literature.

In addition to a thorough revision of the various sections, there has also been a rearrangement of a part of the subject matter in the present edition. The Teeth have been transferred from the section on Osteology to the Digestive System. The Tongue and Nose are transferred to the Digestive System and Respiratory System, respectively, excepting those portions forming the organs of Taste and Smell, which have been retained in the section on Special Sense Organs. The Pelvic Outlet has been discontinued as a separate section, the subject matter being divided between Musculature and Clinical and Topographical Anatomy. The Ductless Glands have been included in the section with the Skin and Mammary Glands.

Due credit has been given throughout the book wherever illustrations have been taken, or modified, from other works. Special acknowledgment should be made of our indebtedness to the works of Toldt, Rauber-Kopsch, Poirier and Charpy, Henle and Spalteholz.

The number of figures in the present edition has been increased about one hundred and sixty and in addition many of the older figures have been improved or replaced. For the generosity of the publishers in this connection, and for the hearty coöperation of the contributors in the revision of the various sections, the editor desires to express his deep indebtedness. Valuable assistance has been rendered by Mr. Walter E. Camp in the reading of proof and preparation of the index.

CLINICAL AND TOPOGRAPHICAL ANATOMY

By John Morley, Ch.M., F.R.C.S.

INTRODUCTION

By C. M. JACKSON, M.S., M.D.

PROFESSOR OF ANATOMY, UNIVERSITY OF MINNESOTA.

ANATOMY, as the term is usually employed, denotes the study of the structure of the human body. Properly, however, it has a much wider significance, including within its scope not man alone, but all animal forms, and, indeed, plant forms as well; so that, when its application is limited to man, it should be qualified by the adjective human. *Human Anatomy*, then, is the study of the structure of the human body, and stands in contrast to, or rather in correlation with, *Human Physiology*, which treats of the functions of the human body, the two sciences, Anatomy and Physiology, including the complete study of man's organization and functional activities.

In the early history of the sciences these terms sufficed for all practical needs, but as knowledge grew, specialization of necessity resulted and new terms were from time to time introduced to designate special lines of anatomical inquiry. With the improvement of the microscope a new field of anatomy was opened up and the science of *Histology* came into existence, assuming control over that portion of Anatomy which dealt with the minuter details of structure. So, too, the study of the development of the various organs gradually assumed the dignity of a more or less independent study known as *Embryology*, and the study of the structural changes due to disease was included in the science of *Pathology;* so that the term Anatomy is sometimes limited to the study of the macroscopic structure of normal adult organisms.

It is clear, however, that the lines of separation between Anatomy, Histology, Embryology, and Pathology are entirely arbitrary. Microscopic anatomy necessarily grades off into macroscopic anatomy; the development of an organism is a progressive process and the later embryonic or fœtal stages shade gradually into the adult; and structural anomalies lead insensibly from the normal to the pathological domains. Furthermore it is found that in its individual development the organism passes through stages corresponding to those of its ancestry in evolution; in other words, Ontogeny repeats Phylogeny. A comprehensive study of Anatomy must therefore include more or less of the other sciences, and since an appreciation of the significance of structural details can only be obtained by combining the studies of Anatomy, including Histology and Embryology, and since, further, much light may be thrown on the significance of embryological stages by comparative studies, Anatomy, Embryology, and Comparative Anatomy form a triumvirate of sciences by which the structure of an organism, the significance of that structure, and the laws which determine it are elucidated. For this combination it is convenient to have a single term, and that which is used is *Morphology*, a word meaning literally the science of form.

In morphological comparisons, the term *homology* denotes similarity of structure, due to a common origin in the evolution of organs or parts; while *analogy* denotes merely physiological correspondence in function. Thus the arm of man and the wing of a bird are homologous, but not analogous, structures; on the other hand, the wing of a bird and the wing of an insect are analgous, but not homologous. *Serial homology* refers to corresponding parts in successive segments of the body.

Nomenclature.—Formerly there was much confusion in the anatomical nomenclature, due to the multiplicity of names and the lack of uniformity in using them. Various names were applied to the same organs and great diversity of usage prevailed, not only between various countries, but also even among authors of the same country. Recently, however, a great improvement has been made by the general adoption of an international system of anatomical nomenclature. This system was first adopted by the German Anatomical Society at a meeting in Basel, in 1895, and is hence called the Basel Nomina Anatomica, or briefly, the BNA. The BNA provides each term in Latin form, which is especially desirable for international usage. Each nation, however, is expected to translate the terms into its own language, wherever it is deemed preferable for everyday usage. Thus in the present work the Anglicised form of the BNA is generally used. Where not identical, however, the Latin form is added once for each term in a place convenient for reference, and is designated by enclosure in brackets [ ]. Where necessary the older terms have also been added as synonyms.

The Commission by whom the BNA was prepared included eminent anatomists representing various European nations. The work of the Commission was very thorough and careful, and extended through a period of six years. Among the guiding principles in the difficult task of selecting the most suitable terms were the following: (1) Each part should have one name only. (2) The names should be as short and simple as possible. (3) Related structures should have similar names. (4) Adjectives should be in opposing pairs. A few exceptions were found necessary, however.

On account of its obvious merits, the BNA system has been generally adopted throughout the civilised world, and the results are very satisfactory. Comparatively few new terms have been thereby introduced, over 4000 of the 4500 names in the BNA corresponding almost exactly to older terms already in use by the English-speaking nations. Certain minor defects in the system have been criticised; but these are outweighed by the advantages of this uniform system.

Abbreviations.—Certain frequently used words in the BNA are abbreviated as follows: a., arteria (plural, aa., arteriæ); b., bursa; g., ganglion; gl., glandula; lig., ligamentum (plural, ligg., ligamenta); m., musculus (plural, mm., musculi); n., nervus (plural, nn., nervi); oss., ossis (or ossium); proc., processus; r., ramus (plural, rr., rami); v., vena (plural, vv., venæ).

Terms of position and direction.—The exact meaning of certain fundamental terms used in anatomical description must be clearly understood and kept in mind. In defining these terms, it is supposed that the human body is in an upright position, with arms at the sides and palms to the front.

The three **fundamental planes** of the body are the sagittal, the transverse and the frontal. The vertical plane through the longitudinal axis of the trunk, dividing the body into right and left halves, is the *median* or *mid-sagittal* plane; and any plane parallel to this is a *sagittal* plane. Any vertical plane at right angles to a sagittal plane, and dividing the body into front and rear portions is a *frontal* (or coronal) plane. A plane across the body at right angles to sagittal and coronal planes is a *transverse* or *horizontal* plane.

Terms pertaining to the front of the body are *anterior* or *ventral*; to the rear, *posterior* or *dorsal*; upper is designated as *superior* or *cranial*; and lower as *inferior* or *caudal*.

The term *medial* means nearer the mid-sagittal plane, and *lateral*, further from that plane. These terms should be carefully distinguished from internal (inner) and external (outer), which were formerly synonymous with them. *Internal*, as now used (BNA), means deeper, i. e., nearer the central axis of the body or part; while *external* refers to structures more superficial in position. *Proximal*, in describing a limb, refers to position nearer the trunk; while *distal* refers to a more peripheral position.

Adverbial forms are also employed, e. g., anteriorly or ventrally (forward, before); posteriorly or dorsally (backward, behind); superiorly or cranially (upward, above); and inferiorly or caudally (downward, below).

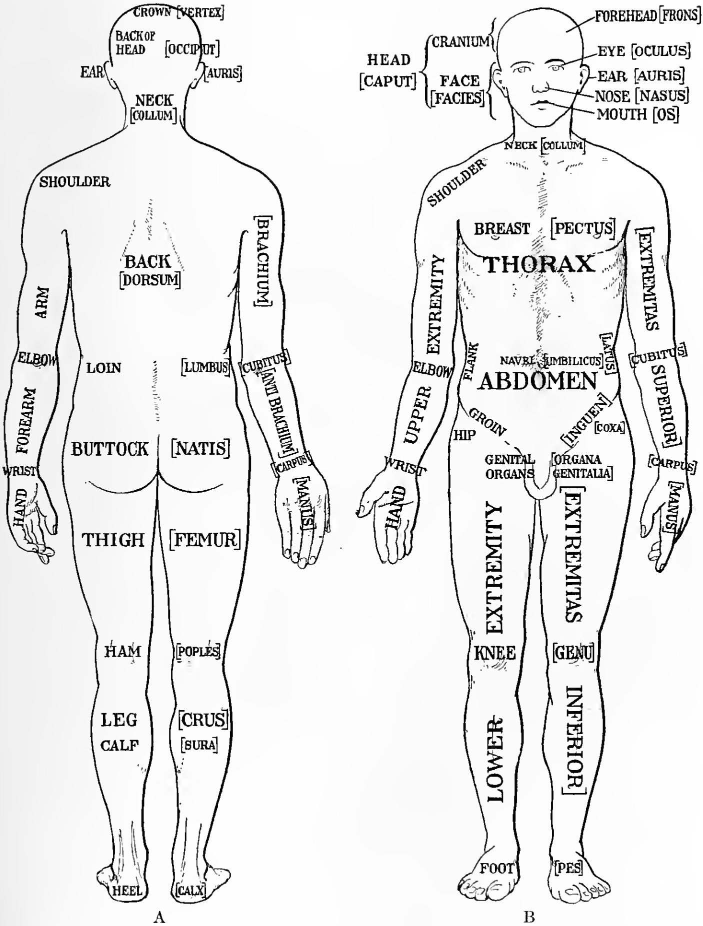
It should also be noted that the terms ventral, dorsal, cranial and caudal are independent of the body posture, and therefore apply equally well to corresponding surfaces of vertebrates in general with horizontal body axis. On this account these terms are preferable, and will doubtless ultimately supplant the terms anterior, posterior, superior and inferior.

The discrimination in the use of several similar terms of the BNA should also receive attention. Thus *medianus* (median) refers to the median plane. *Medialis* (medial) means nearer the median plane and is opposed to lateral, as above stated. *Medius* (middle) is used to designate a position between anterior and posterior, or between internal and external. Between medialis and lateralis, however, the term *intermedius* is used. Finally, *transversalis* means transverse to the body axis; *transversus*, transverse to an organ or part; and *transversarius*, pertaining to some other structure which is transverse.

Parts of the body.—The primary divisions of the human body (fig. 1) are the head, neck, trunk and extremities. The *head* [caput] includes *cranium* and *face* [facies]. The *neck* [collum] connects head and trunk. The *trunk* [truncus] includes *thorax*, *abdomen*, and *pelvis*. The *upper extremity* [extremitas superior] includes *arm* [brachium], *forearm* [antibrachium], and *hand* [manus]. The *lower extremity* [extremitas inferior] includes *thigh* [femur], *leg* [crus], and *foot* [pes].

Each of the parts mentioned has further subdivisions, as indicated in fig. 1. The cranium includes: *crown* [vertex]; *back* of the head [occiput]; *frontal* region [sinciput], including *forehead* [frons]; *temples* [tempora]; *ears* [aures], including *auricles* [auriculæ].

Fig. 1.—Parts of the Human Body. A, Posterior view. B, Anterior view.



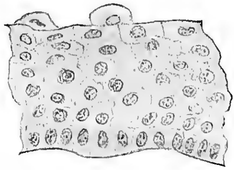
The face includes the regions of the *eye* [oculus], *nose* [nasus], and *mouth* [os], the subdivisions of which will be given later under the appropriate sections.

The thorax includes: *breast* [pectus]; *mammary gland* [mamma]; and *thoracic cavity* [cavum thoracis]. The *back* [dorsum] includes the vertebral column [columna vertebralis]. The abdomen includes: *navel* [umbilicus]; *flank* [latus]; *groin* [inguen]; *loin* [lumbus]; and the *abdominal cavity* [cavum abdominis]. The pelvis includes: *pelvic cavity* [cavum pelvis]; *genital organs* [organa genitalia], *buttocks* [nates], separated by a cleft [crena ani] at the *anus*. The *hip* [coxa] connects the pelvis with the lower extremity.

In the lower extremity, the thigh is joined to the leg by the *knee* [genu]. The foot includes: *heel* [calx]; *sole* [planta]; *instep* [tarsus]; *metatarsus;* and five *toes* [digiti I–V], including the *great toe* [hallux] and *little toe* [digitus minimus].

The upper extremity is joined to the thorax by the *shoulder*. The arm is joined to the forearm at the *elbow* [cubitus]. The hand includes: *wrist* [carpus];

Fig. 2.—Section of the Epidermis of a Finger, from a Human Embryo of 10.2 cm.

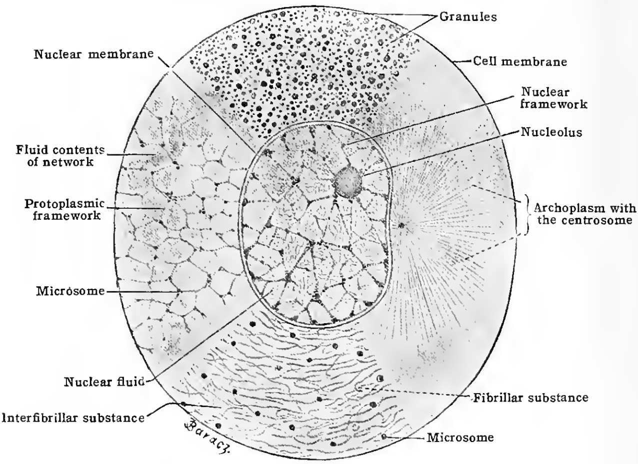


metacarpus, with *palm* [vola or palma] and *back* [dorsum manus]. The five *fingers* [digiti I–V] include: *thumb* [pollex], *index* finger [index]; *middle* finger [digitus medius]; *ring* finger [digitus annularis] and *little* finger [digitus minimus].

Organ-systems.—Each of the various parts of the body above outlined is composed of various *organs*, and the groups of related organs make up *organ-systems*.

The various organ-systems are treated as special branches of descriptive anatomy. The study of the *bones* is called *osteology;* of the *ligaments* and *joints*,

Fig. 3.—Diagram of a Typical Cell. (Szymonowicz.)



syndesmology (or arthrology); of the *vessels*, *angiology*; of the *muscles*, *myology;* of the *nervous system*, *neurology*; and of the *viscera*, *splanchnology*. Further subdivisions are also made. The viscera, for example, include the *digestive* tract, *respiratory* tract, *urogenital* tract, etc.

Tissues and cells.—The body, as above stated, has various parts, each of which may be subdivided into its component systems and organs. A further analysis reveals a continued series of structural units of gradually decreasing complexity. Thus each organ is found to consist of a number of *tissues* (epithelial, connective, muscular or nervous). Finally, each tissue is composed of a group of similar units called *cells* (figs. 2, 3) which are the ultimate structural units of the body. The body may therefore be regarded as composed of myriads of cell units, organized into units of gradually increasing complexity, very much as a social community is composed of individuals organized into trades, municipalities, etc.

Most of the individual tissues can be recognized by their gross appearance. In fact, the principal tissues were first demonstrated by Bichat through skilful dissection, maceration, etc., and without the aid of the microscope. The cellular structure of the tissues was later discovered by Schwann in 1839.

Each cell (fig. 3) is composed of a material called *protoplasm*, a viscid substance variable in appearance and exceedingly complex in chemical composition. It readily breaks down into simpler chemical compounds, whereby energy (chiefly in the form of heat and mechanical energy) is liberated. It has also the power of absorbing nutritive material to build up and replace what was lost. Its decomposition results from stimuli of various kinds, and hence it is said to be irritable. The mechanical energy which it liberates is manifested by its contractility, especially in the muscle cells. It excretes the waste products produced by its decomposition. Each cell has the power, under favourable conditions, of reproducing itself by division. Protoplasm presents, in short, all the forms of activity manifested by the body as a whole; and, indeed, the activities of the body are the sum of the activities of its constituent cells.

In the protoplasm of each cell is a specially differentiated portion, the *nucleus* (fig. 3). The nucleus plays an important part in regulating the activities of the *cytoplasm*, the general protoplasm of the cell body. The nucleus differs from the cytoplasm both structurally and chemically, and contains a very important substance, *chromatin*, which during cell division is aggregated into a definite number of masses called *chromosomes*. The cytoplasm of actively growing cells also contains the *archoplasm* and *centrosome*, structures of importance in the process of cell division. Further details concerning the cells and tissues may be found in the text-books of cytology and histology.

In earlier days Human Anatomy was almost entirely a descriptive science, but little attention being paid to the significance of structure, except in so far as it could be correlated with physiological phenomena as they were at the time understood. In recent years attention has been largely paid to the morphology of the human body and much valuable information as to the meaning of the structure and relations of the various organs has resulted. Since the form and structure of the body are the final result of a series of complicated developmental changes, the science of Embryology has greatly contributed to our present knowledge of human Morphology; and, accordingly, a brief sketch of some of the more important phases of morphogenesis will form a fitting introduction to the study of the adult.

References.—*General:* For looking up the literature upon any anatomical topic, the best guide is the "Jahresbericht ueber die Fortschritte der Anatomie und Entwicklungsgeschichte," which contains classified titles and brief abstracts of the more important papers in gross anatomy, histology and embryology. Other useful aids are the "Zentralblatt fuer normale Anatomie," the "Index Medicus" and the catalogue of the Surgeon Genera 's Library of the War Dep't. (Washington, D. C.). The latter two contain titles only, but cover the whole field of medicine. The "Concilium Bibliographicum" also provides a convenient card-index system of references for the biological sciences, including Anatomy.

For *nomenclature:* His, Archiv f. Anat., 1895 (BNA system); Barker, Anatomical Nomenclature. *Cells and tissues:* Wilson, The Cell; Hertwig, Zelle und Gewebe (also English transl.); Schaefer, Microscopic Anatomy (in Quain's Anatomy, 11th ed.); Heidenhain, Plasma und Zelle.

SECTION I

MORPHOGENESIS

REVISED FOR THE FIFTH EDITION

By C. M. JACKSON, M.S., M.D.

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF MINNESOTA

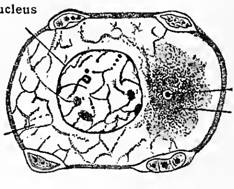
CHANGE is a fundamental characteristic of all living things. The human body during its life cycle accordingly passes through various phases of form and structure. In the earliest embryonic phases of development the changes are very rapid, decreasing in rapidity during the later fœtal stages, but continuing at a diminishing rate throughout infancy, childhood and youth up to the adult. Following the acme of maturity, changes continue which lead gradually to senescence and final death of the body.

This cycle of change in the body depends upon similar changes in its various component organs, each having its own characteristic life cycle. In a few of the organs this cycle is very short, as in some of the organs of the embryo (e. g., mesonephros). Other organs persist only during childhood (e. g., thymus); while the majority continue, with varying degrees of change, throughout postnatal life. The final death of the body is due to the breakdown of some of the essential organs.

A further analysis reveals the fact that the characteristic life cycles of the organs depend ultimately upon similar changes in their constituent tissues and cells. Every cell has a definite life cycle, an early period characterised by rapid and vigourous changes, later periods of differentiation and maturity, followed by stages of degeneration and death. This cycle of cell changes has been designated by Minot as *cytomorphosis*.

Growth.—Associated with the process of cell differentiation (cytomorphosis), and even more important as a factor in the morphogenesis of the body, is the process of *growth*. The developmental changes in form and structure of the body are due largely to the unequal growth of its various parts. Growth, like other changes in the body and its parts, depends ultimately upon the characteristics of the constituent cells.

FIG. 4.—THE OVUM OF A NEW-BORN CHILD, WITH FOLLICLE CELLS. (After Mertens.)



The cell changes during growth may be grouped under two heads. The first, or growth proper, involves merely the *enlargement* (hypertrophy) of the individual cells and intercellular products. The second includes the *multiplication* (hyperplasia) of the cells, which is accomplished by mitotic division. Cell division is necessary in cell growth, for otherwise the cell would soon reach a size where its surface (for nutritive, respiratory and excretory purposes) would be inadequate for its mass. In general, however, cell division is most active in the earlier embryonic periods, during which the cells remain small. Later, cell division diminishes or ceases, and growth is due chiefly to enlargement of the cells already present. It is also during the later period, when the cells have ceased rapid division, that the process of cell differentiation and tissue formation is most marked.

The principle of the *ratio of surface to mass* often applies to the growing organs as well as to the individual cells. To maintain the necessary ratio, the surface area is increased by the formation, through localised unequal growth, of *projections* (e. g., villi or folds) or *invaginations* (e. g., glands) from surfaces. Innumerable modifications of this principle occur throughout the process of morphogenesis.

Fig. 5.—Ovum from Ovary of a Woman Thirty Years of Age. *cr*, corona radiata. *n*, nucleus. *y*, yolk. *p*, clear protoplasmic zone, *ps*, perivitelline space. *zp*, zona pellucida. (McMurrich's Embryology, from Nagel.)

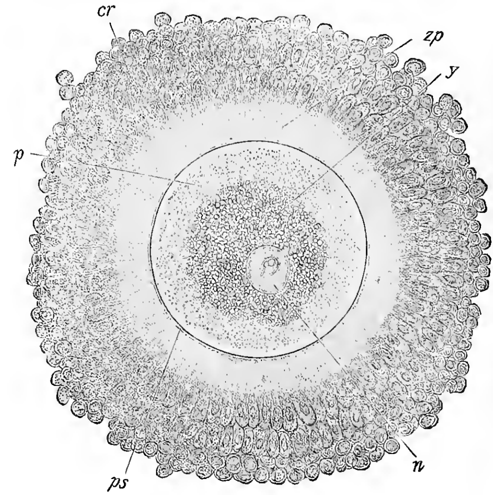


Fig. 6.—Stages of Segmentation in the Ovum of the Mouse. *x*, polar body. (McMurrich's Embryology, from Sobotta.)

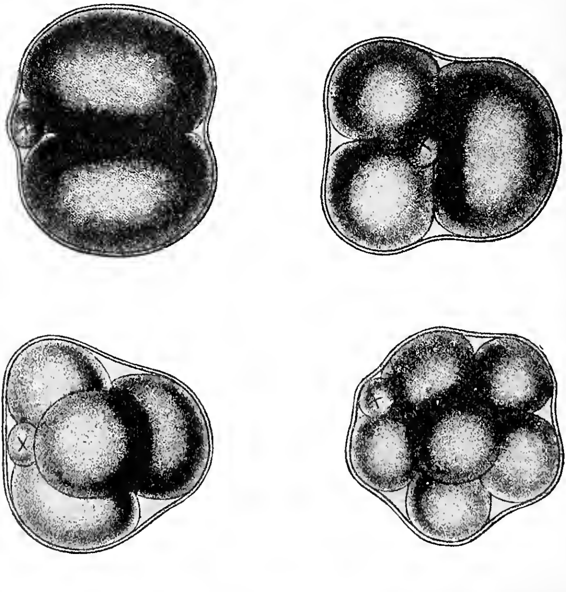

While the present work deals primarily with the adult human organism in the stage of maturity, reference is made also to its changes according to age. Although these changes for the various systems of organs are described under the appropriate sections, it is desirable to consider first some of the more fundamental features pertaining to the body as a whole. This applies particularly to the earlier embryonic period, which includes the more general phases of morphogenesis. No attempt will be made to describe fully the process of development, the details of which are to be found in text-books of embryology.

Segmentation of the ovum.—The human body, like all living organisms, arises from a single cell, the egg-cell or *ovum*. An early stage in the development of the ovum is shown in fig. 4, and a later stage, approaching maturity, in fig. 5. The mature human ovum is about 0.2 mm. in diameter. In the uterine (Fallopian) tube, the fertilised ovum undergoes segmentation, the various stages of which are represented in figs. 6 and 7.

Fig. 7.—Diagram of Section through a Mammalian Ovum at the Morula Stage.

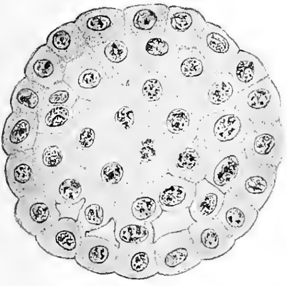

Fig. 8.—Diagram of Section of a Mammalian Ovum Showing the Inner Cell Mass.

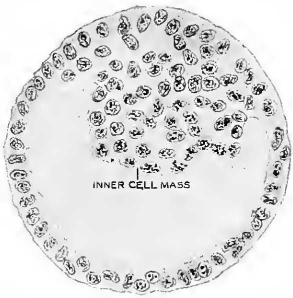
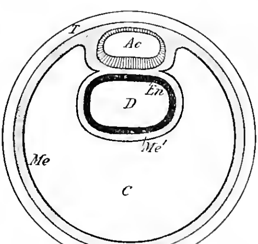


While the processes of maturation, fertilisation and segmentation have not as yet been observed in the human ovum, the evidence of comparative anatomy makes it very probable that in all essential respects these processes are like those found in other mammals. As a result of the successive divisions of the ovum in segmentation, a spherical mass of cells, the *morula* (fig. 7) is formed. In this mass, an excentric cavity forms (fig. 8) whereby the mass is transformed into a hollow vesicle. The wall of this vesicle is probably formed throughout the greater part of its extent by a single layer of cells; but at one point of the circumference there is a group of cells termed the *inner cell mass* (fig. 8). Probably about this time the ovum enters the uterine cavity, and through the activity of the outer layer of cells (*trophoblast*) becomes embedded in the uterine mucosa.

Formation of the embryonic disc and germ layers.—In the earliest human embryos which have been described, development has already proceeded beyond

Fig. 9.—Diagram Showing the Relations of the Germ Layers in an Early Embryo. *Ac*, amniotic cavity, lined by ectoderm. *D*, yolk-sac, lined by endoderm (*En*). *Mc,Me'*, mesoderm, *C*, extra-embryonic cœlom. *B*, chorion. *T*, trophoblast. (McMurrich.)

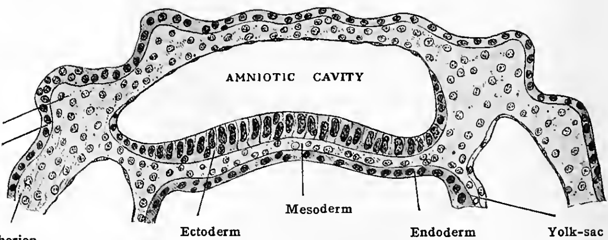


the stage represented by fig. 8, and has reached that of fig. 9. Within the inner cell mass, two cavities have appeared. The more superficial (ac) is the *amniotic* *cavity;* the deeper (D) is the cavity of the *yolk-sac;* while between them is a plate of cells forming the *embryonic disc.* The embryonic disc (figs. 9 and 10) contains three layers of cells,—the fundamental *germ layers,—ectoderm* (Ec), *endoderm* (En), and *mesoderm.*

The germ layers of the embryonic disc are of prime importance in the development of the body. From the *ectoderm,* which lies next to the amniotic cavity and represents the upper (later outer) germ layer, are derived the epidermis and the entire nervous system. From the *endoderm,* which lies next to the yolk-sac, and represents the lower (later inner) germ layer, is derived the epithelial lining of the digestive mucosa and its derivatives. From the *mesoderm,* or middle germ layer, is differentiated the remainder of the body, including the skeletal and supporting tissues, vascular system, muscle and most of the urogenital organs.

The germ layers also extend beyond the embryonic disc, as shown in figs. 9 and 10. The *yolk-sac* is made up of a lining of endoderm and an outer layer of mesoderm. The *amnion,* which later becomes separated from the chorion, is composed of mesoderm lined by endoderm. The outer cell layers form the *chorion,* which likewise shows two layers, the outermost of which (trophoblast) is ectoderm, the inner, mesoderm. In fig. 10 the chorion is beginning to send out root-like projections (villi) which invade the uterine mucosa.

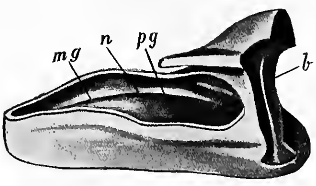
FIG. 10.—DIAGRAM OF SECTION OF A MAMMALIAN OVUM SHOWING THE EMBRYONIC DISC, AMNIOTIC CAVITY AND THE GERM LAYERS.



It is thus noteworthy that of the cells derived from the ovum relatively only a few—those of the embryonic disc—enter directly into the formation of the body. The yolk-sac, a rudimentary organ of phylogenetic significance, is later chiefly absorbed, although the proximal portion may enter slightly into the formation of the intestinal wall. The amnion is a protective membrane, while the chorion forms the fœtal part of the placenta.

Development of the embryonic disc.—When first formed, the surface of the embryonic disc shows no trace of differentiation. A slightly later but still comparatively early stage in its development is shown in fig. 11. It is here viewed from above, the amnion having been removed. The disc is an elliptical plate, whose long axis represents the mid-line of the embryo. Near the center is a small rounded depression, the *primitive pit.* Extending backward (toward the tail end of the embryo) from this is a dark line, the *primitive streak,* corresponding to a groove, the *primitive groove.* Extending forward from the primitive pit is an indistinct wide shallow groove, the *neural groove.*

FIG. 11.—MODEL SHOWING THE EMBRYONIC DISC FROM AN EMBRYO 1.17 MM. IN LENGTH. Viewed from above and laterally, the roof of the amniotic cavity having been removed. *n,* primitive pit (neurenteric canal). *pg,* primitive groove. *mg,* neural groove. *b,* body-stalk. (McMurrich. from Frassi.)

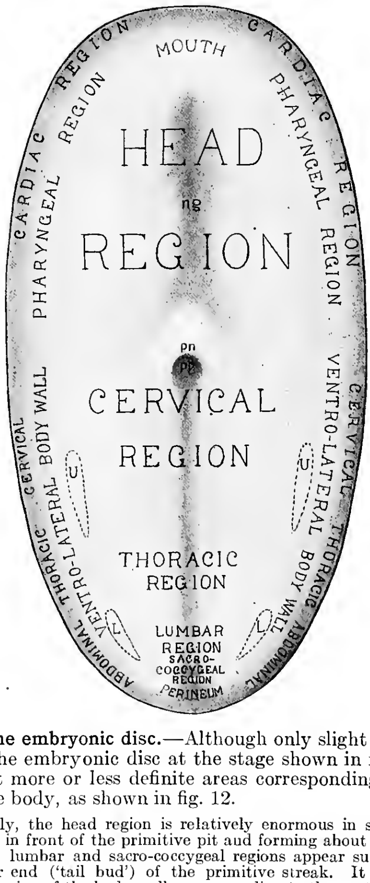


At an earlier stage, the primitive streak extends further forward, possibly to the anterior end of the embryonic disc (Spee). The primitive streak and groove probably correspond to the fused lips of a primitive blastopore. They represent a centre of proliferation from which the mesoderm is budded off from the ectoderm and spreads out to form the middle germ layer of the embryonic disc.

At the anterior end of the primitive streak this proliferation extends forward as a plate of cells, the so-called *'head process.'* The axial portion of this process is the anlage of the *notochord*, the embryonic skeletal axis. It contains a canal, which opens into the primitive pit. The notochordal anlage soon fuses with the underlying endoderm, and its canal forms the transient *neurenteric canal.*

In the mid-line anterior to the primitive streak there appears the shallow *neural groove* (fig. 11), corresponding to a thickened plate of ectodermic cells, the *neural plate.* The neural groove is slightly forked at its posterior extremity, in the region of the *primitive node* (Hensen's node), which forms the dorsal lip of the primitive pit. As development proceeds, the neural plate extends posteriorly, and the primitive pit is accordingly shifted backward, the corresponding part of the primitive groove being converted into 'head process.' The primitive streak thus becomes progressively shortened (cf. figs. 11 and 13).

FIG. 12.—TOPOGRAPHY OF THE EMBRYONIC DISC. DIAGRAM OF RELATIONS AT THE LENGTH OF ABOUT 1 MM. *ng*, neural groove. *pn*, primitive node. *pp*, primitive pit. *U*, upper limb. *L*, lower limb.



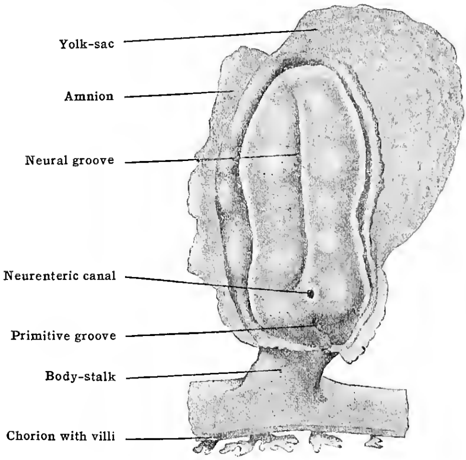
Topography of the embryonic disc.—Although only slight signs of differentiation are visible in the embryonic disc at the stage shown in fig. 11, it is already possible to map out more or less definite areas corresponding to all the various regions of the future body, as shown in fig. 12.

Beginning anteriorly, the head region is relatively enormous in size, occupying at this time the entire portion in front of the primitive pit and forming about half of the entire disc. The cervical, thoracic, lumbar and sacro-coccygeal regions appear successively smaller, approaching the posterior end ('tail bud') of the primitive streak. It is also a striking fact that the future dorsal region of the body wall, corresponding to the central portion of the disc, along each side of the mid-line, is now larger than the ventro-lateral regions, which occupy a relatively narrow area around the periphery of the disc.

The topography of the germinal areas in the embryonic disc shown in fig. 12 is based partly upon a study of the succeeding stages of development, and partly upon the results of experiments upon the germinal disc in lower forms, especially in the chick (Assheton, Peebles, Kopsch).

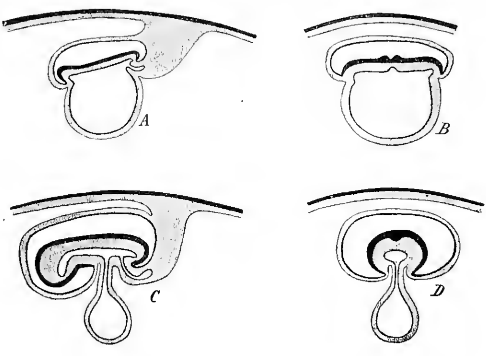
Law of developmental direction.—In the relative size of the various embryonic areas is foreshadowed what may be termed the law of direction in development. In general it is found that development (including growth and differentiation) in

FIG. 13.—HUMAN EMBRYO 1.54 mm. long. Viewed from above, the roof of the amniotic cavity having been removed. (Minot, after Graf Spee.)



the long axis of the body appears first in the head region and progresses toward the tail region. Similarly in the transverse plane development begins in the mid-dorsal region and progresses latero-ventrally (in the limbs, proximo-distally). These principles are of great importance in morphogenesis.

FIG. 14.—DIAGRAMS SHOWING THE CONSTRICTION OF THE EMBRYO FROM THE YOLK-SAC. *A* and *C*, longitudinal sections; *B* and *D*, corresponding cross-sections. (McMurrich.)

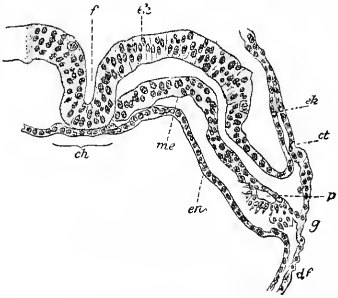


The law of developmental direction is also probably of phylogenetic significance. The *cranio-caudal* direction of development is in accordance with the theory that the head is the most primitive portion of the body, and hence precocious in development. The trunk is perhaps a secondary acquisition, hence arising as an extension of the primitive head region.

The *dorso-ventral* direction of development, together with the plate-like form of the embryonic disc, has a different phylogenetic significance. Both are probably inherited from an ancestral type with a yolk-laden ovum. In such an ovum, with the meroblastic type of segmentation, the flattened embryonic disc gradually spreads from the dorsal surface in a ventral direction around the underlying yolk-mass.

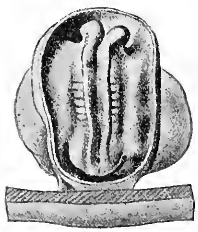
Derivation of body tube from embryonic disc.—The primary result of the precocious growth in the dorsal region of the embryonic disc is the conversion of the disc into the body tube, curved ventrally in its long axis (fig. 14).

Fig. 15.—Portion of Cross Section of the Embryo shown in Fig. 13. *ch*, notochord. *ct*, somatic mesoderm. *df*, splanchnic mesoderm. *g*, junction of extra-embryonic somatic and splanchnic mesoderm. *ek*, ectoderm. *en*, endoderm. *me*, embryonic mesoderm. *f*, neural groove, *p*, beginning of embryonic cœlom (pericardial cavity). (Minot, after Graf Spee.)



As a result of the more rapid expansion of the germ layers (especially the ectoderm) near the mid-line, the dorsal surface of the embryonic disc in general becomes convex, with a depression laterally (where growth is less rapid) forming a groove at the line of attachment of the amnion (figs. 11, 12, 13, 14 B). The unequal growth in the germ layers is clearly evident in the cross section shown in fig. 15. By a continuation of this process, the margins of the embryonic disc become still further depressed and finally folded in ventrally so as to transform the disc into a tube (fig. 14 D). Similarly, by a more rapid expansion of the dorsal layer of the disc in the longitudinal axis, the head and tail ends of the disc are folded and tucked in ventrally, and the primitive body tube is thus correspondingly curved in its long axis (figs. 14 A, 14 C).

Fig. 16.—Model of Human Embryo 1.8 mm. Long. Viewed from above, the roof of the amniotic cavity having veen removed. Near the caudal end of the neural groove, the primitive pit (opening of neurenteric canal) is visible. The primitive somites are appearing in the occipital region, the fourth corresponding to the boundary between head and neck. (McMurrich, from Keibel and Elze.)



The embryonic disc is thus converted into a tube composed of an outer layer of ectoderm, a middle layer of mesoderm and an inner layer of endoderm. The yolk-sac now presents an expanded *yolk-vesicle* lined by endoderm which is still continuous through the constricted *yolk-stalk* with the endoderm lining the primitive *enteric cavity* (fig. 14 C). The enteric cavity (or archenteron) has a blind tubular prolongation (fore gut) into the head region, and another (hind gut) into the tail region. From the latter a slender diverticulum, the *allantois*, extends into the body stalk (later the umbilical cord). The allantois is an organ of phylogenetic importance, with which the urinary bladder is later connected.

Formation of the neural tube.—The principle of unequal growth applies to the formation not only of the body as a whole, but also of its constituent parts. Thus the anlage of the nervous system arises from the ectoderm as a wide groove whose edges (neural ridges) by local growth are folded upward so as to meet in the mid-line where they fuse, thus transforming the groove into the *neural tube* (figs. 11, 12, 13, 15, 16, 17, 18).

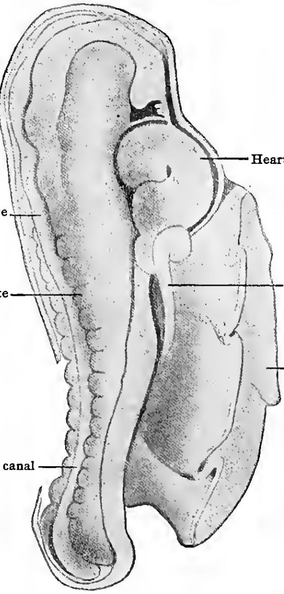
The closure begins, not at the anterior end (as might be expected from the general law of cranio-caudal development), but in the cervical region, extending forward into the brain region, and backward along the spinal cord. Thus the extreme ends (anterior and posterior neuropores) are the last to close.

The precocious and energetic growth of the neural anlage is largely responsible for the ventral flexure of the embryonic body axis, especially in the head region, where the flexures of the brain are very conspicuous (figs. 22, 26).

With the closure of the neural tube dorsally and of the alimentary canal ventrally the human embryo assumes the typical vertebrate form. The cylindrical body wall now encloses two tubes (neural and enteric) with the longitudinal axis (notochord) between them (figs. 18, 24).

After the embryonic disc has been transformed into a tube, the body of the human embryo in cross section appears not circular but elongated dorso-ventrally. This is the typical form for vertebrates with horizontal body axis. In later fœtal stages, the body becomes more rounded in cross section, and finally, with the assumption of the erect posture in postnatal life, becomes decidedly flattened dorso-ventrally (figs. 20, 21).

FIG. 17.—A HUMAN EMBRYO 2.5 MM. IN LENGTH. (After Kollmann.)



Development of the mesoderm.—The mesodermic layer on each side of the notochord in the embryonic disc develops in two divisions. The medial (or dorsal) divisions form a series of hollow segments, the *somites* (figs. 16, 17, 18). The lateral (later ventral) divisions each split into an upper (outer) or somatic layer and a lower (inner) or visceral layer. When the embryonic disc becomes folded, the corresponding somatic and visceral layers unite ventrally and enclose between them the common *cœlom* or primitive body cavity (fig. 18).

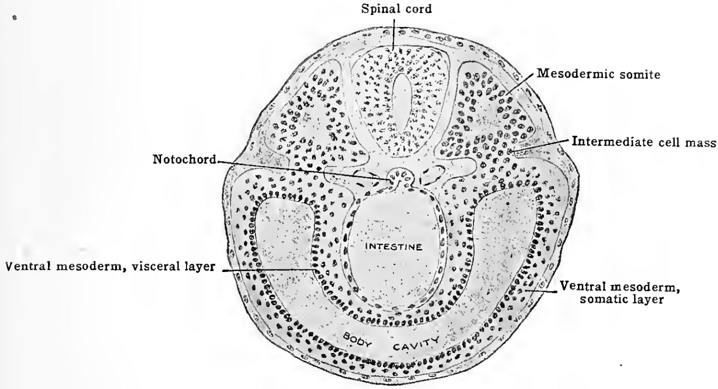
As previously noted, the mesoderm arises chiefly from the lateral portions of the 'head process.' A comparatively early stage before the appearance of the somites is shown in cross section in fig. 15. The somites appear first in the occipital region, and rapidly differentiate successively in the cranio-caudal direction (figs. 16, 17, 22). In embryos 7 or 8 mm. in length, about 40 somites may be distinguished, 3 to 5 occipital, 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 5 or 6 coccygeal (in the rudimentary tail region).

The *cœlom* or body cavity is unsegmented. Two primitive pericardial cavities appear separate at first, but soon fuse and unite with the general cœlom. Later the general cœlom becomes secondarily divided into the permanent pericardial, pleural and peritoneal cavities.

The outer layer of the lateral mesodermic division forms the somatic or parietal layer of the peritoneum, etc. The inner layer forms the visceral or splanchnic layer, and develops not only the serous membrane, but also the muscular and connective tissue of the walls of the alimentary canal and its derivatives.

Development of the somites. Metamerism.—The appearance of the somites marks the beginning of *metamerism*, the arrangement of the body in successive

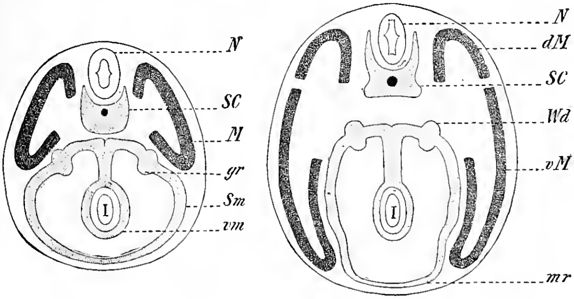
FIG. 18.—DIAGRAM OF A CROSS SECTION OF A HUMAN EMBRYO.



segments or metameres. Each somite develops a primitive muscle segment, *myotome*, and a skeletal segment, *sclerotome* (figs. 18, 19). Moreover, the corresponding nerves and blood-vessels likewise assume a metameric arrangement. This metamerism persists (more or less modified) in the adult neck and trunk.

The differentiation of the somites is illustrated by figs. 18 and 19. The medial wall of each somite forms the *sclerotome*. Its cells migrate to form the corresponding vertebra, rib, etc., as

FIG. 19.—DIAGRAMS ILLUSTRATING THE HISTORY OF THE MESODERM. *M*, myotome, *dM*, dorsal portion of myotome. *vM*, ventral portion of myotome. *SC*, sclerotome. *gr*, genital ridge. *Wd*, Wolffian duct. *Sm*, somatic layer of mesoderm. *vm*, visceral layer of mesoderm. *mr*, membrana reuniens. *I*, intestine. *N*, neural tube. (McMurrich.)



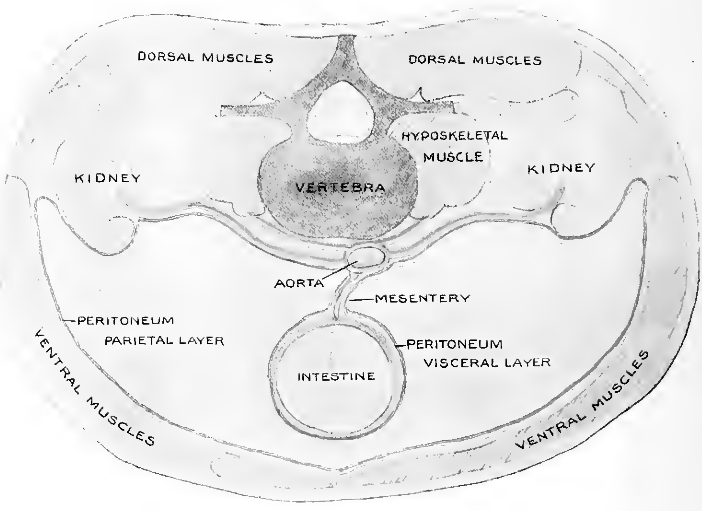
well as the *mesenchyme* forming the various connective tissues in this region. The remainder of the somite forms the *myotome*, from which the voluntary musculature of the trunk, the neck and (in part) the head is derived. The dorsal portions of the myotomes develop the muscle in the dorsal region of the trunk, while the ventral portions extend ventralward to form the musculature of the latero-ventral body walls (figs. 19, 20, 21, 23).

At the junction of the dorsal and ventral divisions of the mesoblast is a group of cells called the *intermediate cell mass.* This mass becomes segmented (corresponding to the somites) and each segment, or *nephrotome*, gives rise to a portion of the *mesonephros*, the provisional kidney. Other cells of the mass become *mesenchyme*, which is converted into blood-vessels, connective tissue, etc.

As development proceeds, the metamerism of the muscles and arteries becomes more or less obscured, but that of the vertebræ and nerves is fully retained even in the adult. In the case of the muscle plates, from which all the voluntary musculature of the trunk is derived, great modifications occur. Extensive fusion of successive plates occurs, the intervening connective tissue disappearing more or less completely; associated with this fusion there is longitudinal and tangential splitting of the somites to form individual muscles; and portions of some of the plates may wander far from their original position. But notwithstanding these complicated changes, indications of the primary metameric arrangement of the muscle plates are abundant, and even in the most extreme cases of modification the developmental history of a muscle can be determined by means of its nerve supply. For the fibres derived from each plate will usually retain, no matter what changes of independence or position they may undergo, the innervation by their originally corresponding segmental nerve; so that the occurence in the lumbar region of the body of muscle-fibres (the diaphragm) supplied by nerve-fibres from a cervical nerve is evidence that the muscle-fibres have been derived from a cervical mesodermic somite and have subsequently migrated to the position they finally occupy.

As regards the arteries, they arise primarily from a longitudinal stem, the aorta, in a strictly segmental manner, each metamere having distributed to it two pairs of arteries and a single median one (fig. 20). One pair of arteries supplies the body wall, and these retain very distinctly their original metameric arrangement; the other pair passes to the paired viscera, such as the lungs, kidneys, ovaries (or testes), so many of the pairs disappearing, however, that their metameric arrangement is not very evident in the adult. The unpaired vessels supply the digestive tract and its unpaired appendages, such as the liver and pancreas, and undergo great modifications, those of the lower thoracic and lumbar regions becoming reduced by fusion and degeneration to three main trunks.

Fig. 20.—Diagram of a Transverse Section through the Abdominal Region.



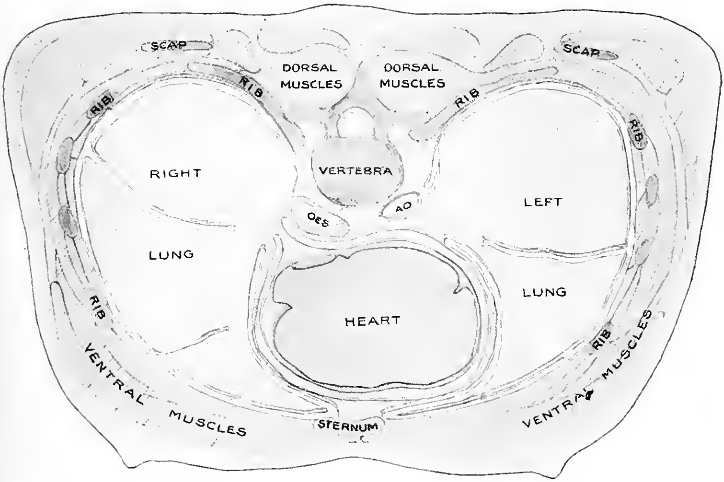
Branchiomerism.—Throughout the trunk and neck regions, then, a fundamental metameric plan underlies and determines the arrangement of many parts. In the head there is also evident a primary arrangement of the parts in succession; but this arrangement appears to be somewhat different from that of the trunk in that it involves the ventral instead of the dorsal mesoderm and is associated with the occurrence of branchial arches rather than with true mesodermic somites. It is consequently termed *branchiomerism.*

Not but that there are also indications of metamerism in the head, the muscles of the orbit, and the majority of the extrinsic muscles of the tongue, together with the nerves supplying these muscles, being apparently metameric structures, but the metamerism of this region of the body is largely overshadowed by the branchiomerism.

If an embryo of about the fifth week of development (fig. 22) be examined, there will be observed on the surface of the body in the pharyngeal region three or four linear depressions, and sections will show that similar and corresponding grooves also occur upon the inner surface of the pharyngeal wall. These are the *branchial grooves*, and since they are four in number (with a rudimentary fifth) in the human embryo, they mark off five *branchial* (*or visceral*) *arches*, the first of which lies between the oral depression and the first branchial groove, while the fifth is situated behind the fourth groove. These branchial arches are so named because they represent the arches which (excepting the first) support the gills (branchiæ) in the lower vertebrates, the grooves representing the branchial slits, even although they do not become perforated in the human embryo.

Each *branchiomere* consists of an axial skeletal structure, of muscles which act on this skeleton, of a nerve which supplies the muscles and the neighbouring integument and mucous membrane, and of an artery which carries blood to all these structures. The arches, however, do not in the human embryo retain their original branchial function, but undergo extensive modifications, becoming adapted to various functions and showing less in the adult of their originally simple arrangement than do the metameres. Nevertheless no matter what modifications the musculature of any arch may undergo, it will retain its original innervation and, to a large extent, its relations to the skeletal elements of its arch; and even the arteries in their distribution show clear indications of being arrauged in correspondence to the various arches.

FIG. 21.—DIAGRAM OF A TRANSVERSE SECTION THROUGH THE THORACIC REGION. (The pleura is represented in blue and the pericardium in red.)



With respect to the fate of the various structures pertaining to each branchial arch, their general arrangement in the adult body may be stated in the following table:—

RELATIONS OF THE BRANCHIAL ARCHES IN THE ADULT

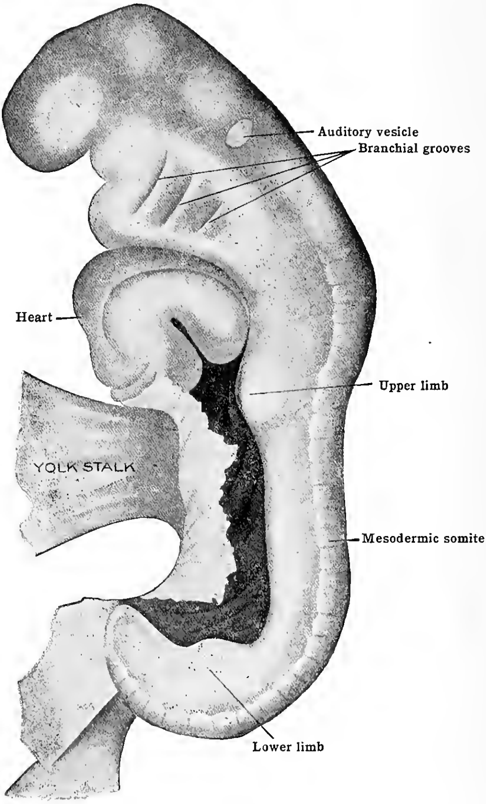
Arch	Skeleton	Muscles	Nerve
First arch.......	Mandible, malleus and incus.	Masticatory, mylohoid and digastric (ant.), tensor tympani.	Trigeminus.
Second arch.....	Hyoid (lesser cornu), styloid process and stapes.	Stylohyoid, digastric (post.), muscles of expression, stapedius.	Facialis.
Third arch......	Hyoid (greater cornu)...	Pharyngeal..................	Glossopharyngeus.
Fourth and fifth arches.	Thyreoid cartilage......	Pharyngeal and laryngeal.....	Vagus.

Branchial grooves.—Of the *external branchial grooves*, the first (lying between mandibular and hyoid arches) becomes deepened to form the *external auditory meatus*, the margins becoming elevated to form the *auricle* (fig. 26). The region corresponding to the second, third and fourth external grooves becomes depressed, forming the *sinus cervicalis*, which soon closes up and disappears.

The *internal branchial grooves* or pouches communicate with the pharyngeal cavity and are lined with endoderm. The first internal groove becomes transformed into the *auditory* (Eustachian) *tube, tympanic cavity*, etc. The second internal groove persists in part as the fossa of the *palatine tonsil.* The third and fourth grooves are probably represented in part by the *vallecula* and *recessus piriformis*, detached portions of their lining endoderm giving rise to the *thymus, parathyreoid glands*, etc. The rudimentary fifth groove is said to give rise to the *ultimobranchial body*, a structure of uncertain significance (fig. 27).

Development of the face.—The facial region is at first relatively small. It includes the sense organs (eye, ear, nose) and mouth region. Some of the more important developmental features may be briefly mentioned. In an embryo of the sixth week (fig. 28) the wide mouth aperture is seen to be bounded below (posteriorly) by the lower (*mandibular*) portion of the

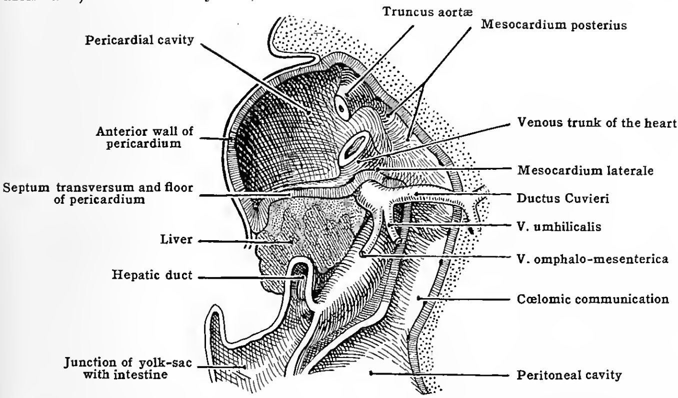
Fig. 22.—Human Embryo of 4.2 mm., Showing Three Branchial Grooves. (After His.)



first arch, laterally by the upper (*maxillary*) process of the first arch. Above it is bounded by a median plate, the *nasal process*, which on either side forms a protuberance, the *globular process*. Lateral to the globular process is a rounded depression, the *nasal pit*. The maxillary process extends forward and fuses with the globular process to form the upper jaw region (failure to unite resulting in the malformation known as 'hare-lip'). The nose is at first broad, due to the width of the nasal process, which later becomes the nasal septum (fig. 29). The nasal pits deepen and later acquire openings into the primitive mouth cavity.

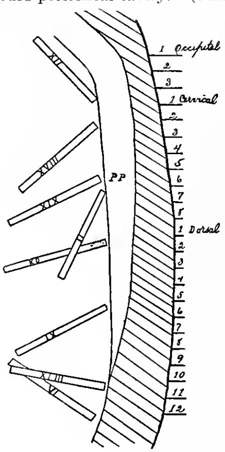
The viscera.—The structures so far considered belong, for the most part, to the body wall; it remains to consider the general plan of arrangement of the viscera. It has been pointed out that the body may be regarded as a cylinder enclosing two tubes, one of which constitutes the central nervous system and the other the digestive tract. The latter may be regarded as being primarily a straight tube traversing lengthwise the body cavity enclosed by the body wall (figs. 18, 20). The layers of both the visceral and somatic plates which im-

FIG. 23.—SAGITTAL SECTION SHOWING THE PRIMITIVE PERICARDIAL AND CŒLOMIC COMMUNICATION, SEPTUM TRANSVERSUM, LIVER, ETC., IN A HUMAN EMBRYO OF 3 MM. (After Kollmann, from a model by His.)



mediately enclose the body cavity become transformed into a characteristic pleuro-peritoneal membrane. Near the mid-dorsal line, a vertical double plate of peritoneum extends ventrally connecting the somatic (parietal) and visceral layers of peritoneum, and constituting what is termed the *mesentery* (fig. 20).

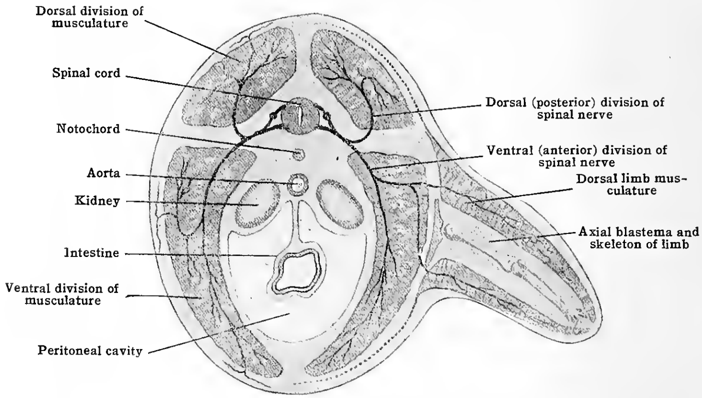
FIG. 24.—DIAGRAM ILLUSTRATING THE RECESSION OF THE DIAPHRAGM (SEPTUM TRANSVERSUM) IN THE HUMAN EMBRYO. On the right are indicated the vertebral levels; on the left, the position of the septum transversum in a series of embryos from 2 mm. (XII) to 24 mm. (VI) in length. *pp*, pleuro-peritoneal cavity. (Mall.)



As development proceeds the digestive tract grows in length more rapidly than the cavity which contains it, and so gradually becomes thrown into numerous coils in the abdominal region, these changes leading to numerous modifications of the original arrangement of the mesentery. These will be described later on in the section on the digestive system. Several outgrowths also arise from the primitive digestive tract, to form important organs, such as the lungs, the liver, the pancreas and the urinary bladder; and, with the exception of the bladder, each of these becomes completely invested by primitive peritoneum. In the case of the liver this original condition is practically retained, but the investment of the pancreas later becomes a partial one on account of the modifications which ensue in the mesentery. The bladder has only a portion of its surface in contact with the peritoneum, but the investment of the lungs remains complete, each lung, indeed, appropriating to itself the entire visceral layer of its half of the thorax, with the exception of a small ventral portion which forms the investment of the heart. Furthermore, the cavities which surround each of the three organs named, the two lungs and the heart, become completely separated from one another; and since each investment consists of a visceral and a parietal layer, each of the organs is enclosed within a double-walled sac, which in the case of each lung forms its *pleura*, while that of the heart is known as the *pericardium*. The spaces which occur within the thorax between the pleuræ of the two sides are known as the *mediastina*, which include the heart, œsophagus, etc. (fig 21).

In addition to the viscera mentioned there are some organs, such as the spleen and genito-urinary organs, which are developments of the mesoderm, the spleen arising in the mesentery which passes to the stomach and the genito-urinary organs primarily from the intermediate cell mass. The morphogeny of these structures and also of the vascular system, nervous system, and sense organs will be considered later in connection with their structure.

Fig. 25.—Diagram of a Cross Section of the Embryonic Body and Limb. (McMurrich, after Kollman.)



Recession of the diaphragm and heart.—In the early stages of development the heart is situated far forward, in what will eventually be the pharyngeal region (figs. 12, 17). Just behind (caudal to) the heart, between it and the yolk-sac, is a plate of connective tissue, the *septum transversum*, which serves for the passage of large veins from the body wall to the heart (figs. 17, 23). This septum together with certain accessory structures eventually gives rise to the diaphragm, which becomes a complete partition separating the thoracic and abdominal portions of the body cavity.

The diaphragm and heart are therefore originally situated far above (cranial to) their final position and recede in the course of development, producing an elongation of the vessels and nerves associated with them and forcing downward such organs as the stomach and liver (fig. 24). The chief factor in this displacement is probably the ventral head flexion and the precocious growth and expansion of the organs in the head region. The effects of this recession are especially noticeable in the nerves, these passing to the various organs concerned arising from a much higher level than that occupied by the organs. The nerve to the diaphragm, for instance, comes from the fourth cervical segment, those passing to the cardiac and pulmonary plexuses from the cervical region, and those to the plexus in relation with the stomach, liver and adjacent organs from the thoracic region. The blood-vessels, however, may shift their origins from the main trunks by successive anastomotic roots, so that in general they keep pace with the viscera in the migration caudalward.

The limbs.—Each limb at its first appearance (fig. 22) is a flat, plate-like outgrowth from the side of the body, and consists of an axial mass (blastema) of mesodermic tissue from which the limb skeleton will develop, and, surrounding this, a layer, also of mesodermic tissue, from which the muscles and blood-vessels will arise. It is as yet uncertain whether the muscle blastema is derived from the myotomes (as in lower vertebrates) or whether it develops from the mesenchyme.

As the muscles become differentiated, nerves grow to them from a definite number of spinal segments (fig. 25).

At first each limb plate is so placed that one of its surfaces looks dorsally and the other ventrally, and one border (that corresponding to the thumb or great toe) is anterior (i. e., cranial) and the other posterior (caudal). Later, however, each limb becomes bent caudally through about ninety degrees, so that the limbs whose long axes were at first at right angles to the long axis of the body come to lie parallel to that axis. In addition there occurs a rotation of each fore-limb in such a manner that the thumb turns latero-dorsally, while in the lower limb the direction of the movement is exactly the opposite, the great toe turning ventro-medially. As a result there is an apparent reversal of the surfaces in the two limbs, the flexor muscles of the arm reaching on the surface which is directed anteriorly, while in the lower limb the corresponding muscles occupy the posterior surface. The dorsum of the foot and the great toe side correspond respectively to the back and thumb side of the hand, the tibia corresponds to the radius and the fibula to the ulna. The limb anlage soon becomes divided into three primary segments. The distal segment (hand or foot) is a flattened rounded disc, in which the digits soon appear (fig. 26). The proximal portion forms the forearm or leg and the arm or thigh. In general, the extremities follow the law of cranio-caudal and dorso-ventral (proximo-distal) development.

*X	33.6	50.0	3200.0	0.33

Prenatal growth.—The prenatal growth of the human body in length and weight is indicated in the preceding table. According to Hasse, the age of the fœtus may be estimated from its total length as follows. Before the fifth month, the square of the age in (lunar) months gives the length in centimetres. After this, the age in months multiplied by five gives the length. This gives approximate results, except for the first month.

While the growth in *absolute* weight increases from month to month, it is important to note that the real (relative) growth rate rapidly diminishes. The ovum increases in weight during the first month about 1000 times, or 100,000 per cent. (not including the extra-embryonic structures). This rate diminishes rapidly, however, so that the increase during the last fœtal month is only about 33 per cent.

The continuation of growth in length and weight during the **postnatal period** is shown in the following chart (fig. 30).

The following chart is based upon data from Camerer (1–5 yrs.), Porter (6–17 yrs.), and Roberts (18–20 yrs.), showing the average postnatal growth in height and weight by sexes. The average height at birth is about 50 cm. (20 inches); weight, about 3200 g. (7 pounds). The male is slightly heavier and taller than the female, except during the acceleration at the period

* 270 days (Mall).

Fig. 29.—Face of a Human Embryo after Completion of the Upper Jaw. (McMurrich from His.)

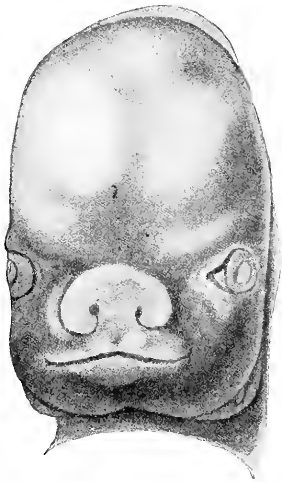

Fig. 30.—Chart Showing Average Postnatal Growth in Height and Weight.

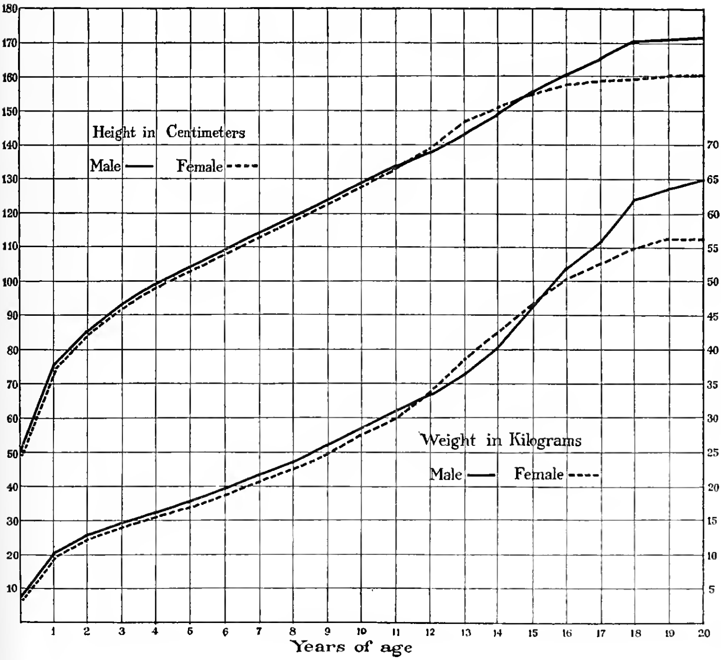


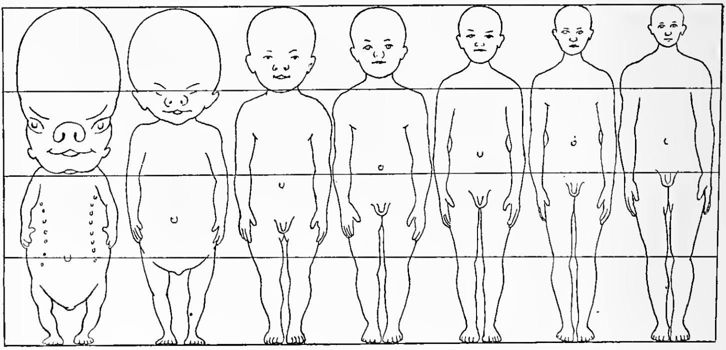
of puberty. Puberty occurs earlier in the female, so that between the ages of 12 and 15 the girls exceed the boys in average height and weight. With the exception of this period of acceleration, the (relative) growth rate in general diminishes steadily from birth, and has practically ceased at 20 years. The average height at this time is about 160 cm. (5 ft., 3 in.) in the female, and 170 cm. (5 ft., 7 in.) in the male; average weight, about 56 kilograms (126 lbs.) in the female, and 65 kilograms (146 lbs.) in the male. Under favourable conditions, growth in height may continue slowly up to about 25 years, and in weight even longer; but in old age there is a slight decrease in both height and weight.

The following measurements (from Holt, "Diseases of Infancy and Childhood" may be taken as a normal average standard of growth during the first three years. The weights are taken without clothing. The height is taken by placing the baby on a perfectly flat surface like a table, and having some one hold the child's knee down so that he lies out straight, then taking a tape-measure and measuring from the top of his head to the bottom of his foot, holding the tape line absolutely straight. The chest is measured by means of a tape line passed directly over the nipples around the child's body and midway between full inspiration and full expiration. The head measurement is taken directly around the circumference of the head, over the forehead and occipital bone.

		Weight, pounds	Height, inches	Chest, inches	Head, inches
Birth	Boys	7.55	20.6	13.4	13.9
	Girls	7.16	20.5	13.0	13.5
6 months	Boys	16.0	25.4	16.5	17.0
	Girls	15.5	25.0	16.1	16.6
12 months	Boys	20.5	29.0	18.0	18.0
	Girls	19.8	28.7	17.4	17.6
18 months	Boys	22.8	30.0	18.5	18.5
	Girls	22.0	29.7	18.0	18.0
2 Years	Boys	26.5	32.5	19.0	18.9
	Girls	25.5	32.5	18.5	18.6
3 Years	Boys	31.2	35.0	20.1	19.3
	Girls	30.0	35.0	19.8	19.0

Relative growth of the parts.—The growth of the body is not uniform in the various parts, and changes in proportions therefore occur during development, as

Fig. 31.—Figures Illustrating the Changes in Proportion During Prenatal and Postnatal Growth. (Stratz.)



shown in fig. 31. It will be noted that the changes are in accordance with the law of developmental direction previously explained, the growth impulse passing along the body in a cranio-caudal direction.

The *head* is therefore largest in the earlier stages, forming about half the body, decreasing to 25 per cent. in the newborn, and to 7 or 8 per cent. of the body in the adult. The *upper limbs* increase to about 10 per cent. of the body at birth, maintaining thereafter about the same relative size. The *trunk* as a whole remains of about the same relative size (about 45 per cent.), although the thoracic portion reaches its maximum in the earlier stages, and the pelvic portion not until adult life. The *lower limbs*, like the pelvis, develop slowly, forming about 20 per cent. of the body at birth and reaching 35 per cent. in the adult.

Relative growth of the systems.—There is also a marked difference in the relative growth of the various systems. Data for the *skin* and *skeleton* are somewhat scanty and unsatisfactory. The *musculature*, however, is relatively small in the embryo, increasing to about 25 per cent. of the body in the newborn, and to 40 or 45 per cent. in the adult. The visceral group (including brain and spinal cord), on the other hand, is relatively largest in the early embryo, decreasing from about 35 per cent. of the body to about 24 per cent. in the newborn and to about 10 per cent. in the adult.

Relative growth of the organs.—While in general, the individual organs follow the course of relative growth of the visceral group, each organ has its own characteristic course of growth. As a rule, after its appearance in the embryo, each organ increases more or less rapidly to its maximum relative size, after which, although increasing in *absolute* size, it decreases in *relative* size through subsequent prenatal and postnatal life up to the adult.

Thus the *brain* in the embryo of the second month forms more than 20 per cent. of the body, but steadily declines to about 13 or 14 per cent. in the newborn, and about 2 per cent. in the adult. The *spinal cord* and *eyeballs* have a similar course of growth. The *heart* declines from about 5 per cent. of the body in the embryo of the second month to about .75 per cent. in the newborn and .46 per cent. in the adult. The *liver* decreases from a maximum of nearly 10 per cent. in the third month to 5 per cent. in the newborn and 2.7 per cent in the adult. The *suprarenal glands* decrease from about .46 per cent. of the body in the third month to .23 per cent. in the newborn and .01 per cent. in the adult. The *lungs* decrease from 3.3 per cent. in the fourth month to about 2 per cent. of the body at birth and 1 per cent. (bloodless weight) in the adult. The *kidneys* reach a maximum of about 1 per cent. of the body toward the end of the fœtal period, decreasing to about .46 per cent. in the adult. The *thymus, thyroid, spleen* and *alimentary canal* likewise reach their maximum slowly, being probably relatively largest about the time of birth. The *ovary* and *testis*, however, appear to be relatively largest during the prenatal period.

Variability.—It must be borne in mind that all statements concerning structure refer to the *average* or *norm*, and are always subject to variation. This is therefore a topic of importance to students of anatomy. Variations are classified as either *germinal* or *somatic*.

Germinal variations are due to fundamental differences in the germ plasm, and are transmitted by heredity. These include many of the characters whereby one individual differs from another. Variations according to sex are included under this class. Variations inherited from more or less remote ancestors are termed *atavistic* or *reversional*.

Somatic variations, or 'acquired characters,' are due to environmental influences, such as nutrition, temperature, shelter, disease, training, etc. While somatic variations may be very great, they do not affect the germ plasm and are not transmitted by heredity.

In many cases it is exceedingly difficult to distinguish germinal from somatic variations Size, for example, may be due to either or both. Moreover, somatic variations may be produced at any time after the fertilisation of the ovum. Very slight environmental changes are sometimes sufficient to produce a marked effect upon the delicately balanced mechanism of the developing embryo. Malformations and pathological conditions are thus often to be explained. As to the *extent* of variability, some characters are much more variable than others. Height, for example, is less variable than weight. Moreover, variability differs in the various parts and organs. In general, the head and head organs are less variable than the remainder of the body. The skeleton and musculature appear less variable than the integument and viscera.

Details concerning variations and methods for their measurement may be found in works on genetics and biometrical statistics.

SECTION II

OSTEOLOGY

Revised for the Fifth Edition

By PETER THOMPSON, M.D.,

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF BIRMINGHAM; EXAMINER IN ANATOMY, THE UNIVERSITY OF CAMBRIDGE; FORMERLY EXAMINER IN ANATOMY FOR THE UNIVERSITIES OF LONDON, ABERDEEN, MANCHESTER, DUBLIN AND FOR THE CONJOINT BOARD OF ENGLAND

THE SKELETON

THE skeleton forms the solid framework of the body, and is composed of bones, and in certain parts, of pieces of cartilage. The various bones and cartilages are united by means of ligaments, and are so arranged as to give the body definite shape, protect from injury the more important delicate organs, and afford attachment to the muscles by which the various movements are accomplished.

In its widest acceptance, the term **skeleton** includes all parts of the framework, whether internal or external, and as in many of the lower animals there are, in addition to the deeper osseous parts, hardened structures associated with the integument, it is convenient to refer to the two groups as **endoskeleton** and **exoskeleton** or **dermal skeleton**, respectively. All vertebrate—i. e., back-boned—animals possess an endoskeleton, and many of them a well-developed exoskeleton also, but in mammals, the highest group of vertebrates, the external skeleton, when it exists, plays a relatively subordinate part. In most of the invertebrates the endoskeleton is absent and the dermal skeleton alone is found.

In man by far the greater part of the endoskeleton is formed of bone, a tissue of definite chemical composition, being formed mainly of a gelatine basis strongly impregnated with lime salts.

The number of bones in the skeleton varies at different ages, some, which are originally quite independent, becoming united as age advances. They are arranged in an **axial set,** which includes the vertebral column, the skull, the ribs, and the sternum, and an **appendicular set,** belonging to the limbs. The following table shows the number of bones usually distinct in middle life, excluding the auditory ossicles:—

		Bones.
Axial Skeleton	The vertebral column	26
	The skull	23
	The ribs and sternum	25
Appendicular Skeleton	The upper limbs	64
	The lower limbs	62
	Total	200

Several of the skull bones are **compound,** i. e., in the immature skeleton they consist of separate elements which ultimately unite to form a single bone. In order to comprehend the nature of such bones it is advantageous to study them in the various stages through which they pass in the process of development in the fœtus and the child.

It follows, therefore, that to appreciate the **morphology** of the skeleton—i. e., the history of the osteological units of which it is composed—the **osteogenesis** or mode of development of the bones must be studied, as well as their **topography** or position.

Some bones arise by ossification in **membrane,** others in **cartilage.** In the embryo, many portions of the skeleton are represented by cartilage which may become infiltrated by lime salts —**calcification.** This earthy material is taken up and redeposited in a regular manner— **ossification.** Portions of the original cartilage persist at the articular ends of bones, and, in young bones, at the **epiphysial** lines, i. e., the lines of junction of the main part of a bone with the extremities or epiphyses. Long bones increase in length at the **epiphysial cartilages**, and increase in thickness by ossification of the deeper layers of the investing membrane or **periosteum.** These processes—intracartilaginous and intramembranous ossification—proceed concurrently in the limb-bones of a young and growing mammal.

There is no bone in the human skeleton which, though pre-formed in cartilage, is perfected in this tissue. The ossification is completed in membrane. On the other hand, there are numerous instances in the skull, of bones the ossification of which begins in, and is perfected by, the intramembranous method. Ossification in a few instances commences in membrane, but later invades tracts of cartilage; occasionally the process begins in the **perichondrium** and remains restricted to it, never invading the underlying cartilage, which gradually disappears as the result of continued pressure exerted upon it by the growing bone. The vomer and nasal bones are the best examples of this mode of development. Further details of development and ossification are included in the description of each bone.

The **limb-bones** differ in several important particulars from those of the skull. Some of the long bones have many centres of ossification, but these have not the same significance as those of the skull. It is convenient to group the centres into two sets, **primary** and **secondary.** The **primary** nucleus of a long bone appears quite early in fœtal life, and the main part (shaft) thus formed is called the **diaphysis.** In only three instances does a **secondary** centre appear before birth, e. g., the lower end of the femur, the head of the tibia, and occasionally the head of the humerus. Many **primary** ossific nuclei appear after birth, e. g., those for the carpal bones, the cuneiform and navicular bones of the foot, the coracoid process of the scapula, and for the third, fourth, and fifth pieces of the sternum.

When a bone ossifies from one nucleus only, this nucleus may appear before or after birth. Examples: the talus (astragalus) at the seventh month of fœtal life, and the lesser multangular (trapezoid) at the eighth year. When a bone possesses one or more secondary centres, the primary nucleus, as a rule, appears early. Examples: the femur, humerus, phalanges, and the calcaneus.

Secondary centres which remain for a time distinct from the main portion of a bone are termed **epiphyses.** An epiphysis may arise from a single nucleus, as is the case at the lower end of the femur, or from several, as at the upper end of the humerus. Prominences about the ends of long bones may be capped by separate epiphyses, as illustrated at the upper end of the femur.

According to Professor F. G. Parsons, there are at least three kinds of epiphyses:—(1) Those which appear at the articular ends of long bones, which, since they transmit the weight of the body from bone to bone, may be termed *pressure* epiphyses. (2) Those which appear as knob-like processes, where important muscles are attached to bones; and as these are concerned with the pull of muscles, they may be described as *traction* epiphyses. (3) The third kind includes those epiphyses which represent parts of the skeleton at one time of functional importance but which, having lost their function, have now become fused with neighbouring bones and only appear as separate ossifications in early life. These may be termed *atavistic* epiphyses and include such epiphyses as the tuberosity of the ischium, the representative of the hypoischium of reptiles.

The epiphyses of bones seem to follow certain rules, thus:—

1. Those epiphyses whose centres of ossification appear last are the first to unite with the shaft. There is one exception, however, to this statement, viz., the upper end of the fibula, which is the last to unite with the shaft, although its centre appears two years after that for the lower end. This may perhaps be accounted for by the rudimentary nature of the proximal end of the fibula in man and many other mammals.

2. The epiphysis toward which the nutrient artery is directed is the first to be united with the shaft. It is also found that while the increase in length of the long bones takes place at the epiphysial cartilages, the growth takes place more rapidly and is continued for a longer period at the end where the epiphysis is the last to unite. It follows, therefore, that the shifting of the investing periosteum, which results from these two factors, leads to obliquity of the vascular canal by drawing the proximal portion of the nutrient artery toward the more rapidly growing end. Moreover, when a bone has only one epiphysis, the nutrient artery will be directed toward the extremity which has no epiphysis.

3. The centres of ossification appear earliest in those epiphyses which bear the largest relative proportion to the shafts of the bones to which they belong.

4. When an epiphysis ossifies from more than one centre, the various nuclei coalesce before the shaft and epiphysis consolidate, e. g., the upper end of the humerus.

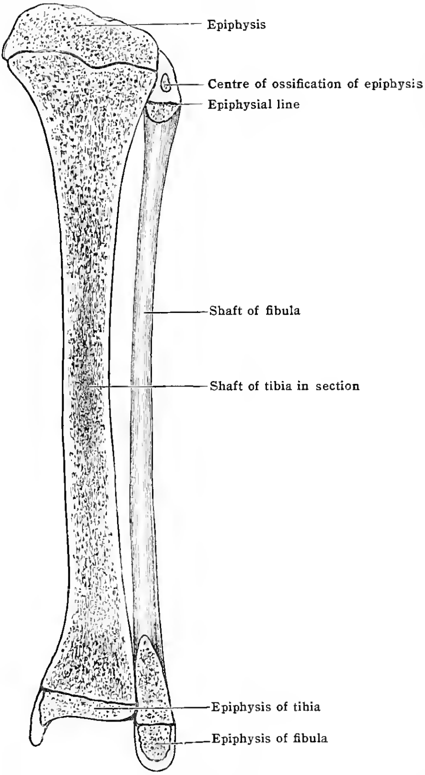
On section, the shaft of a fœtal long bone is seen to be occupied by red marrow lodged in bony cells which do not present any definite arrangement. In an adult the central portion of the shaft is filled with fat or marrow held together by a delicate reticulum of connective tissue, whence the space is known as the **medullary cavity.** The expanded ends of the bones contain a network of cancellous tissue, the intervals being filled with red marrow. This cancellous tissue differs from that of the fœtal bone in being arranged in a definite manner according to the direction of pressure exerted by the weight of the body, and the tension produced by the muscles. The arrangement of the cancelli in consequence of the mechanical conditions to which bones are subject is noticed in the description of a vertebra, the femur, and the humerus.

Bones are divisible into four classes:—**long, short, flat,** and **irregular.** The **long bones,** found chiefly in the limbs, form a system of levers sustaining the weight of the trunk and providing the means of locomotion. The **short bones,** illustrated by those of the carpus and tarsus, are found mainly where compactness, elasticity, and limited motion are the principal requirements. **Flat bones** confer protection or provide broad surfaces for muscular attachment, as in the case of the cranial bones and the shoulder-blade. Lastly, the **irregular** or **mixed bones** constitute a group of peculiar form, often very complex, which cannot be included under either of the preceding heads. These are the vertebræ, sacrum, coccyx, and many of the bones of the **skull.**

The **shafts** of long bones at the time of birth are mainly cylindrical and free from ridges. The majority of the lines and ridges so conspicuous on the shafts of long bones in adults are due to the ossification of muscle-attachments. The more developed the muscles, the better marked the ridges become.

The surfaces of bones are variously modified by environing conditions. Pressure at the extremities causes enlargement, and movement renders them smooth. The two causes combined produce an articular surface. When rounded and supported upon a constricted portion of bone, an articular surface is termed a **head**, sometimes a **condyle**; when depressed, a **glenoid fossa**. Blunt, non-articular processes are called **tuberosities**; smaller ones, **tubercles**; sharp projections, **spines**. Slightly elevated ridges of bones are **crests**; when narrow and pronounced, **lines** and

FIG. 32.—THE TIBIA AND FIBULA IN SECTION TO SHOW THE EPIPHYSES.



borders. A shallow depression is a **fossa**; when narrow and deep, a **groove**; a perforation is usually called a **foramen**.

In addition to these, other terms are employed which do not require any explanation, such as **canal**, **notch** or **incisura**, **sulcus** or **furrow**, and the like.

I. THE AXIAL SKELETON

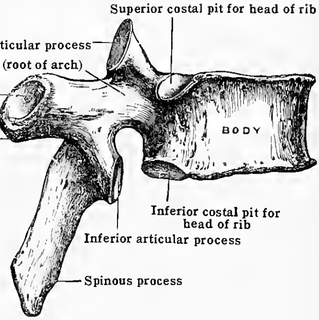
A. THE VERTEBRAL COLUMN

The **vertebral column** [columna vertebralis] consists of a series of bones called **vertebræ**, closely connected by means of fibrous and elastic structures, which allow of a certain but limited amount of motion between them. In the young subject the vertebræ are thirty-three in number. Of these, the upper twenty-four remain separate throughout life, and are distinguished as **movable** or **true vertebræ.** The succeeding five vertebræ become consolidated in the adult to form one mass, called the **sacrum,** and at the terminal part of the column are four rudimentary vertebræ, which also tend to become united as age advances, to form the **coccyx.** The lower nine vertebræ thus lose their mobility as individual bones, and are accordingly known as the **fixed** or **false vertebræ.** Of the true vertebræ, the first seven are called **cervical** [cervicales], the succeeding twelve **thoracic** [thoracales] or **dorsal,** and the remaining five **lumbar** [lumbales].

Although the vertebræ of the different regions of the column differ markedly in many respects, each vertebra is constructed on a common plan, which is more or less modified in different regions to meet special requirements. The essential characters are well seen in the vertebræ near the middle of the thoracic region, and it will be advantageous to commence the study of the vertebral structures with one selected from this region.

Description of a thoracic vertebra (figs. 33, 34).—The vertebra consists of two essential parts—a body in front and an arch behind.

Fig. 33.—A Thoracic Vertebra. (Side view.)



The **body** [corpus vertebræ] or **centrum** is a solid disc of bone, somewhat heart-shaped, deeper behind than in front, slightly concave on its superior and inferior surfaces, and wider transversely than antero-posteriorly. The upper and lower surfaces are rough for the intervertebral discs which are interposed between the bodies of the vertebræ, and the margins are slightly lipped. The circumference of the body is concave from above downward in front, convex fron side to side, and perforated by numerous vascular foramina. Posteriorly it is concave from side to side and presents one or two large foramina for the exit of veins from the cancellous tissue. On each side of the body, at the place where it joins the arch, are two costal pits (superior and inferior) [fovea costalis superior; inferior] placed at the upper and lower borders, and when two vertebræ are superimposed, the adjacent costal pits form a complete articular pit for the head of a rib. The superior and inferior costal pits were formerly designated as "demi-facets."

The **arch** [arcus vertebræ] is formed by two pedicles and two laminæ, and supports seven processes—one spinous, two transverse, and four articular. The pedicles or **roots** of the vertebral arch [radices arcus vertebræ] are two short, constricted columns of bone, projecting horizontally backward from the posterior surface of the body. The concavities on the upper and lower borders of each pedicle, of which the lower is much the deeper, are named **vertebral notches** [incisurae], and when two vertebræ are in position, the notches are converted into **intervertebral foramina** for the transmission of the spinal nerves and blood-vessels.

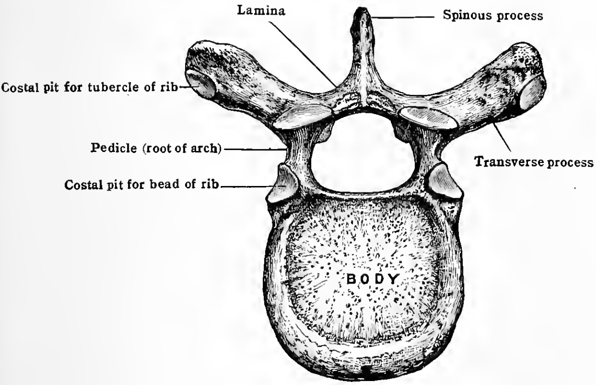
The **laminæ** are two broad plates of bone which connect the spinous process with the roots (pedicles) and complete the arch posteriorly. The superior border and the lower part of the anterior surface of each lamina is rough for the insertion of the ligamenta flava. The upper part of the anterior surface is smooth where it forms the posterior boundary of the vertebral canal. When articulated, the laminæ in the thoracic region are imbricated or sloped, one pair over the other, somewhat like tiles on a roof.

The **spinous process** [processus spinosus], long and three-sided, projects backward and downward from the centre of the arch and terminates in a slight tubercle. It gives attachment by its prominent borders to the interspinous ligaments and by its free extremity to the supraspinous ligament. It serves mainly as a process for muscular attachment.

The **transverse processes** [processus transversus] are two in number and extend laterally from the arch at the junction of the pedicles and laminæ. They are long, thick, backwardly directed columns of bone terminating in a clubbed extremity, on each of which is a costal pit for articulation with the tubercle of a rib. The transverse processes, in addition to supporting the ribs, afford powerful leverage to muscles.

The **articular processes,** two superior and two inferior, project upward and downward opposite the attachments of the transverse processes. The superior are flat and bear facets or surfaces [facies articulares superiores] which are directed

Fig. 34.—A Thoracic Vertebra. (From above.)



upward, backward, and laterally, and are situated a little in advance of the inferior, the facets of which [facies articulares inferiores] are oval, concave, and directed downward, forward, and medially.

The **vertebral foramen** is bounded anteriorly by the body, posteriorly and on each side by the arch. It is nearly circular, and is smaller than in the cervical or the lumbar region. When the vertebræ are articulated, the series of rings constitute the **spinal** or **vertebral** canal [canalis vertebralis], in which is lodged the spinal cord.

THE CERVICAL VERTEBRÆ

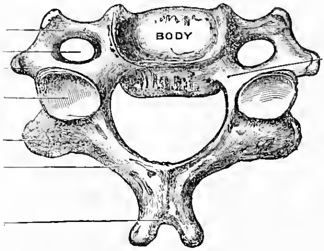
A typical cervical vertebra (from the third to the sixth inclusive) presents the following characteristics (fig. 35):—The **body** is smaller than in other regions of the column and is of oval shape with the long axis transverse. The lateral margins of the upper surface are raised into prominent lips, so that the surface is concave from side to side; it is also sloped downward in front. The inferior surface, on the contrary, projects downward in front and is rounded off at the sides to receive the corresponding lips of the adjacent vertebra. It is concave anteroposteriorly and convex in an opposite direction.

The **roots** (pedicles) are directed laterally and backward and spring from the body about midway between the upper and lower borders. The superior and inferior notches are nearly equal in depth, but the inferior are usually somewhat deeper. The **laminæ** are long, narrow, and slender. The **spinous process** is short and bifid at the free extremity.

Articular processes.—Both the superior and inferior articular processes are situated at the junction of the root with the lamina and they form the upper and lower extremities of a small column of bone. The articular surfaces are oblique and nearly flat, the superior looking backward and upward, and the inferior forward and downward.

The **transverse process** presents near its base a round **costo-transverse foramen** [foramen transversarium] for the transmission of the vertebral artery, vein, and a plexus of sympathetic nerves. Moreover, each process is deeply grooved above for a spinal nerve, and is bifid at its free extremity, terminating in two tubercles—anterior and posterior. The **costo-transverse foramen** is very characteristic of a cervical vertebra. It is bounded medially by the pedicle, posteriorly by the transverse process (which corresponds to the transverse process of a thoracic vertebra), anteriorly by the costal process (which corresponds to the rib in the thoracic region), and laterally by the costo-transverse lamella. The latter is a bar of bone joining the two processes and directed obliquely upward and forward in the upper vertebræ and horizontally in the lower. The **vertebral foramen** is triangular with rounded angles, and is larger than in the thoracic or lumbra vertebræ.

Fig. 35.—A Cervical Vertebra.



Peculiar cervical vertebræ.—The various cervical vertebræ possess distinguishing features, though, with the exception of the first, second, and seventh, which are so different as to necessitate separate descriptions, these are largely confined to the direction of the costo-transverse lamella, and the size and level of the anterior and posterior tubercles. In the third the anterior tubercle is higher than the posterior and the costo-transverse lamella is oblique; in the fourth the anterior tubercle is elongated vertically, so that its lower end is nearly on a level with the posterior, though the lamella still remains oblique. In the fifth and sixth they are nearly on the same level, but in the latter the anterior tubercle is markedly developed to form the **carotid tubercle.**

The Atlas or First Cervical Vertebra

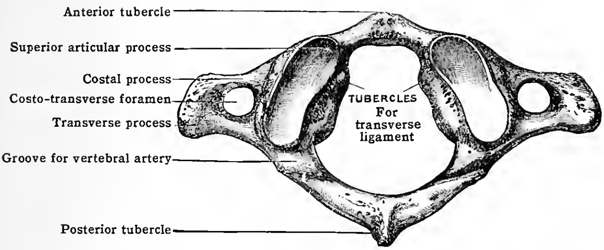
This vertebra (fig. 36) is remarkable in that it has neither body nor spinous process. It has the form of an irregular ring, and consists of two thick portions, the **lateral masses,** united in front and behind by bony arches. The **anterior arch** joins the lateral masses in front and constitutes about one-fifth of the entire circumference of the ring. On its anterior surface it presents a **tubercle** for the attachment of the *longus colli* muscle and the anterior longitudinal ligament, and on its posterior surface a circular facet [fovea dentis] for articulation with the odontoid process [dens] of the axis. The upper and lower borders serve for the attachment of ligaments uniting the atlas to the occipital bone and axis respectively.

The **lateral masses** are thick and strong, supporting the articular processes above and below and extending laterally into the transverse processes. The superior articular surfaces are elongated, deeply concave, and converge in front. Directed upward and medially they receive the condyles of the occipital bone, and occasionally each presents two oval facets united by an isthmus. The inferior articular surfaces are circular and almost flat; they are directed downward and medially and articulate with the axis. The articular processes, like the superior articular processes of the axis, differ from those of other vertebræ in being situated in front of the places of exit of the spinal nerves.

Between the upper and lower articular surfaces on the inside of the ring are two smooth rounded **tubercles,** one on each side, to which the transverse ligament is attached. This ligament divides the interior of the ring into a smaller anterior part for the dens of the axis, and a larger posterior part, corresponding to the foramina of other vertebræ, for the spinal cord and its membranes.

The **transverse processes** are large and extend farther outward than those of the vertebræ immediately below. They are flattened from above downward and each is perforated by a large **costo-transverse foramen**; the extremity is not bifid, but, on the contrary, is broad and rough for the attachment of numerous muscles. The **posterior arch** unites the lateral masses behind and forms about two-fifths of the entire circumference. It presents in the middle line a rough elevation or tubercle representing a rudimentary spinous process. At its junction with the lateral mass on the superior surface is a deep **groove**, the **sulcus arteriæ vertebralis**, which

FIG. 36.—THE FIRST CERVICAL VERTEBRA OR ATLAS.

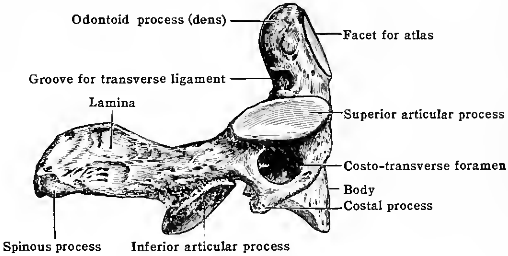


lodges the vertebral artery and the sub-occipital (first spinal) nerve. The groove corresponds to the superior notches of other vertebræ and occasionally it is converted into a foramen by a bony arch—the ossified oblique ligament of the atlas. A similar but much shallower notch is present on the inferior surface of the posterior arch, and, with a corresponding notch on the axis, forms an intervertebral foramen for the exit of the second spinal nerve. The upper and lower surfaces of the arch afford attachment to ligaments uniting the atlas to the occipital bone and the axis.

The atlas gives attachment to the following muscles:—

Anterior arch...............Longus colli.
Posterior arch...............Rectus capitis posterior minor.
Transverse process..........Rectus capitis anterior (minor), rectus capitis lateralis, obliquus capitis inferior, obliquus capitis superior, splenius cervicis, levator scapulæ, and intertransversarii, anterior and posterior.

FIG. 37.—THE EPISTROPHEUS OR AXIS.

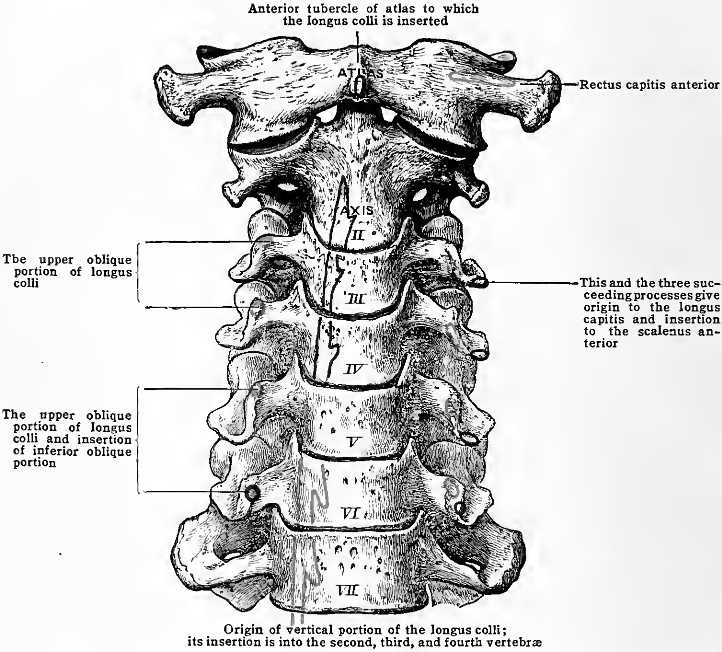


THE EPISTROPHEUS (AXIS)

The **epistropheus** (axis) (fig. 37) is the thickest and strongest of the bones of this region, and is so named from forming a pivot on which the atlas rotates, carrying the head. It is easily recognised by the rounded **dens** (odontoid process) which surmounts the upper surface of the **body.** This process, which represents the displaced body of the atlas, is large, blunt, and tooth-like, and bears on its anterior surface an oval facet for articulation with the anterior arch of the atlas; posteriorly it presents a smooth groove which receives the transverse ligament. To the apex a thin narrow fibrous band (the apical dental ligament) is attached, and on each side of the apex is a rough surface for the attachment of the alar ligaments which connect it with the occipital bone. The enlarged part of the process is sometimes termed the **head,** and the constricted basal part the **neck.** The inferior surface of the body resembles that of the succeeding vertebræ and is concave from front to back and slightly convex from side to side. Its anterior surface is marked by a median ridge separating two lateral depressions for the insertion of the *longus colli.*

The **roots** (pedicles) are stout and broad; the **laminæ** are thick and prismatic; the **spinous process** is large and strong, deeply concave on its under surface, and markedly bifid; the **transverse processes** are small, not bifurcated and not grooved. The costo-transverse foramen is directed very obliquely upward and laterally and the costal process is larger than the transverse.

Fig. 38.—The Cervical Vertebræ. (Anterior view.)



The **superior articular surfaces** are oval, and directed upward and laterally for articulation with the atlas. They are remarkable in being supported partly by the body, and partly by the pedicles, and in being situated in front of the superior notches. The **inferior articular surfaces** are similar in form and position to those of the succeeding vertebræ.

The axis gives attachment to the following muscles:—

Body	Longus colli.
Spinous process	Obliquus capitis inferior, rectus capitis posterior major semispinalis cervicis, interspinales, multifidus.
Transverse process	Splenius cervicis, intertransversarii, levator scapulæ, longissimus (transversalis) cervicis, scalenus medius.

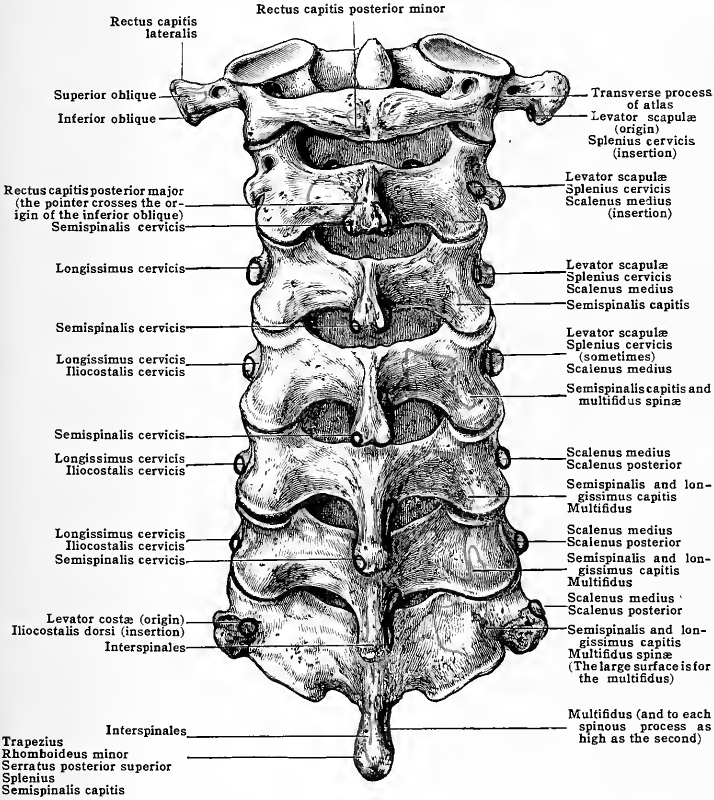
The Seventh Cervical Vertebra

Situated at the junction of the cervical and thoracic regions of the vertebral column, the seventh cervical vertebra (figs. 38, 39) may be described as a transitional vertebra—i. e., possessing certain features characteristic of both regions.

The **spinous process** is longer than that of any of the other cervical vertebræ. It is not bifurcated, but ends in a broad tubercle projecting beneath the skin, whence the name **vertebra prominens** has been applied to this bone. The **transverse process** is massive; the costal element of the process is very small, but, on the other hand, the posterior or vertebral part of the process is large and becoming more like the transverse process of a thoracic vertebra.

The costo-transverse foramen is the smallest of the series and may be absent. It does not, as a rule, transmit the vertebral artery, but frequently gives passage to a vein. Occasionally the costal process is segmented off and constitutes a cervical rib. The body sometimes bears on each side near the lower border a costal pit for the head of the first rib. When this is present, there is usually a well-developed cervical rib.

Fig. 39.—The Cervical Vertebræ. (Posterior view.)



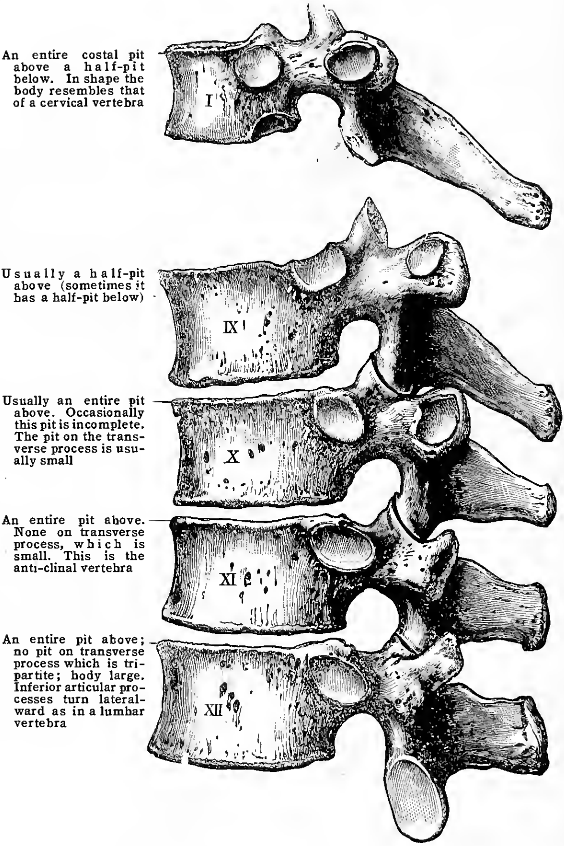
The seventh cervical vertebra gives attachment to the following muscles:—

Body.....................Longus colli.
Spinous process.............Trapezius, rhomboideus minor, serratus posterior superior, splenius capitis, multifidus, interspinales, semispinalis dorsi.
Transverse process..........Intertransversarii, levator costæ, scalenus posterior, iliocostalis dorsi (musculus accessorius), scalenus medius, semispinalis capitis (complexus).
Articular process...........Multifidus, longissimus capitis (trachelomastoid).

The cervical vertebræ exhibit great variation in regard to the extremities of their spinous processes. As a rule among Europeans, the second, third, fourth, and fifth vertebræ possess bifid spines. The sixth and seventh exhibit a tendency to bifurcate, their tips presenting two small lateral tubercles; sometimes the sixth has a bifid spine, and more rarely the seventh presents the same condition. Occasionally all the cervical spines, with the exception of the second, are non-bifid, and even in the axis the bifurcation is not extensive. In the lower races of men the cervical spines are relatively shorter and more stunted than in Europeans generally and, as a rule, are simple. The only cervical vertebra which presents a bifid spine in all races is the axis; even this may be non-bifid in the Negro, and occasionally in the European. (Owen, Turner, Cunningham.)

The laminæ of the lower cervical vertebræ frequently present posteriorly distinct tubercles from which fasciculi of the *multifidus* muscle arise. They are usually confined to the sixth and seventh vertebræ, but are fairly frequent on the fifth, and are occasionally seen on the fourth.

Fig. 40.—Peculiar Thoracic Vertebræ.



THE THORACIC VERTEBRÆ

The general characters of the thoracic (or dorsal) vertebræ have already been considered. Their most distinguishing features are the **pits on the transverse processes** and sides of the **bodies** for the **tubercles** and **heads of the ribs** respectively.

Peculiar thoracic vertebræ.—Several vertebræ in this series differ from the typical example. The exceptional ones are—the **first, ninth, tenth, eleventh,** and **twelfth** (fig. 40).

The **first** thoracic vertebra is a transitional vertebra. The **body** in its general conformation approaches very closely the seventh cervical, in that the greatest diameter is transverse, its upper surface is concave from side to side, and its lateral margins bear two prominent lips. On each side is an entire pit, close to the upper border, for the head of the first rib, and a very small pit (inferior costal pit) below for the head of the second rib. The **spinous process** is thick, strong, almost horizontal and usually more prominent than that of the seventh cervical, an important point to remember when counting the spines in the living subject. Occasionally the transverse process is perforated near the root.

The **ninth** has superior costal pits, and usually no inferior; when the inferior pits are present, this vertebra is not exceptional.

The **tenth** usually has an entire costal pit at its upper border, on each side, but occasionally only a superior costal pit. It has no lower pits and the pits on the transverse processes are usually small.

The **eleventh** has a large body resembling a lumbar vertebra. The pits are on the pedicles and they are complete and of large size. The transverse processes are short, show evidence of becoming broken up into three parts, and have no pits for the tubercles of the eleventh pair of ribs.

In many mammals, the spines of the anterior vertebræ are directed backward, and those of the posterior directed forward, whilst in the centre of the column there is usually one spine vertical. The latter is called the anti-clinal vertebra, and indicates the point at which the thoracic begin to assume the characters of lumbar vertebræ. In man the eleventh thoracic is the anti-clinal vertebra.

The **twelfth** resembles in general characters the eleventh, but may be distinguished from it by the articular surfaces on the inferior articular processes being convex and turned laterally as in the lumbar vertebræ. The transverse process is rudimentary and tripartite, presenting for examination three tubercles, *superior*, *inferior*, and *lateral*, which correspond respectively to the mammillary, accessory, and transverse processes of the lumbar vertebra. There is one complete pit on the root (pedicle) for the head of the twelfth rib.

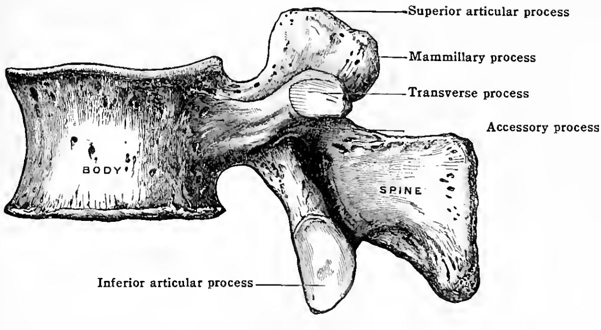
A peculiarity, more frequent in the thoracic and lumbar than in the cervical and sacral regions of the column, is the existence of a half-vertebra. Such specimens have a wedge-shaped half-centrum, to which are attached a lamina, a transverse, superior, and inferior articular, and half a spinous process. As a rule, a half-vertebra is ankylosed to the vertebræ above and below.

THE LUMBAR VERTEBRÆ

The **lumbar vertebræ** (figs. 41, 42) are distinguished by their large size and by the absence of costal articular surfaces.

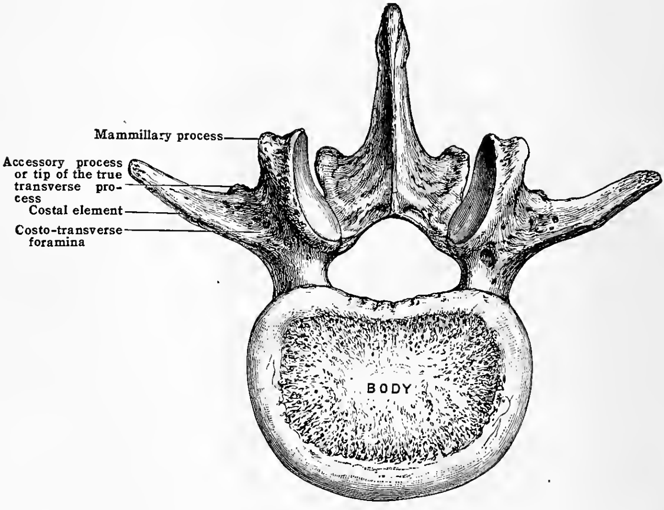
The **body** is somewhat reniform, with the greatest diameter transverse, flat above and below, and generally slightly deeper in front than behind. The **roots**

Fig. 41.—A Lumbar Vertebra. (Side view.)



(pedicles) are strong and directed straight backward, and the lower vertebral notches are deep and large. The **laminæ** are shorter and thicker than those of the thoracic or cervical vertebræ, and the **vertebral foramen** is triangular, wider than in the thoracic, but smaller than in the cervical region. The **spinous process**, thick, broad, and somewhat quadrilateral, projects horizontally backward. It is thicker below than above and terminates in a rough posterior edge. The **articular processes** are thick and strong. The superior articular surface is concave and directed backward and medially; the inferior is convex and looks forward and laterally. The superior pair are more widely separated than the inferior pair and embrace the inferior articular processes of the vertebra above. The posterior margin of each superior articular process is surmounted by the **mammillary process** or tubercle (metapophysis) which corresponds to the superior tubercle of the transverse process of the last thoracic vertebra. In man the mammillary tubercles are rudimentary, but in some animals they attain large proportions, as in the kangaroo and armadillo. The **transverse processes** are long, slender, somewhat spatula-shaped, compressed from before backward, and directed laterally and a little backward. They are longest in the third vertebra and diminish in the fourth, second, and fifth, in this order, to the first, in which they are shortest of all. Their extremities are in series with the lateral tubercles of the transverse processes of the twelfth thoracic vertebra and also with the ribs. With the latter the so-called transverse processes in the lumbar region are homologous, and hence they are sometimes called the **costal processes.** Occasionally the costal element differentiates and becomes a well-developed lumbar rib.

Fig. 42.—A Lumbar Vertebra.
(Showing the compound nature of the transverse process. Upper view.)



Behind the base of each transverse or costal process is a small eminence, directed downward, which corresponds with the inferior tubercle of the lower thoracic transverse process, and with the transverse processes of the thoracic vertebræ above, and is named the **accessory process** (anapophysis). The accessory process represents the tip of the partially suppressed true transverse process of a lumbar vertebra. It is well developed in some of the lower animals, as in the dog and cat.

Each of the five lumbar vertebræ is readily recognized. The body of the first is deeper behind than in front; the body of the second is equal in depth in front and behind; the bodies of the third, fourth, and fifth are deeper in front than behind, but the third has long transverse processes and the inferior articular processes are not widely separated. The fourth has shorter transverse processes and the inferior articular processes are placed more widely apart. The fifth lumbar vertebra deviates in some of its features so widely from the other members of the series that special prominence must now be given them.

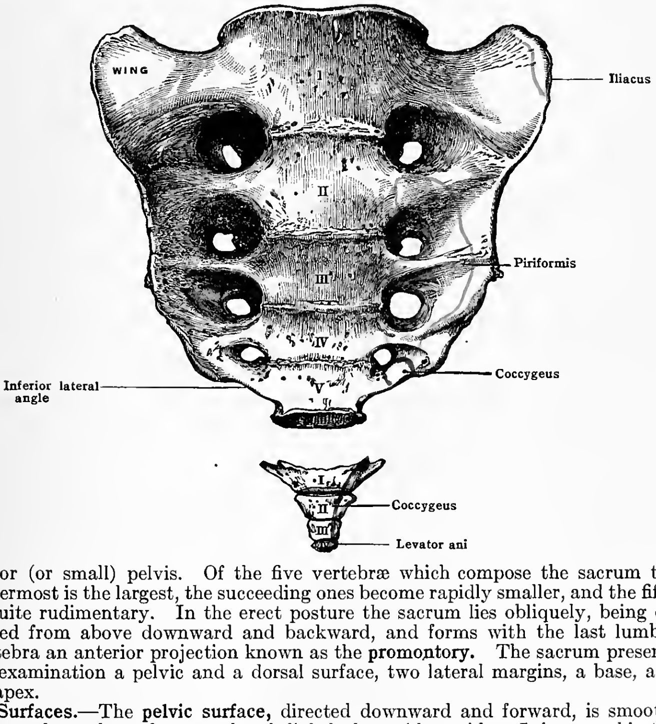
The **fifth lumbar vertebra** is massive, and the **body** is much thicker in front than behind in consequence of being bevelled off to form with the sacrum the *sacro-vertebral angle.* The **transverse processes** are short, thick, conical, and spring from the body as well as from the roots of the arch. They are very strong for the attachment of the ilio-lumbar ligaments. The **spinous process** is smaller than that of any of the other lumbar vertebræ; the **laminæ** project into the vertebral foramen on each side; and the **roots** are stout and flattened from above downward. The **inferior articular processes** are separated to such a degree as to be wider apart than the superior, and they articulate with the first sacral vertebra.

The roots of the arch in this vertebra are liable to a remarkable deviation from the conditions found in other parts of the spine. The peculiarity consists of a complete solution in the continuity of the arch immediately behind the superior articular processes. In such specimens the anterior part consists of the body carrying the roots, transverse and superior articular processes; whilst the posterior segment is composed of the laminæ, spine, and inferior articular processes. The posterior segment of the ring of this vertebra may even consist of two pieces. There is reason to believe that this abnormality of the fifth lumbar vertebra occurs in five per cent. of all subjects examined. Sir William Turner, in his report on the human skeletons in the Challenger Reports, found seven examples among thirty skeletons examined. The skeletons in which this occurred were:—a Malay, an Andamanese, a Chinese, two Bushmen, an Eskimo, and a Negro. Turner has also seen it in the skeleton of a Sandwich Islander. A similar condition is occasionally met with either unilaterally or bilaterally in the thoracic vertebræ.

THE SACRUM

The five sacral vertebræ (figs. 43, 44) are united in the adult to form the **os sacrum,** a large, curved, triangular bone, firmly wedged between the innominate bones, and completing, together with the coccyx, the posterior boundary of the

Fig. 43.—The Sacrum and Coccyx. (Anterior view.)

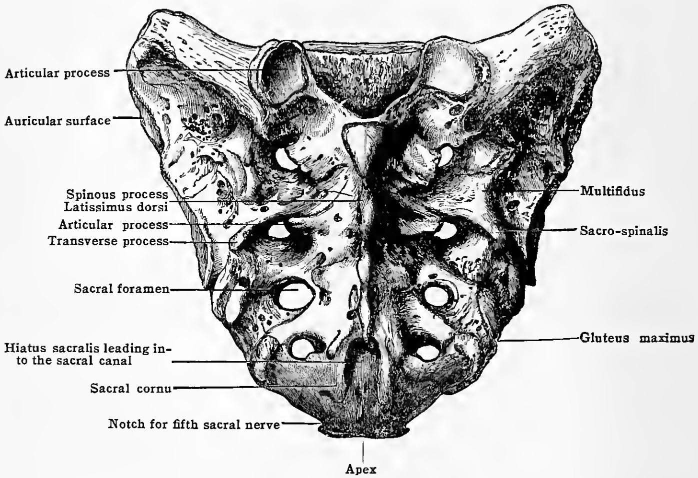


minor (or small) pelvis. Of the five vertebræ which compose the sacrum the uppermost is the largest, the succeeding ones become rapidly smaller, and the fifth is quite rudimentary. In the erect posture the sacrum lies obliquely, being directed from above downward and backward, and forms with the last lumbar vertebra an anterior projection known as the **promontory.** The sacrum presents for examination a pelvic and a dorsal surface, two lateral margins, a base, and an apex.

Surfaces.—The **pelvic surface,** directed downward and forward, is smooth, concave from above downward and slightly from side to side. It is crossed in the middle by four transverse ridges [lineæ transversæ] which represent the ossified intervertebral discs and separate the bodies of the five sacral vertebræ. Of the bodies, the first and second are nearly equal in size and are larger than the third, fourth, and fifth, which, in vertical depth, are also nearly equal to each other. At the extremities of the transverse ridges on each side are four openings, called the **anterior sacral foramina,** which correspond to the intervertebral foramina in other regions of the column, and transmit the anterior divisions of the first four sacral nerves; they are also traversed by branches of the lateral sacral arteries. The foramina are separated by wide processes, representing the costal processes of the vertebræ, which unite laterally to form the **lateral portion** (or mass) [pars lateralis]. The latter is grooved for the sacral nerves, and rough opposite the second, third, and fourth sacral vertebræ, for the origin of the *piriformis* muscle. The lateral part of the fifth sacral vertebra gives insertion to fibres of the *coccygeus.*

The **dorsal surface** is strongly convex and rough. The middle line is occupied by four eminences representing the somewhat suppressed **spinous processes.** Of these the first is the largest, the second and third may be confluent, and the fourth is often absent. The processes are united to form an irregular ridge or

Fig. 44.—The Sacrum. (Posterior view.)



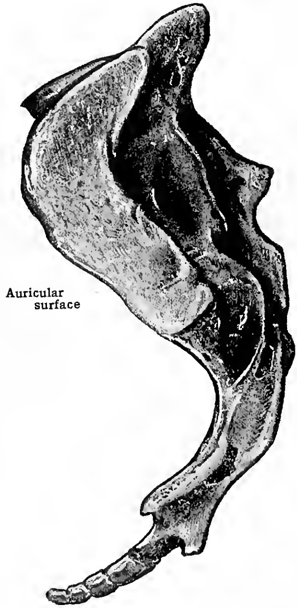
crest [crista sacralis media]. The bone on each side of the spines is slightly hollowed and is formed by the united **laminæ.** In the fourth sometimes, but always in the fifth, the laminæ fail to meet in the middle line, leaving a gap [**hiatus sacralis**] at the termination of the spinal canal, the lateral margins of which are prolonged downward as the **sacral cornua.** They represent the lower articular processes of the fifth sacral vertebra and give attachment to the posterior sacrococcygeal ligaments. Lateral to the laminæ is a second series of small eminences which represent the **articular** and **mammillary processes** of the vertebræ above. The first pair are large for the last lumbar vertebra, the second and third are small, and the fourth and fifth are inconspicuous. Together they form a pair of irregular ridges [cristæ sacrales articulares].

Immediately lateral to the articular processes are the **posterior sacral foramina,** four on each side; they are smaller than the anterior, and give exit to the posterior primary divisions of the first four sacral nerves. Lateral to the foramina on each side are five elevations representing the **transverse processes.** The first pair, situated at the junction of the posterior surface with the base, are large and conspicuous, and serve all for the attachment of ligaments and muscles.

Together they form on each side of the sacrum an irregular ridge [crista sacralis lateralis]. The space between the spinous and transverse processes presents a shallow concavity known as the **sacral groove**, continuous above with the vertebral groove of the movable part of the column, and, like it, lodging the *multifidus* muscle. Bridging across the groove and attached to the sacral spines medially, and to the lower and back part of the sacrum laterally, is the flat tendon of origin of the *sacro-spinalis* (*erector spinæ*). The *gluteus maximus* takes origin from the back of the lower two pieces of the sacrum.

The **base** or upper surface of the sacrum bears considerable resemblance to the upper surface of the fifth lumbar vertebra. It presents in the middle the body, of a reniform shape, posterior to which is the upper end of the sacral canal bounded by two laminæ. On each side of the canal are two articular processes bearing well-marked mammillary tubercles. The conjoined transverse and costal processes form on each side a broad surface, the wing or **ala** of the sacrum, continuous with the iliac fossa of the hip bone, and giving attachment to a few fibres of the *iliacus*.

Fig. 45.—Left Lateral View of Sacrum and Coccyx.



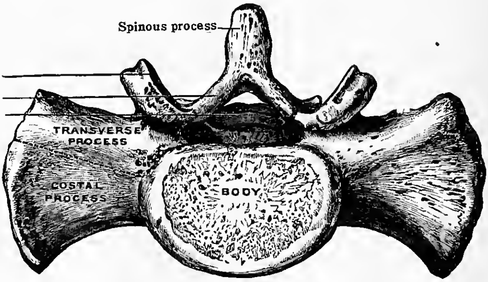
The lateral margins.—It has already been noted that the lateral portion of the sacrum is the part lateral to the foramina. It is broad and thick above, where it forms the ala, but narrowed below. The lateral aspect of the upper part presents in front a broad irregular surface, covered in the recent state with fibro-cartilage, which articulates with the ilium and is known as the **auricular surface.** It is bounded posteriorly by some rough depressions for the attachment of the posterior sacro-iliac ligaments. Below the auricular surface, the lateral margin is rough for the sacro-tuberous (greater) and sacro-spinous (lesser sacro-sciatic) ligaments, and terminates in the projection known as the **inferior lateral angle.** Immediately below the angle is a notch, converted into a foramen by the transverse process of the first coccygeal vertebra, and a ligament connecting this with the inferior lateral angle of the sacrum. Through this foramen passes the anterior branch of the fifth sacral nerve.

The **apex** is directed downward and forward and is formed by the inferior aspect of the body of the fifth sacral vertebra. It is transversely oval and articulates by means of an intervertebral disc with the coccyx. In advanced life the apex of the sacrum becomes united to the coccyx by bone.

The **sacral canal** is the continuation of the spinal canal through the sacrum. Like the bone, it is curved and triangular in form at the base and flattened toward the apex. It terminates at the hiatus sacralis between the sacral cornua, where the laminæ of the fourth and fifth sacral vertebræ are incomplete. The canal opens on the surface by the anterior and posterior sacral foramina and lodges the lower branches of the cauda equina, the filum terminale, and the lower extremity of the dura and arachnoid. The sub-dural and sub-arachnoid spaces extend downward within the canal as far as the body of the third sacral vertebra.

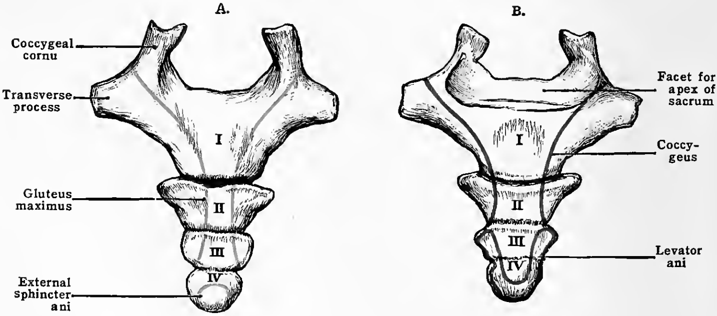
Differences in the two sexes.—The sacrum of the female is usually broader in proportion to its length, much less curved, and directed more obliquely backward than in the male. The curvature of the female sacrum belongs chiefly to the lower part of the bone, whereas in the male it is equally distributed over its whole length; but the curvature is subject to considerable variation in different skeletons.

Fig. 46.—Base of Sacrum.



Racial differences.—The human sacrum is characterised by its great breadth in comparison with its length, though in the lower races it is relatively longer than in the higher. The proportion is expressed by the *sacral index* $= \frac{\text{breadth} \times 100}{\text{length}}$. The average sacral index in the British male is 112, in the female 116. Sacra in which the index is above 100 are *platyhieric*, as in Europeans; those under 100 are *dolichohieric*, as in most of the black races (Sir W. Turner).

Fig. 47.—The Coccyx. A. Posterior view; B. Anterior view.



THE COCCYGEAL VERTEBRÆ

The four coccygeal vertebræ are united in the adult to form the **coccyx** [os coccygis] (fig. 47). While four is the usual number of these rudimentary vertebræ, occasionally there are five, and rarely three. In middle life the first piece is usually separate, and the original division of the remaining portion of the coccyx into three parts is indicated by transverse grooves. In advanced life the pieces of the coccyx, having previously united to form one bone, may also become joined to the sacrum.

The first piece of the coccyx is much broader than the others. It consists of a body, transverse processes, and rudiments of a neural arch. The body presents on its upper surface an oval facet for articulation with the apex of the sacrum. On each side of the body a **transverse process** projects laterally and is joined either by ligament or bone to the inferior lateral angle of the sacrum, forming a foramen for the anterior division of the fifth sacral nerve. From the posterior surface of the body two long **coccygeal cornua** project upward and are connected to the sacral cornua by the posterior sacro-coccygeal ligaments, enclosing on each side an aperture —the last intervertebral foramen—for the exit of the fifth sacral nerve. The coccygeal cornua represent the roots and superior articular processes of the first coccygeal vertebra.

The **second** piece of the coccyx is much smaller than the first, and consists of a body, traces of transverse processes, and a neural arch, in the form of slight tubercles at the sides and on the posterior aspect of the body.

The **third** and **fourth** pieces of the coccyx, smaller than the second piece, are mere nodules of bone, corresponding solely to vertebral bodies.

The **anterior surface** of the coccyx gives attachment to the anterior sacro-coccygeal ligament and near the tip to the *levator ani;* it is in relation with the posterior surface of the rectum.

The **posterior surface** of the coccyx is convex, and the upper three pieces afford attachment to the *gluteus maximus* on each side, and the last piece to the coccygeal portion of the *sphincter ani externus.*

The **lateral margins** are thin, and receive parts of the sacro-sciatic ligaments, of the *coccygei* muscles, and of the *levatores ani.*

THE VERTEBRAL COLUMN AS A WHOLE

The vertebral column (fig. 48) is the central axis of the skeleton and is situated in the median line at the posterior aspect of the trunk. Superiorly it supports the skull; laterally it gives attachment to the ribs, through which it receives the weight of the upper limbs, and inferiorly it is supported by the hip bones, by which the weight of the trunk is transmitted to the lower limbs. Its length varies in different skeletons, but on an average it measures about 70 cm. (28 in.) in the male and about 2.5 cm. (1 in.) less in the female. To the entire length the cervical region contributes 12.5 cm. (5 in.), the thoracic 27.5 cm. (11 in.), the lumbar 17.5 cm. (7 in.), and the sacro-coccygeal portion the remaining 12.5 cm. (5 in.). The vertebral column presents a series of curvatures, four when viewed in profile and one when viewed from the front or back. The former are directed alternately forward and backward, and are named, from the regions of the column in which they occur, **cervical, thoracic, lumbar,** and **sacral.** The fifth curve is **lateral,** being in most cases directed toward the right side.

The cervical, thoracic and lumbar curvatures pass imperceptibly into one another, but at the junction of the last lumbar vertebra with the sacrum a well-marked angle occurs, known as the **sacro-vertebral** or **lumbo-sacral** angle, with the result that the promontory of the sacrum overhangs the cavity of the minor (small) pelvis and forms a portion of the superior aperture of the small pelvis.

The thoracic and sacral curves have their concavities directed forward and are developed during intra-uterine life. They are in obvious relation to two great cavities of the trunk, thoracic and pelvic, and may be regarded as **primary** or **accommodation** curves, for the thoracic and pelvic viscera. The thoracic curve extends from the second to the twelfth thoracic vertebra and the sacral curve coincides with the sacrum and coccyx.

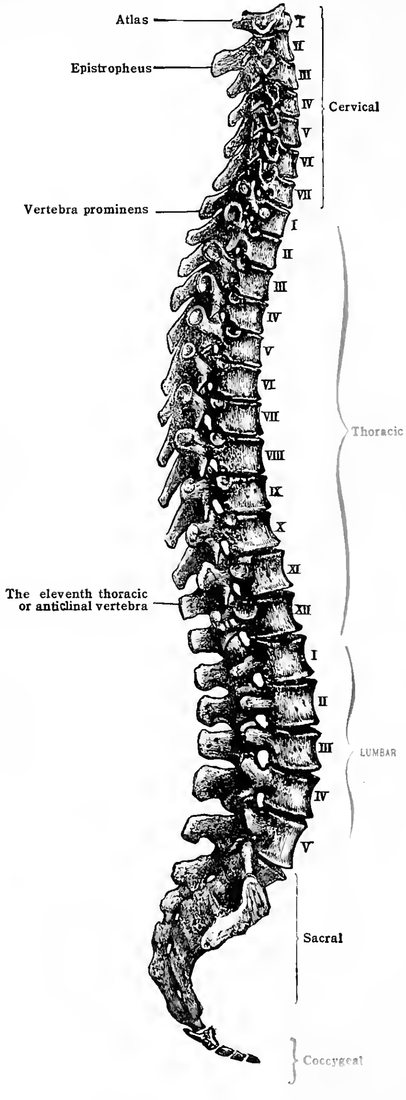
The cervical and lumbar curves have their convexities directed forward, and are developed during the first year after birth. They are essentially curves of **compensation,** necessary for the maintenance of the upright posture, and are brought about by modifications in the shape of the intervertebral discs. The cervical curve is formed about the third month, or as soon as the infant can sit upright. The great peculiarity of the curve is that it is never consolidated, being present when the body is placed in the erect position and obliterated by bending the head down upon the chest. The lumbar curve is developed about the end of the first year or when the child begins to walk, but is not consolidated until adult life. (Symington.) The cervical curve extends from the atlas to the second thoracic vertebra, and the lumbar curve from the twelfth thoracic to the promontory of the sacrum.

The lateral curve is situated in the upper thoracic region, and when directed to the right is probably associated with the greater use made of the right hand. This curve, however, is particularly liable to modification in different occupations and in different races.

Viewed from the front, the vertebral column presents a series of **pyramids** due to the successive increase and decrease in size of the bodies. These become broader from the axis to the first thoracic vertebra and then decrease to the fourth thoracic. The first pyramid therefore includes all the cervical vertebræ except the atlas, and has the apex directed upward and its base downward, whilst the second is inverted and formed by the first four thoracic vertebræ. The third pyramid, much the longest, is the result of the increase in size from the fourth thoracic to the fifth lumbar vertebra, and the fourth, which is inverted, is produced by the rapid contraction of the sacral and coccygeal vertebræ.

Viewed from behind, the spinous processes project in the middle line, and the transverse processes as two lateral rows. Of the spines, those of the axis, seventh cervical, first thoracic, and the lumbar vertebræ appear most prominent. On each side is the **vertebral groove,** the floor of which is formed in the cervical and lumbar regions by the laminæ and articular processes,

Fig. 48.—Vertebral Column. (Lateral view.)

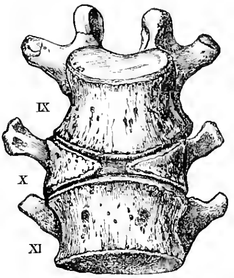


and in the thoracic region, by the laminæ and transverse processes. The transverse processes project laterally for a considerable distance in the atlas, first thoracic, and the middle of the lumbar series; they are shortest in the third cervical and the twelfth thoracic.

In the lateral view, the intervertebral foramina appear oval in shape, and are small in the cervical, larger in the thoracic, and largest in the lumbar region.

Structure of a vertebra.—The bodies of the vertebræ are largely composed of cancellous tissue, with a thin outer covering of compact tissue. In a vertical section through the centrum

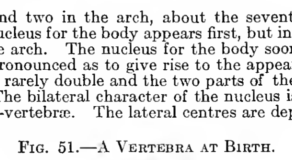
FIG. 49.—A DIVIDED THORACIC VERTEBRA. (After Turner.)



the fibres of the cancellous tissue are seen to be arranged vertically and horizontally, the vertical fibres being curved with their concavities directed toward the centre of the bone. The horizontal fibres are slightly curved parallel with the upper and lower surfaces, and have their convexities toward the centre of the bone. They are not so well defined as the vertical set. (Wagstaffe.)

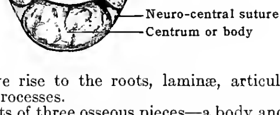
Ossification.—The vertebræ in general.—The ossification of each vertebra takes place in cartilage from three primary and five secondary centres. The three primary centres

FIG. 50.—A VERTEBRAL CENTRUM IN SECTION TO SHOW THE PRESSURE CURVES.



appear, one in the body and two in the arch, about the seventh week of intra-uterine life. In the thoracic region the nucleus for the body appears first, but in the cervical region it is preceded by the centres for the arch. The nucleus for the body soon becomes bilobed, and this condition is sometimes so pronounced as to give rise to the appearance of two distinct nuclei. Indeed, the nucleus is very rarely double and the two parts of the body may remain separate throughout life (fig. 49). The bilateral character of the nucleus is further emphasised by the occasional formation of half-vertebræ. The lateral centres are deposited near the bases of the

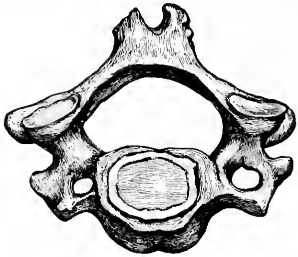
FIG. 51.—A VERTEBRA AT BIRTH.



superior articular processes and give rise to the roots, laminæ, articular, and the greater parts of the transverse and spinous processes.

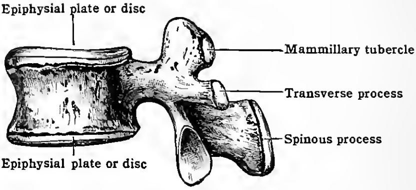
At birth a typical vertebra consists of three osseous pieces—a body and two lateral masses, which constitute the arch, the parts being joined together by hyaline cartilage. The line of union of the lateral portion with the body is known as the *neuro-central suture*, and is not actually obliterated for several years after birth. In the thoracic region the central ossification does not pass beyond the point with which the head of the rib articulates, and leaves a portion of the body on each side formed from the lateral ossification. A thoracic vertebra at the fifth year shows that the pits for the heads of the ribs are situated behind the neuro-central suture, which is directed obliquely backward and medially. The laminæ unite during the first year after birth; and by the gradual extension of ossification into the various processes, the vertebræ have attained almost their full size by the time of puberty. Subsequently the secondary centres appear in the cartilaginous extremities of the spinous and transverse processes, and in the carti-

FIG. 52.—CERVICAL VERTEBRA SHOWING THE EPIPHYSIAL PLATE ON THE UPPER SURFACE OF THE BODY.



lage on the upper and lower surfaces of the bodies, forming in each vertebra two annular plates, thickest at the circumference and gradually thinning toward the central deficiency. The epiphyses appear from the fifteenth to the twentieth year and join with the vertebra by the twenty-fifth year.

FIG. 53.—LUMBAR VERTEBRA AT THE EIGHTEENTH YEAR WITH SECONDARY CENTRES.

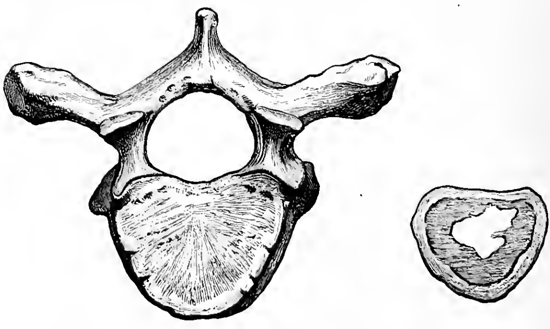


In several vertebræ the mode of ossification differs from the account given above—in some cases considerably—and necessitates separate consideration.

Atlas.—The lateral portions and posterior arch are formed from two centres of ossification, which correspond to the lateral centres of other vertebræ and appear about the seventh week.

FIG. 54.—UPPER THORACIC VERTEBRA WITH AN EPIPHYSIAL PLATE REMOVED AND DRAWN AT THE SIDE.

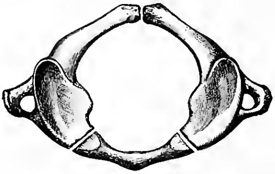
The plate shows the characteristic deficiency in the centre. (Natural size.)



The anterior arch is ossified from one centre, which, however, does not appear until a few months after birth. Union of the lateral parts occurs posteriorly in the third year, being sometimes preceded by the appearance of a secondary centre of ossification in the intervening cartilage, and the union of the lateral parts with the anterior arch occurs about the sixth year.

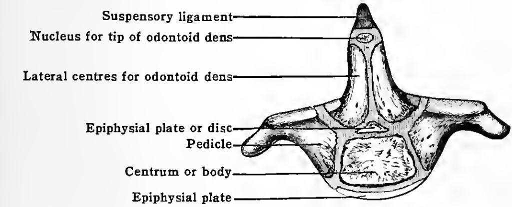
Epistropheus.—The arch, and the processes associated with it, are formed from two lateral centres which appear, like those in the other vertebræ, about the seventh week. The common piece of cartilage which precedes the body and dens is ossified from four (or five) centres, one (or two) for the body of the axis, in the fourth month, two, laterally disposed, for the dens, a

FIG. 55.—IMMATURE ATLAS. (Third year.)



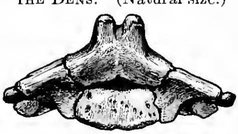
few weeks later, and one, for the apex of the dens, in the second year. The two collateral centres for the main part of the dens soon coalesce, so that at birth the axis consists of four osseous pieces —two lateral portions which constitute the arch, the body, and the dens, surmounted by a piece of cartilage. During the third or fourth year the dens joins with the body, the line of

FIG. 56.—DEVELOPMENT OF THE EPISTROPHEUS.



union being indicated even in advanced life by a small disc of cartilage, and the arch unites in front and behind about the same time or a little later. The apical nucleus of the dens, which represents an epiphysis, joins the main part about the twelfth year and in the seventeenth year

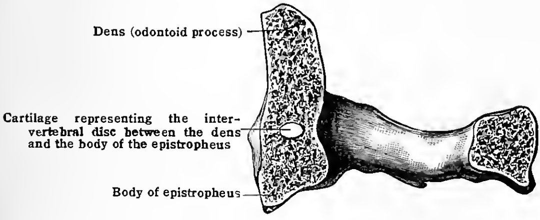
FIG. 57.—THE EPISTROPHEUS AT FOUR YEARS OF AGE, SHOWING THE SIZE AND EXTENT OF THE DENS. (Natural size.)



an epiphysial plate appears for the lower surface of the body. There are also rudiments, adjoining the cartilaginous disc, of the upper epiphysial plate of the body.

Cervical vertebræ.—In the cervical vertebræ the lateral centres form a larger share of the body than in the vertebræ of other regions, and the neuro-central suture runs almost in a sag-

FIG. 58.—THE EPISTROPHEUS (FROM AN ADULT) IN SAGITTAL SECTION.

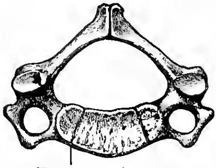


ittal direction. The sixth, seventh, and even the fifth have additional centres which appear before birth for the anterior or costal divisions of the transverse processes. In the other cervical vertebræ the costal processes are ossified by extension of the lateral nuclei. The costal processes of the seventh cervical sometimes remain separate, constituting cervical ribs.

Lumbar vertebræ.—In the lumbar vertebræ the neuro-central suture is almost transverse, and to the usual number of centres of ossification, two other epiphyses for the mammillary tubercles are added, the centres appearing about puberty. The transverse process of the first lumbar vertebra is occasionally developed from an independent centre.

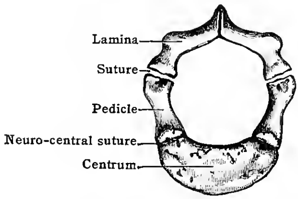
The fifth lumbar exhibits in some cases a special mode of ossification in the arch. Instead of two centres, there are four—one on each side for the root, transverse process, and superior articular process, and another on each side for the lamina, inferior articular process, and the lateral half of the spinous process (fig. 60). There may be failure of union of roots with the laminæ or of the laminæ with one another.

Fig. 59.—An Immature Cervical Vertebra.



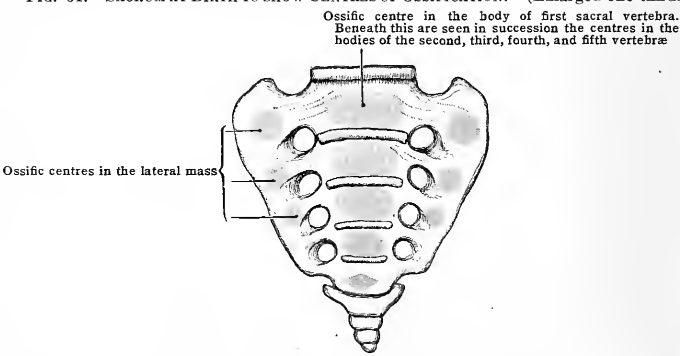
Sacral vertebræ.—The sacrum ossifies from thirty-five centres, which may be classified as follows:—In each of the five vertebræ there are three primary nuclei—one for the body and two for the arch; in each of the first three the costal element of the lateral mass on each side is formed from a separate nucleus; associated with each body are two epiphysial plates; and on each lateral margin are two irregular epiphyses, one for the auricular surface and another for the rough edge below.

Fig. 60.—Ossification of the Fifth Lumbar Vertebra.



The centres for the bodies appear about the eighth or ninth week and for the vertebral arches about the sixth month. The arches join the bodies at different times in the different vertebræ, ranging from the second year below, to the fifth or sixth year above, and union of the laminæ takes place behind some years later, from about the ninth to the fifteenth year.

Fig. 61.—Sacrum at Birth to show Centres of Ossification. (Enlarged one-third.)

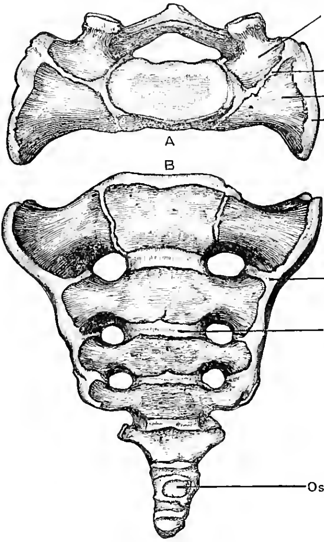


The centres for the costal elements appear outside the anterior sacral foramina, from the fifth to the seventh month, and these unite with the bodies somewhat later than the arches.

The centres for the epiphysial plates appear about the fifteenth year, and for the auricular epiphyses and the edges below, from the eighteenth to the twentieth year.

Consolidation begins soon after puberty by fusion of the costal processes, and this is followed by ossification from below upward in the intervertebral discs, resulting in the union of the adjacent bodies and the epiphysial plates, the ossific union of the first and second being completed by the twenty-fifth year or a little later. The marginal epiphyses are also united to the

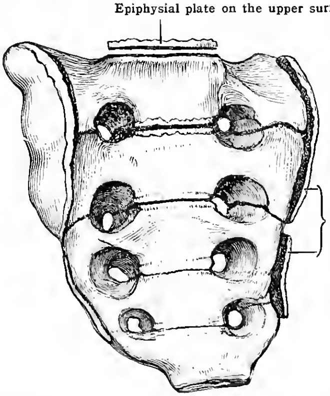
FIG. 62.—THE SACRUM AT FOUR YEARS OF AGE (B). THE FIGURE AT THE TOP (A) SHOWS THE BASE DRAWN FROM ABOVE. (Three-fourths natural size.)



sacrum by the twenty-fifth year. Even in advanced life intervertebral discs persist in the more central parts of the bone and can be well seen in sections.

Coccygeal vertebræ.—The coccygeal vertebræ are cartilaginous at birth and each is usually ossified from a single centre, though there may be two for the first piece. Ossification begins soon after birth in the first segment, and in the second from the fifth to the tenth year.

FIG. 63.—SACRUM AT ABOUT TWENTY-TWO YEARS. (Three-fifths natural size.)



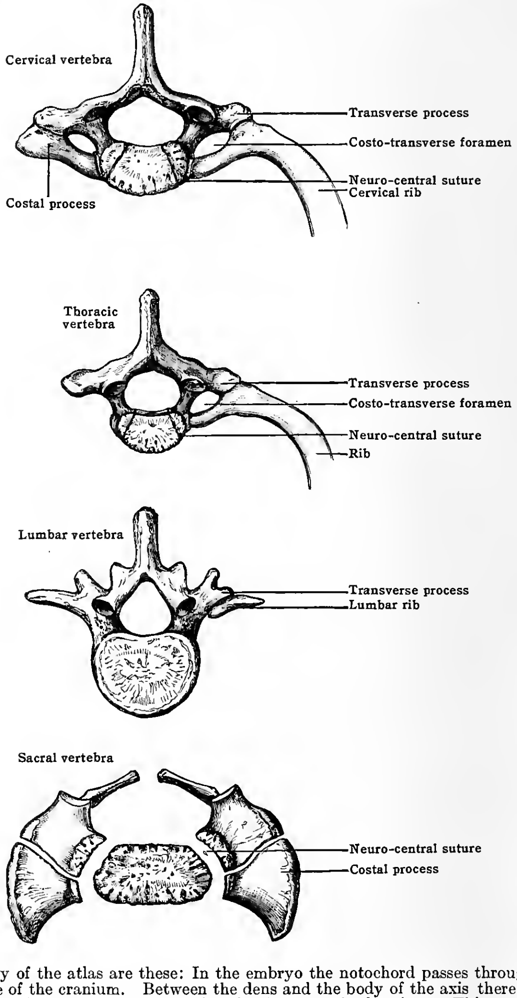
The centres for the third and fourth segments appear just before, and after, puberty respectively. As age advances the various pieces become united with each other, the three lower uniting before middle life and the upper somewhat later. In advanced life the coccyx may join with the sacrum, the union occurring earlier and more frequently in the male than in the female.

The Serial Morphology of the Vertebræ

Although at first sight many of the vertebræ exhibit peculiarities, nevertheless a study of the mode by which they develop, and their variations, indicates the serial homology of the constituent parts of the vertebræ in each region of the column.

The body (centrum) of the vertebra is that part which immediately surrounds the notochord. This part is present in all the vertebræ of man, but the centrum of the atlas is dissociated from its arch, and ankylosed to the body of the epistropheus. The reasons for regard-

Fig. 64.—Morphology of the Transverse and Articular Processes.



ing the dens as the body of the atlas are these: In the embryo the notochord passes through it on its way to the base of the cranium. Between the dens and the body of the axis there is a swelling of the notochord in the early embryo as in other intervertebral regions. This swelling is later indicated by a small intervertebral disc hidden in the bone, but persistent even in old age. Moreover, the dens ossifies from primary centres, and in chelonians it remains as a separate ossicle throughout life; in Ornithorhynchus it remains distinct for a long time, and it has been found separate even in an adult man. Lastly, in man and many mammals, an epiphysial plate develops between it and the body of the axis. The anterior arch of the atlas represents a cartilaginous *hypochordal bar*, which is present in the early stages of development of the vertebræ, but disappears in all but the atlas in the ossification of the body.

The *arches* and *spinous processes* are easily recognised throughout the various parts of the column in which complete vertebræ are present.

The *articular processes* or *zygapophyses* are of no morphological value, and do not require consideration here.

The *transverse processes* offer more difficulty. They occur in the simplest form in the thoracic series. Here they articulate with the tubercles of the ribs, whence the term *tubercular processes* or *diapophyses* has been given them (the place of articulation of the head of the rib with the vertebra is the *capitular process* or *parapophysis*), and the transverse process and the neck of the rib enclose an arterial foramen named the costo-transverse foramen. In the cervical region the costal element (*pleurapophysis*) and the transverse process are fused together, and the conjoint process thus formed is pierced by the costo-transverse foramen. The compound nature of the process is indicated by the fact that the anterior or costal processes in the lower cervical vertebræ arise from additional centres and occasionally retain their independence as cervical ribs, and in Sauropsida (birds and reptiles) these processes are represented by free ribs. In the lumbar region, the compound nature of the transverse process is further marked. The true transverse process is greatly suppressed, and its extremity is indicated by the accessory tubercle. Anterior to this in the adult vertebræ a group of holes represents the costo-transverse foramen, and the portion in front of this is the costal element. Occasionally it persists as an independent ossicle, the lumbar rib.

In the sacral series the costal elements are coalesced in the first three vertebræ to form the greater portion of the lateral portion for articulation with the ilium, the costo-transverse foramina being completely obscured. In rare instances the first sacral vertebra will articulate with the ilium on one side, but remain free on the other, and under such conditions the free process exactly resembles the elongated transverse process of a lumbar vertebra. The first three sacral vertebræ which develop costal processes for articulation with the ilium are termed *true sacral* vertebræ, while the fourth and fifth are termed *pseudo-sacral*. A glance at fig. 64 will show the homology of the various parts of a vertebra from the cervical, thoracic, lumbar, and sacral regions.

B. BONES OF THE SKULL

The skull is the expanded upper portion of the axial skeleton and is supported on the summit of the vertebral column. It consists of the **cranium,** a strong bony case enclosing the brain and made up of eight bones—viz., *occipital*, two *parietal*, *frontal*, two *temporal*, *sphenoid*, *ethmoid;* and the **bones of the face,** surrounding the mouth and nose, and forming with the cranium the orbital cavity for the reception of the eye. The bones of the face are fourteen in number—viz., two *maxillæ*, two *zygomatic* (*malar*), two *nasal*, two *lacrimal*, two *palate*, two *inferior conchæ* (*turbinates*), the *mandible*, and the *vomer*. All the bones enumerated above, with the exception of the mandible, are united by suture and are therefore immovable. The proportion between the facial and cranial parts of the skull varies at different periods of life, being in the adult about one (facial) to two (cranial), and in the new-born infant about one to eight. A group of movable bones, comprising the *hyoid*, suspended from the basilar surface of the cranium, and three small bones, the *incus*, *malleus*, and *stapes*, situated in the middle ear or tympanic cavity, is also included in the enumeration of the bones of the skull.

According to the BNA nomenclature, the term *cranium* is used in a wider sense as synonymous with *skull*, and is subdivided into *cranium cerebrale* (cranium in the narrower sense) and *cranium viscerale* (facial skeleton). In the BNA, seven bones above listed with the facial,—two inferior conchæ, two lacrimal, two nasal and the vomer—are classed with the cranium cerebrale.

THE OCCIPITAL

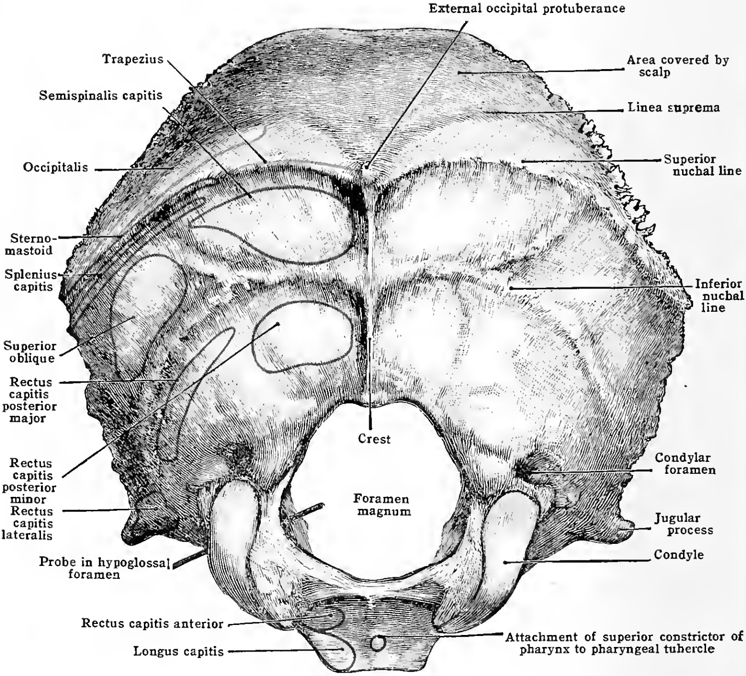
The **occipital bone** [os occipitale] (fig. 65) is situated at the posterior and inferior part of the cranium. In general form it is flattened and trapezoid in shape, curved upon itself so that one surface is convex and directed backward and somewhat downward, while the other is concave and looks in the opposite direction. It is pierced in its lower and front part by a large aperture, the **foramen magnum,** by which the vertebral canal communicates with the cavity of the cranium.

The occipital bone is divisible into four parts, **basilar, squamous,** and two **condylar,** so arranged around the foramen magnum that the basilar part lies in front, the condylar parts on either side, and the squamous part above and behind.

Speaking generally, this division corresponds to the four separate parts of which the bone consists at the time of birth (fig. 69), known as the **basi-occipital, supra-occipital,** and **ex-occipital.** In early life these parts fuse together, the lines of junction of the supra-occipital and ex-occipitals extending lateralward from the posterior margin of the foramen magnum, and those of the ex-occipitals and basi-occipital passing through the condyles near their anterior extremities. It must be noted, however, that the upper portion of the squamous part represents an additional bone, the interparietal.

The **squamous part** [squama occipitalis] (supra-occipital and interparietal) presents on its convex **posterior surface,** and midway between the superior angle and the posterior margin of the foramen magnum, a prominent tubercle known as the **external occipital protuberance,** from which a vertical ridge—the **external occipital crest**—runs downward and forward as far as the foramen. The protuberance and crest give attachment to the ligamentum nuchæ.

Fig. 65.—The Occipital. (External view.)



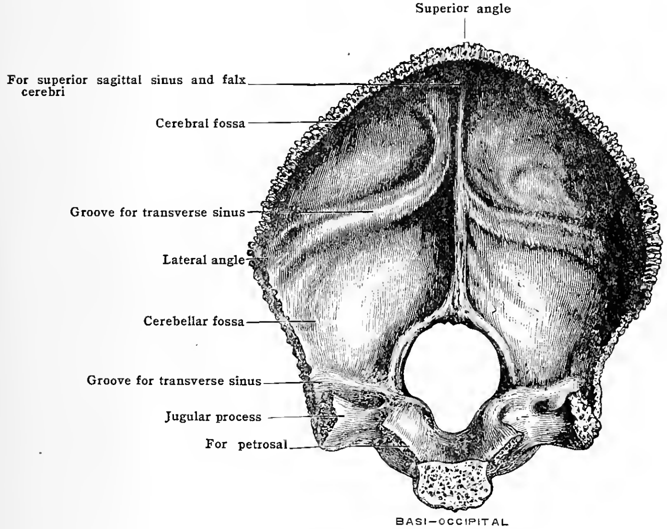
Arching lateralward on each side from the external occipital protuberance toward the lateral angle of the bone is a semicircular ridge, the **superior nuchal line** [linea nuchæ superior], which divides the surface into two parts—an upper [planum occipitale] and a lower [planum nuchale]. Above this line, a second less distinctly marked ridge—the **highest nuchal line** [linea nuchæ suprema]—is usually seen. It is the most curved of the three lines on this surface and gives attachment to the epicranial aproneuosis and to a few fibres of the *occipitalis* muscle. Between the superior and highest curved lines is a narrow crescentic area in which the bone is smoother and denser than the rest of the surface, whilst the part of the bone above the linea suprema is convex and covered by the scalp.

The lower part of the surface is very uneven and subdivided into an upper and a lower area by the **inferior nuchal line,** which runs laterally from the middle of the crest to the jugular process.

The curved lines and the areas thus mapped out between and below them give attachment to several muscles. To the superior nuchal line are attached, medially the *trapezius*, and laterally the *occipitalis* and *sterno-cleido-mastoid;* the area between the superior and inferior curved lines receives the *semispinalis capitis* (*complexus*) medially, and *splenius capitis* and *obliquus capitis superior* laterally; the inferior nuchal line and the area below it afford insertion to the *rectus capitis posterior minor* and *major*.

The **anterior or cerebral surface** is deeply concave and marked by two grooved ridges which cross one another and divide the surface into four fossæ of which the two upper, triangular in form, lodge the occipital lobes of the cerebrum, and the two lower, more quadrilateral in outline, the lobes of the cerebellum. The vertical ridge extends from the superior angle to the foramen magnum and the transverse ridge from one lateral angle to the other, the point of intersection being indicated by the **internal occipital protuberance** [eminentia cruciata]. The

Fig. 66.—Occipital Bone, Cerebral Surface.



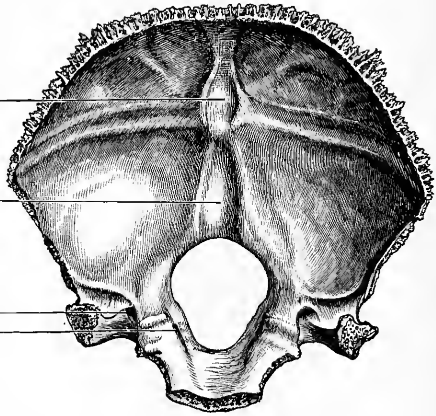
upper part of the vertical ridge is grooved [sulcus sagittalis] for the superior sagittal (*longitudinal*) sinus and gives attachment, by its margins, to the falx cerebri; the lower part is sharp and known as the **internal occipital crest,** and affords attachment to the falx cerebelli. Approaching the foramen magnum the ridge divides, and the two parts become lost upon its margin. The angle of divergence sometimes presents a shallow fossa for the extremity of the vermis of the cerebellum, and is called the **vermiform fossa.** The two parts of the transverse ridge are deeply grooved [sulcus transversus] for the transverse (*lateral*) sinuses, and the margins of the groove give attachment to the tentorium cerebelli. To one side of the internal occipital protuberance is a wide space, where the vertical groove is continued into one of the lateral grooves (more frequently the right), and this is termed the torcular Herophili; it is sometimes exactly in the middle line.

The squamous portion has three angles and four borders. The **superior angle** forming the summit of the bone is received into the space formed by the union of the two parietals. The **lateral angles** are very obtuse and correspond in situation with the lateral ends of the transverse ridges. Above the lateral angle on each side the margin is deeply serrated, forming the **lambdoid** or **superior border** which extends to the superior angle and articulates with the posterior border of the parietal in the lambdoid suture. The **mastoid** or **inferior border** extends from the lateral angle to the jugular process and articulates with the mastoid portion of the temporal.

The **condylar** or **lateral portions** [partes laterales] (ex-occipitals) form the lateral boundaries of the foramen magnum and bear the condyles on their inferior surfaces. The **condyles** are two convex oval processes of bone with smooth articular surfaces, covered with cartilage in the recent state, for the superior articular processes of the atlas. They converge in front, and are somewhat everted. Their margins give attachment to the capsular ligaments of the occipito-atlantal joints and on the medial side of each is a prominent tubercle for the alar (lateral odontoid) ligament. The anterior extremities of the condyles extend beyond the ex-occipitals on the basi-occipital portion of the bone. The **hypoglossal** (anterior condyloid) **foramen** or **canal** [canalis hypoglossi] perforates the bone at the base of the condyle, and is directed from the interior of the cranium, just above the foramen magnum, forward and laterally; it transmits the hypoglossal nerve and a twig of the ascending pharyngeal artery.

The foramen is sometimes double, being divided by a delicate spicule of bone. Above the canal is a smooth convexity known as the **tuberculum jugulare** sometimes marked by an oblique groove for the ninth, tenth and eleventh cranial nerves. Posterior to each condyle is a pit, the

Fig. 67.—Cerebral Surface of the Occipital, Showing an Occasional Disposition of the Channels.

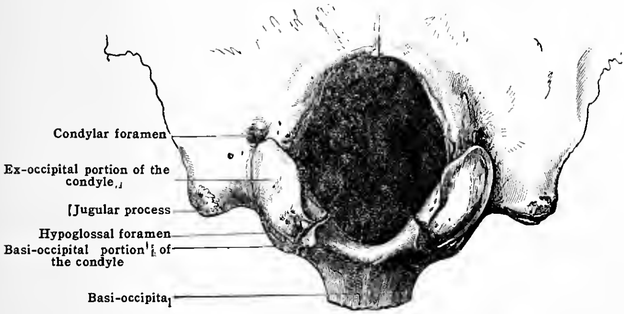


condylar fossa, which receives the hinder edge of the superior articular process of the atlas when the head is extended. The floor of the depression is occasionally perforated by the **condylar** (posterior condyloid) **canal** or **foramen** [canalis condyloideus], which transmits a vein from the transverse sinus. Projecting laterally opposite the condyle is a quadrilateral portion of bone known as the **jugular process**, the extremity of which is rough for articulation with the jugular facet on the petrous portion of the temporal bone. Up to twenty-five years the bones are united here by means of cartilage; about this age ossification of the cartilage takes place, and the jugular process thus becomes fused with the petrosal. Its anterior border is deeply notched to form the posterior boundary of the jugular foramen, and the notch is directly continuous with a groove on the upper surface which lodges the termination of the transverse sinus. In or near the groove is seen the inner opening of the condylar foramen. The lower surface of the process gives attachment to the *rectus capitis lateralis* and the oblique occipito-atlantal ligament. Occasionally the mastoid air cells extend into this process and rarely a process of bone, representing the *paramastoid process* of many mammals, projects downward from its under aspect and may be so long as to join or articulate with the transverse process of the atlas.

The **basilar portion** (basi-occipital) is a quadrilateral plate of bone projecting forward and upward in front of the foramen magnum. Its superior surface presents a deep groove—the **basilar groove** [clivus]; it supports the medulla oblongata and gives attachment to the tectorial membrane (occipito-axial ligament). The lower surface presents in the middle line a small elevation known as the **pharyngeal tubercle** for the attachment of the fibrous raphé of the pharynx, and immediately in front of the tubercle there is frequently a shallow fossa—the **scaphoid fossa**—which originally received the primitive anterior extremity of the foregut.

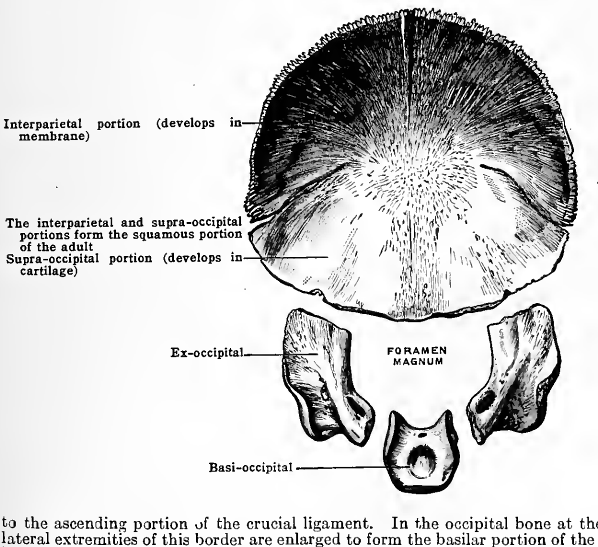
On each side of the middle line are impressions for the insertions of the *longus capitis* (*rectus capitis anterior major*) and *rectus capitis anterior* (*minor*), the impression for the latter being

Fig. 68.—The Foramen Magnum at the Sixth Year.



nearer to the condyle, and near the foramen magnum this surface gives attachment to the anterior occipito-atlantal ligament. Anteriorly the basilar process articulates by synchondrosis with the body of the sphenoid up to twenty years of age, after which there is complete bony union. Posteriorly it presents a smooth rounded border forming the anterior boundary of the foramen magnum. It gives attachment to the apical odontoid ligament, and above this

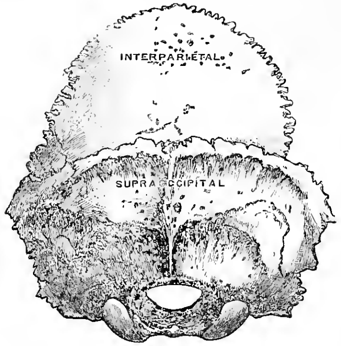
Fig. 69.—The Occipital at Birth. (Anterior view.)



to the ascending portion of the crucial ligament. In the occipital bone at the sixth year the lateral extremities of this border are enlarged to form the basilar portion of the condyles. The lateral borders are rough below for articulation with the petrous portion of the temporal bones, but above, on either side of the basilar groove, is a half-groove, which, with a similar half-groove on the petrous portion of the temporal bone. lodges the inferior petrosal sinus.

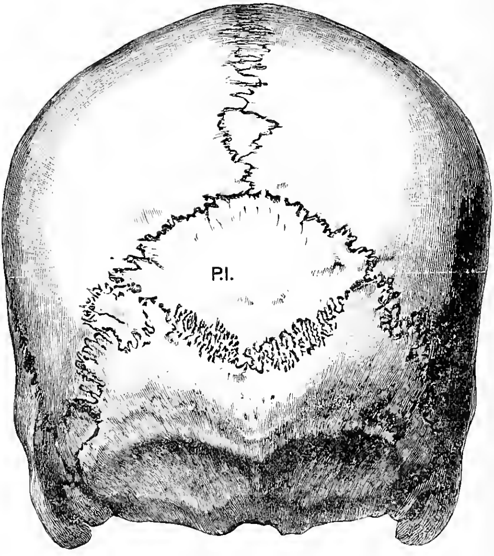
The **foramen magnum** is oval in shape, with its long axis in a sagittal direction. It transmits the medulla oblongata and its membranes, the accessory nerves (spinal portions), the vertebral arteries, the anterior and posterior spinal

FIG. 70.—THE OCCIPITAL WITH A SEPARATE INTERPARIETAL.



arteries, and the tectorial membrane (occipito-axial ligament). It is widest behind, where it transmits the medulla, and is narrower in front, where it is encroached upon by the condyles.

FIG. 71.—SKULL SHOWING A PRE-INTERPARIETAL BONE (P.I.).



Occasionally a facet is present on the anterior margin, forming a *third occipital condyle* for articulation with the dens. Between the condyles and behind the margin of the foramen magnum the posterior occipito-atlantal ligament obtains attachment.

Blood-supply.—The occipital bone receives its blood-supply from the occipital, posterior auricular, middle meningeal, vertebral and the ascending pharyngeal arteries.

Articulations.—The occipital bone is connected by suture with the two parietals, the two temporals, and the sphenoid; the condyles articulate with the atlas, and exceptionally the occipital articulates with the dens of the epistropheus by means of the third occipital condyle.

Ossification.—The occipital bone develops in four pieces. The squamous portion is ossified from four centres, arranged in two pairs, which appear about the eighth week. The upper pair are deposited in membrane, and this part of the squamous portion represents the interparietal bone of many animals. The lower pair, deposited in cartilage, form the true supra-occipital element, and the four parts quickly coalesce near the situation of the future occipital protuberance. For many weeks two deep lateral fissures separate the interparietal and supraoccipital portions, and a membranous space extending from the centre of the squamous portion to the foramen magnum partially separates the lateral portions of the supra-occipital. This space is occupied later by a spicule of bone, and is of interest as being the opening through which the form of hernia of the brain and its meninges, known as occipital meningocele or encephalocele, occurs. The basi-occipital and the two ex-occipitals are ossified each from a single nucleus which appears in cartilage from the eighth to the tenth week.

At birth the bone consists of four parts united by strips of cartilage, and in the squamous portion fissures running in from the upper and lateral angles are still noticeable. The osseous union of the squamous and ex-occipital is completed in the fifth year, and that of the ex-occipitals with the basi-occipital before the seventh year. Up to the twentieth year the basi-occipital is united to the body of the sphenoid by an intervening piece of cartilage, but about that date ossific union begins and is completed in the course of two or three years. Occasionally the interparietal portion remains separate throughout life (fig. 70), forming what has been termed the *inca bone*, or it may be represented by numerous detached ossicles or Wormian bones. In some cases a large Wormian bone, named the pre-interparietal, is found, partly replacing the interparietal bone (fig. 71). A pre-interparietal bone is found in some mammals, and it has occasionally been observed in the human fœtal skull. In fig. 71 the bone is seen in an adult human skull—a distinctly rare condition.

THE PARIETAL

The two **parietal bones** (figs. 72, 73), interposed between the frontal before and the occipital behind, form a large portion of the roof and sides of the cranium. Each parietal bone [os parietale] is quadrilateral in form, convex externally, concave internally, and each presents for examination two surfaces, four borders, and four angles.

The **parietal surface** is smooth and is crossed, just below the middle, by two curved lines known as the **temporal lines.** The superior line gives attachment to the temporal fascia; the lower, frequently the better marked, limits the origin of the *temporal* muscle; whilst the narrow part of the surface enclosed between them is smooth and more polished than the rest. Immediately above the ridges is the most convex part of the bone, termed the **parietal eminence** [tuber parietale], best marked in young bones, and indicating the point where ossification commenced. Of the two divisions on the parietal surface marked off by the temporal lines, the upper is covered by the scalp, and the lower, somewhat striated, affords attachment to the *temporal* muscle. Close to the upper border and near to the occipital angle is a small opening—the **parietal foramen**—which transmits a vein to the superior sagittal (*longitudinal*) sinus.

The **cerebral surface** is marked with depressions corresponding to the cerebral convolutions and by numerous deep furrows, running upward and backward from the sphenoidal angle and the lower border, for the middle meningeal vessels (sinus and artery). A shallow depression running close to the superior border forms, with the one of the opposite side, a channel for the superior sagittal sinus, at the side of which are small irregular pits for the Pacchionian bodies; the pits are usually present in adult skulls, but are best marked in those of old persons. The margins of the groove for the superior sagittal sinus give attachment to the falx cerebri.

Borders.—The **sagittal** or **superior border,** the longest and thickest, is deeply serrated to articulate with the opposite parietal, with which it forms the **sagittal suture.** The **frontal** or **anterior border** articulates with the frontal to form the **coronal suture.** It is deeply serrated and bevelled, so that it is overlapped by the frontal above, but overlaps the edge of that bone below. The **occipital** or **posterior border** articulates with the occipital to form the **lambdoid suture,** and resembles the superior and anterior in being markedly serrated. The **squamosal** or **inferior border** is divided into three portions:—the anterior, thin and bevelled, is overlapped by the tip of the great wing of the sphenoid; the middle portion, arched and also bevelled, is overlapped by the squamous part of the temporal; and the posterior portion, thick and serrated, articulates with the mastoid portion of the temporal bone.

Angles.—The **frontal** or **anterior superior,** almost a right angle, occupies that part of the bone which at birth is membranous and forms part of the anterior fontanelle. The **sphenoidal** or **anterior inferior** angle is thin and prolonged downward to articulate with the tip of the great wing of the sphenoid. Its inner surface is marked by a deep groove, sometimes converted into a canal for a short

Fig. 72.—The Left Parietal. (Outer surface.)

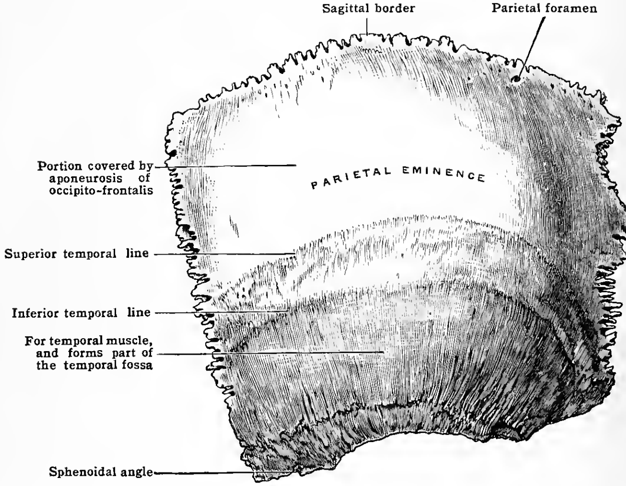


Fig. 73.—The Left Parietal. (Inner surface.)

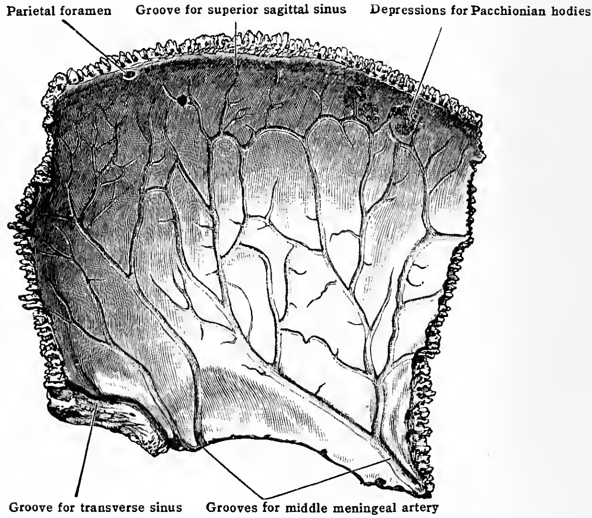


distance, for the middle meningeal vessels (chiefly for the sinus). The **occipital** or **posterior superior** angle is obtuse and occupies that part which during fœtal life enters into formation of the posterior fontanelle. The **mastoid** or **posterior**

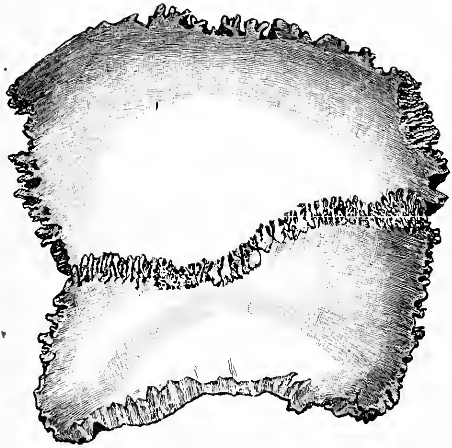
inferior angle is thick and articulates with the mastoid portion of the temporal bone. Its inner surface presents a shallow groove which lodges a part of the transverse (lateral) sinus.

Blood-supply.—The parietal bone receives its blood-supply from the middle meningeal, occipital, and supra-orbital arteries.

Articulations.—The parietal articulates with the occipital, frontal, sphenoid, temporal, its fellow of the opposite side, and the epipteric bone when present. Occasionally the temporal and epipteric bones exclude the parietal from articulation with the great wing of the sphenoid.

Ossification.—The parietal ossifies from a single nucleus which appears in the outer layer of the membranous wall of the skull about the seventh week. The ossification radiates in such a way as to leave a cleft at the upper part of the bone in front of the occipital angle, the

FIG. 74.—UNUSUAL FORM OF PARIETAL EXHIBITING A HORIZONTAL SUTURE SEPARATING THE BONE INTO TWO PIECES, UPPER AND LOWER.



cleft of the two side forming a lozenge-shaped space across the sagittal suture known as the sagittal **fontanelle.** This is usually closed about the fifth month of intra-uterine life, but traces may sometimes be recognised at the time of birth, and the parietal foramina are to be regarded as remains of the cleft. According to Dr. A. W. W. Lea, a well-developed sagittal fontanelle is present in 4.4 per cent. of infants at birth. In such cases it closes within the first two months of life, but at times it may remain open for at least eight months after birth and possibly longer.

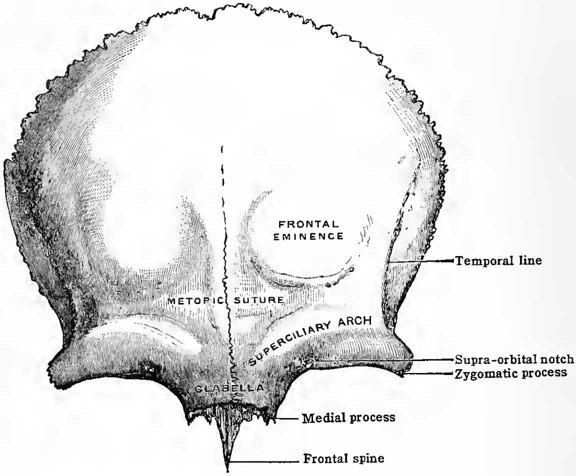
Rarely the parietal bone is composed of two pieces (fig. 74), one above the other, and separated by an antero-posterior suture (sub-sagittal suture), more or less parallel with the sagittal suture. In such cases the parietal is ossified from two centres of ossification.

THE FRONTAL

The **frontal bone** [os frontale] closes the cranium in front and is situated above the skeleton of the face. It consists of two portions—a **frontal** (*vertical*) **portion** [squama frontalis], forming the convexity of the forehead, and an **orbital** (*horizontal*) **portion,** which enters into formation of the roof of each orbit.

Frontal (*vertical*) **portion.**—The **frontal surface** is smooth and convex, and usually presents in the middle line above the root of the nose some traces of the suture which in young subjects traverses the bone from the upper to the lower part. This suture, known as the **frontal** or **metopic suture,** indicates the line of junction of the two lateral halves of which the bone consists at the time of birth; in the adult the suture is usually obliterated except at its lowest part. On each side is a rounded elevation, the **frontal eminence** [tuber frontale], very prominent in young bones, below which is a shallow groove, the **sulcus transversus,** separating the frontal eminence from the **superciliary arch.** The latter forms an arched projection above the margin of the orbit and corresponds to an air-cavity within the bone known as the **frontal sinus;** it gives attachment to the *orbicularis oculi* and the *corrugator* muscles. The ridges of the two sides converge toward the median line, but are separated by a smooth surface called the **glabella** (nasal eminence). Below the arch the bone presents a sharp curved margin, the **supra-orbital border,** forming the upper boundary of the circumference of the orbit and separating the frontal from the orbital portion of the bone. At the junction of its medial and intermediate third is a notch, sometimes converted into a foramen, and known as the **supra-orbital notch** or **foramen;** it transmits the supra-orbital nerve, artery, and vein, and at the bottom of the notch is a small opening for a vein of the diploe which terminates in the supra-orbital. Sometimes, a second less marked notch is present, medial to the supra-orbital, and known as the **frontal notch;** it transmits one of the divisions of the supra-orbital nerve. The extremities of the supra-orbital border are directed downward and form the **medial** and **zygomatic (lateral angular) processes.** The prominent zygomatic process articulates with the zygomatic bone and receives superiorly two well-marked lines which converge somewhat as they curve downward and forward across the bone. These are the **superior** and **inferior temporal lines,** continuous with the

Fig. 75.—The Frontal. (Anterior view.)



temporal lines on the parietal bone, the upper giving attachment to the temporal fascia and the lower to the temporal muscle. Behind the lines is a slight concavity which forms part of the floor of the temporal fossa and gives origin to the *temporal* muscle. The medial angular processes articulate with the lacrimals and form the lateral limits of the **nasal notch,** bounded in front by a rough, semilunar surface which articulates with the upper ends of the nasal bones and the frontal (nasal) processes of the maxillæ.

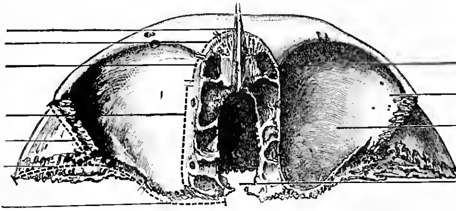
In the concavity of the notch lies the **nasal portion** of the frontal, which projects somewhat beneath the nasal bones and the nasal processes of the maxillæ. It is divisible into three parts: —a median **frontal** (nasal) **spine,** which descends in the nasal septum between the crest of the nasal bones in front and the vertical plate of the ethmoid behind, and, on the posterior aspect of the process, two **alæ,** one on either side of the median ridge from which the frontal (nasal) spine is continued. Each ala forms a small grooved surface which enters into the formation of the roof of the nasal fossa.

The **cerebral surface** presents in the middle line a vertical groove—the **sagittal sulcus**—which descends from the middle of the upper margin and lodges the superior sagittal (longitudinal) sinus. Below, the groove is succeeded by the **frontal crest,** which terminates near the lower margin at a small notch, converted into a foramen by articulation with the ethmoid.

The foramen is called the **foramen cæcum**, and is generally closed below, but sometimes transmits a vein from the nasal fossæ to the superior sagittal (longitudinal) sinus. The frontal crest serves for the attachment of the anterior part of the falx cerebri. On each side of the middle line the bone is deeply concave, presenting depressions for the cerebral convolutions and numerous small furrows which, running medially from the lateral margin, lodge branches of the middle meningeal vessels. At the upper part of the surface, on either side of the frontal sulcus, are some depressions for Pacchionian bodies.

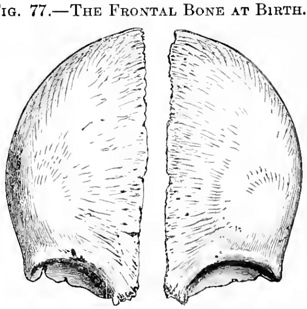
The **horizontal portion** consists of two somewhat triangular plates of bone called the **orbital plates,** which, separated from one another by the **ethmoidal**

Fig. 76.—The Frontal Bone. (Inferior view.)



notch [incisura ethmoidalis], form the greater part of the roof of each orbit. When the bones are articulated, the notch is filled up by the cribriform plate of the ethmoid, and the half-cells on the upper surface of the lateral mass of the ethmoid are completed by the depressions or half-cells which occupy the irregular margins of the notch. Traversing these edges transversely are two grooves which complete, with the ethmoid, the **anterior** and **posterior ethmoidal canals.** The anterior transmits the anterior ethmoidal nerve and vessels; the posterior transmits the posterior ethmoidal nerve and vessels, and both canals open on the medial wall of the orbit. Farther forward, on either side of the nasal spine, are the openings of the **frontal sinuses,** two irregular cavities which extend within

Fig. 77.—The Frontal Bone at Birth.



the bone for a variable distance and give rise to the superciliary arches (ridges). Each is lined by mucous membrane and communicates with the nasal fossa by means of a passage called the infundibulum.

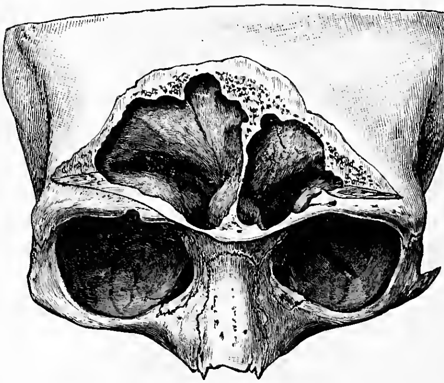
The **inferior surface** of each orbital plate, smooth and concave, presents immediately behind the lateral angular process the **lacrimal fossa,** for the lacrimal gland. Close to the medial angular process is a depression called the **trochlear fossa** [fovea trochlearis], which gives attachment to the cartilaginous pulley for the *superior oblique* muscle. The **superior surface** of each plate is convex and strongly marked by eminences and depressions for the convolutions on the orbital surface of the cerebrum.

Borders.—The articular border of the frontal portion (**parietal margin**) forms a little more than a semicircle. It is thick, strongly serrated, and bevelled so as to overlap the parietal above and to be overlapped by the edge of that bone below. The border is continued inferiorly into a triangular rough surface on either side, which articulates with the great wing of the sphenoid. The posterior border of the orbital portion is thin and articulated with the lesser wing of the sphenoid.

Blood-supply.—The blood-vessels for the supply of the vertical portion are derived from the frontal and supra-orbital arteries, which enter on the outer surface, and from the middle and small meningeal, which enter on the cerebral surface. The horizontal portion receives branches from the ethmoidal, and other branches of the ophthalmic, as well as from the meningeal.

Articulations.—The frontal articulates with the parietal, sphenoid, ethmoid, lacrimal, zygomatic (malar), maxilla, and nasal bones. Also, with the epipteric bones when present, and occasionally with the squamous portion of the temporal, and with the sphenoidal concha when it reaches the orbit.

Fig. 78.—Unusually Large Frontal Sinuses.



Ossification.—The frontal is ossified from two nuclei deposited in the outer layer of the membranous wall of the cranium, in the situations ultimately known as the frontal eminences. These nuclei appear about the eighth week, and ossification spreads quickly through the membrane. At birth the bones are quite distinct, but subsequently they articulate with each other in the median line to form the metopic suture. In the majority of cases the suture is obliterated by osseous union, which commences about the second year, though in a few cases the bones remain distinct throughout life.

After the two halves of the bone have united, osseous material is deposited at the lower end of the metopic suture to form the frontal spine, which is one of the distinguishing features of the human frontal bone. The spine appears about the twelfth year, and soon consolidates with the frontal bone above. Accessory nuclei are sometimes seen between this bone and the lacrimal and may persist as Wormian ossicles.

The frontal sinuses appear about the seventh year as prolongations upward from the hiatus semilunaris and increase in size up to old age. As they grow they extend in three directions, viz., upward, laterally, and backward along the orbital roof. A bony septum, usually complete, separates the sinuses of the two sides, and they are larger in the male than in the female. The superciliary arches are not altogether reliable guides as to the size of the sinuses, since examples are seen in which the arches are low and the sinuses large. In fig. 78 an example of unusually large sinuses is figured, illustrating the extension upward, laterally, and backward.

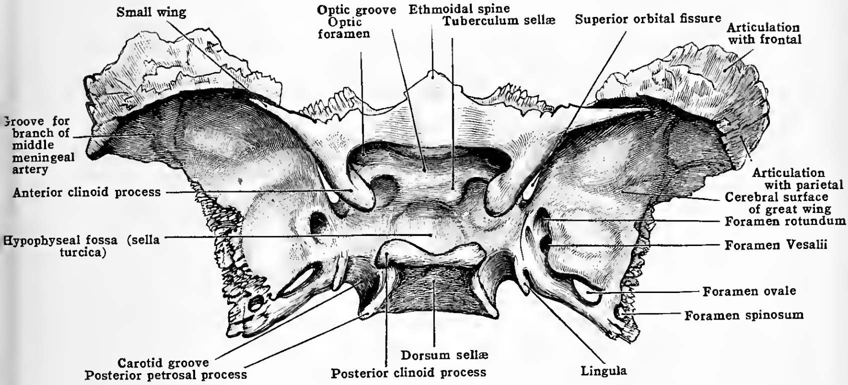
THE SPHENOID

The **sphenoid** [os sphenoidale] (figs. 79, 80, 81, 82) is situated in the base of the skull and takes part in the formation of the floor of the anterior, middle, and posterior cranial fossæ, of the temporal and nasal fossæ, and of the cavity of the orbit. It is very irregular in shape and is described as consisting of a central part or **body,** two pairs of lateral expansions called the **great** and **small wings,** and a pair of processes which project downward, called the **pterygoid processes.**

The **body,** irregularly cuboidal in shape, is hollowed out into two large cavities known as the **sphenoidal sinuses,** separated by a thin **sphenoidal septum** and opening in front by two large apertures into the nasal fossæ. The **superior sur-**

face presents the following points for examination: In front is seen a prominent spine, the **ethmoidal spine,** which articulates with the hinder edge of the cribriform plate of the ethmoid. The surface behind this is smooth and frequently presents two longitudinal grooves, one on either side of the median line, for the olfactory bulbs; it is limited posteriorly by a ridge, the **limbus sphenoidalis,** which forms the anterior border of the narrow transverse **optic groove** [sulcus chiasmatis], above and behind which lies the optic commissure. The groove terminates on each side in the **optic foramen,** which perforates the root of the small wing and transmits the optic nerve and the ophthalmic artery. Behind the optic groove is the **tuberculum sellæ,** indicating the line of junction of the two parts of which the body is formed (pre- and post-sphenoid); and still further back, a deep depression, the **hypophyseal fossa** [sella turcica], which lodges the hypophysis cerebri. The floor of the fossa presents numerous foramina for blood-vessels, and at birth the superior orifice of a narrow passage called the **basi-pharyngeal canal** opens on the tuberculum. The posterior boundary of the fossa is formed by a quadrilateral plate of bone, the **dorsum sellæ** (dorsum

Fig. 79.—The Sphenoid, from Above.



ephippii), the posterior surface of which is sloped in continuation with the basilar groove of the occipital bone. The superior angles of the plate are surmounted by the **posterior clinoid processes,** which give attachment to the tentorium cerebelli and the interclinoid ligaments. Below the clinoid process, on each side of the dorsum sellæ (sometimes at the suture between the sphenoid and apex of petrosal), a notch is seen, converted into a foramen by the dura mater, for the passage of the sixth cranial nerve, and at the inferior angle the **posterior petrosal process,** which articulates with the apex of the petrous portion of the temporal bone, forming the inner boundary of the **foramen lacerum.** The dorsum sellæ is slightly concave posteriorly (the clivus) and supports the pons Varolii and the basilar artery.

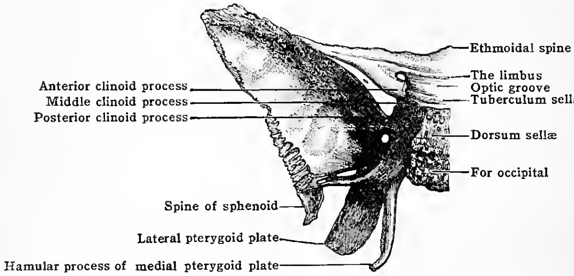
The **inferior surface** presents in the middle line a prominent ridge known as the **rostrum,** which is received into a deep depression between the alæ of the vomer. On each side is the **vaginal process** of the medial pterygoid plate, directed horizontally and medially, which, with the alæ of the vomer, covers the greater part of this surface. The remainder is rough and clothed by the mucous membrane of the roof of the pharynx.

The **anterior surface** is divided into two lateral halves by the **sphenoidal crest,** a vertical ridge of bone continuous above with the ethmoidal spine, below with the rostrum, and articulating in front with the perpendicular plate of the ethmoid. The surface on each side presents a rough lateral margin for articulation with the lateral mass of the ethmoid and the orbital process of the palate bone. Elsewhere it is smooth, and enters into the formation of the roof of the nasal fossæ, presenting superiorly the irregular apertures of the sphenoidal sinuses.

The body is not hollowed until after the sixth year, but from that time the sinuses increase in size as age advances. Except for the apertures just mentioned, they are closed below and in front by the two **sphenoidal conchæ** (turbinate bones), originally distinct, but in the adult usually incorporated with the sphenoid.

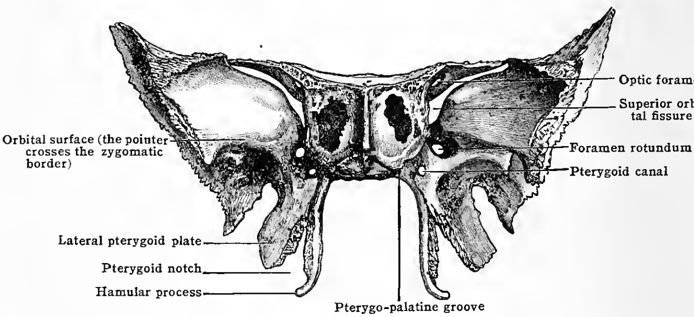
The **posterior surface** is united to the basilar process of the occipital, up to the twentieth year, by a disc of hyaline cartilage forming a synchondrosis, but afterward this becomes ossified and the two bones then form one piece.

Fig. 80.—The Left Half of the Sphenoid.



The **lateral surface** of the body gives attachment to the two wings, and its fore part is free where it forms the medial boundary of the superior orbital fissure and the posterior part of the medial wall of the orbit. Above the line of attachment of the great wing is a broad groove which lodges the internal carotid artery and the cavernous sinus, called the **carotid** groove. It is deepest where it curves behind the root of the process, and this part is bounded along its lateral margin by a slender ridge of bone named the **lingula,** which projects backward in the angle between the body and the great wing.

Fig. 81.—The Sphenoid. (Anterior view.)

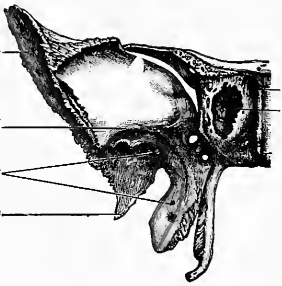


The **small** or **orbital wings** [alæ parvæ] are two thin, triangular plates of bone extending nearly horizontally and laterally on a level with the front part of the upper surface of the body. Each arises medially by two processes or roots, the upper thin and flat, the lower thick and rounded.

Near the junction of the lower root with the body is a small tubercle for the attachment of the common tendon of three ocular muscles—viz., the *superior, medial,* and upper head of *lateral rectus*—and between the two roots is the **optic foramen.** The lateral extremity, slender and pointed, approaches the great wing, but, as a rule, does not actually touch it. The superior surface, smooth and slightly concave, forms the posterior part of the anterior fossa of the cranium. The inferior surface constitutes a portion of the roof of each orbit and overhangs the superior orbital (or sphenoidal) fissure, the elongated opening between the small and great wings. The anterior border is serrated for articulation with the orbital plate of the frontal, and the posterior border, smooth and rounded, is received into the Sylvian fissure of the cerebrum. Moreover, the posterior border forms the boundary between the anterior and middle cranial fossæ and is prolonged at its medial extremity to form the **anterior clinoid process,** which gives attachment to the tentorium cerebelli and the interclinoid ligaments. Between the tuberculum sellæ and the anterior clinoid process is a semicircular notch which represents the termination of the carotid groove. It is sometimes converted into a foramen, the **carotico-clinoid foramen,** by a spicule of bone which bridges across from the anterior clinoid to the **middle clinoid process;** the latter is a small tubercle frequently seen on each side, in front of the hypophyseal fossa, and slightly posterior to the tuberculum sellæ; the foramen transmits the internal carotid artery, and the spicule of bone which may complete the foramen is formed by ossification of the carotico-clinoid ligament.

The **great** or **temporal wings** [alæ magnæ], arising from the lateral surface of the body, extend laterally and then upward and forward. The posterior part is placed horizontally and projects backward into the angle between the squamous and petrous portions of the temporal bone. From the under aspect of its pointed extremity the **spine,** which is grooved medially by the chorda tympani nerve (Lucas), projects downward. The spine serves for the attachment of the spheno-mandibular ligament and a few fibres of the *tensor veli palatini*. Each wing presents for examination four surfaces and four borders.

FIG. 82.—RIGHT HALF OF SPHENOID. (Anterior view.)



The **cerebral** or **superior surface** is smooth and concave. It enters into the formation of the middle cranial fossa, supports the temporo-sphenoidal lobe of the cerebrum, and presents several foramina. At the anterior and medial part is the **foramen rotundum** for the second division of the fifth nerve, and behind and lateral to it, near the posterior margin of the great wing, is the large **foramen ovale,** transmitting the third division of the fifth, the small meningeal artery, and an emissary vein from the cavernous sinus.

Behind and lateral to the foramen ovale is the small circular foramen **spinosum,** sometimes incomplete, for the passage of the middle meningeal vessels, and the recurrent branch of the third division of the fifth. Between the foramen ovale and the foramen rotundum is the inconstant **foramen Vesalii,** which transmits a small emissary vein from the cavernous sinus; and on the plate of bone, behind and medial to the foramen ovale (spheno-petrosal lamina), a minute canal is occasionally seen—the **canaliculus innominatus**—through which the small superficial petrosal nerve escapes from the skull. When the canaliculus is absent, the nerve passes through the foramen ovale.

The **anterior surface** looks medially and forward and consists of two divisions—a quadrilateral or **orbital** surface, which forms the chief part of the lateral wall of the orbit, and a smaller, inferior or **spheno-maxillary** surface, situated above the pterygoid process and perforated by the foramen rotundum; this inferior part forms the posterior wall of the pterygo-palatine fossa.

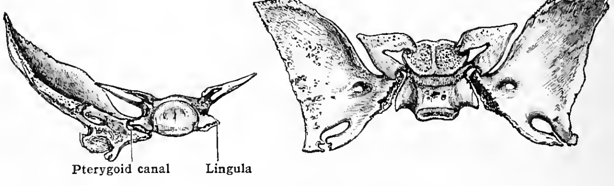
The lateral or **squamo-zygomatic surface** is divided by a prominent **infratemporal ridge** into a superior portion, which forms part of the temporal fossa and affords attachment to the *temporal* muscle, and an inferior part, which looks downward into the zygomatic fossa and gives attachment to the *external pterygoid* muscle; the inferior part joins the lateral surface of the lateral pterygoid plate, and presents the inferior orifices of the foramen ovale, foramen spinosum, and foramen of Vesalius.

Borders.—The **posterior border** extends from the body to the spine. By its lateral third it articulates with the petrous portion of the temporal bone, whilst the medial two-thirds form the anterior boundary of the foramen lacerum. The **squamosal border** is serrated behind and bevelled in front for articulation with the squamous portion of the temporal bone, whilst its upper extremity, or summit, is bevelled on its inner aspect, for the anterior inferior angle of the parietal. Immediately in front of the upper extremity is a rough, triangular, sutural area for the frontal, the sides of which are formed by the upper margins of the superior, anterior, and lateral surfaces respectively. The **zygomatic** or **anterior border** separates the orbital and temporal surfaces and articulates with the zygomatic, and by its lower angle, in many skulls, also with the maxilla. Below the anterior border is a short horizontal ridge, non-articular, which separates the spheno-maxillary and zygomatic surfaces. Above and medially, where the orbital and cerebral surfaces meet, is the sharp **medial border,** which forms the lower boundary of the **superior orbital fissure,** serving for the passage of the third, fourth, three branches of the first division of the fifth, and the sixth cranial nerves, the orbital branch of the middle meningeal artery, a recurrent branch from the lacrimal artery, some twigs from the cavernous plexus of the sympathetic, and one or two ophthalmic veins. Near the middle of the border is a small tubercle for the origin of the lower head of the *lateral rectus* muscle.

The **pterygoid processes** project downward from the junction of the body and the great wings. Each consists of two plates, one shorter and broader, the **lateral pterygoid plate** [lamina lateralis], the other longer and narrower, the **medial pterygoid plate** [lamina medialis]. They are united in front, but diverge behind so as to enclose between them the **pterygoid fossa** in which lie the *internal pterygoid* and *tensor palati* muscles. The lateral pterygoid plate is turned a little laterally and by its lateral surface, which looks into the zygomatic fossa, affords attachment to the *external pterygoid* muscle, whilst from its medial surface the *internal pterygoid* takes origin.

The posterior border of the lateral pterygoid plate frequently presents one or more bony projections, which represent ossified parts of the pterygo-spinous ligaments, and occasionally one may extend across to the spine and complete the bony boundary of the pterygo-spinous foramen. The medial pterygoid plate is prolonged below into a slender, hook-like or **hamular process,** smooth on the under aspect for the tendon of the *tensor palati,* which plays round it. Superiorly, the medial plate extends medially on the under surface of the body, forming the **vaginal process,** which articulates with the ala of the vomer and the sphenoïdal process of the palate. The vaginal process presents, on the under surface, a small groove which, with the sphenoidal process of the palate, forms the **pharyngeal canal** for the transmission of branches of the spheno-palatine vessels and ganglion. The medial surface of the medial pterygoid plate forms part of the lateral boundary of the nasal fossa, and the lateral surface, the medial boundary of the pterygoid fossa. The posterior border presents superiorly a well-marked prominence, the **pterygoid tubercle,** above and to the lateral side of which is the posterior orifice of the **pterygoid canal.** The latter pierces the bone in the sagittal direction at the root of the medial pterygoid plate and transmits the Vidian vessels and nerve. Some distance below the tubercle is a projection, called the **processus tubarius,** which supports the cartilage of the tuba auditiva (Eustachian tube). From the lower third of the posterior border and from the hamular process, the *superior constrictor* of the pharynx takes origin, and from the depression known as the **scaphoid fossa,** situated in the upper part of the recess between the two pterygoid plates, the *tensor palati* arises.

Fig. 83.—The Sphenoid at Birth.



In front, the two plates are joined above, but diverge below, leaving a gap—the **pterygoid notch**—occupied, in the articulated skull, by the pyramidal process of the palate. Superiorly, they form a triangular surface which looks into the pterygo-palatine fossa and presents the anterior orifice of the pterygoid canal. The anterior border of the medial pterygoid plate articulates with the posterior border of the vertical plate of the palate.

Blood-supply.—The sphenoid is supplied by branches of the middle and small meningeal arteries, the deep temporal and other branches of the internal maxillary artery—viz., the Vidian and spheno-palatine. The body of the bone also receives twigs from the internal carotid.

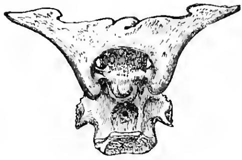
Articulations.—The sphenoid articulates with all the bones of the cranium—viz., occipital, parietal, frontal, ethmoid, temporal, and sphenoidal conchæ. Also with the palate, vomer, zygomatic, epipteric bone when present, and occasionally with the maxilla.

Ossification.—The sphenoid is divided, up to the seventh or eighth month of intra-uterine life, into an anterior or **pre-sphenoid** portion, including the part of the body in front of the tuberculum sellæ and the small wings, and a **post-sphenoid** portion, the part behind the tuberculum sellæ including the hypophyseal fossa and the great wings. The two portions of the body join together before birth, but in many animals the division is persistent throughout life.

The pre-sphenoid portion ossifies in cartilage from four centres, one of which gives rise to each lesser wing (**orbito-sphenoid**) and a pair to the body of the pre-sphenoid.

In the formation of the post-sphenoidal portion both cartilage and membrane bone participate, the pterygoid plates being formed in membrane, while the rest of the portion, together with the hamular process, ossifies from cartilage. (Fawcett.) At about the eighth week a

Fig. 84.—The Jugum Sphenoidale.

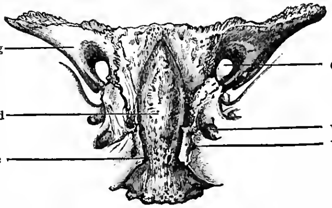


centre appears at the base of each greater wing (**ali-sphenoid**), and at about the same time a pair of centres appear in the body (**basi-sphenoid**) and later one in each lingula (**sphenotic**). The medial pterygoid plates are pre-formed in cartilage, in which a centre appears for the hamular process, but the rest of the plate is formed from membrane bone which invests the cartilage. The lateral plate is formed in membrane and a considerable part of the greater wing is also membranous in origin (see epipteric bone).

At birth the bone consists of three pieces. The median piece includes the basi-sphenoid and lingulæ, conjoined with the pre-sphenoid, carrying the orbito-sphenoids.

The two lateral pieces are the ali-sphenoids, carrying the medial pterygoid plates. The dorsum sellæ is cartilaginous. A canal, known as the **basi-pharyngeal canal,** extends into the

Fig. 85.—The Inferior Surface of Pre-sphenoid at the Sixth Year.



body from the sella turcica and sometimes reaches its under surface. It contains a process of dura mater, and represents the remains of the canal in the base of the cranium, through which the diverticulum of Rathke extended upward to form part of the hypophysis.

The great wings are joined to the lingulæ by cartilage, but in the course of the first year bony union takes place. About the same time the orbito-sphenoids meet and fuse in the middle line to form the **jugum sphenoidale,** which thus excludes the anterior part of the pre-sphenoid from the cranial cavity. For some years the body of the pre-sphenoid is broad and rounded inferiorly (fig. 85). The posterior clinoid processes chondrify separately, a fact which throws some light on the occasional absence of these processes.

THE SPHENOIDAL CONCHÆ

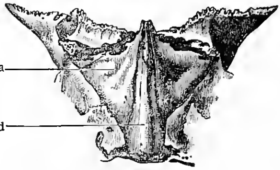
The **sphenoidal conchæ** (or **turbinate bones**; bones of Bertin) (figs. 86, 87) may be obtained as distinct ossicles about the fifth year, and resemble in shape two hollow cones flattened in three planes. At this date each is wedged in between the under surface of the pre-sphenoid and the orbital and sphenoidal processes of the palate bone, with the apex of the cone directed backward as far as the vaginal process of the medial pterygoid plate. Of its three surfaces, the lateral is in relation with the pterygo-palatine fossa, and occasionally extends upward between the sphenoid and the lamina papyracea of the ethmoid, to appear on the medial wall of the orbit (fig. 105). The inferior surface forms the upper boundary of the spheno-palatine foramen and enters into formation of the posterior part of the roof of the nasal fossa. The superior surface lies flattened against the under surface of the pre-sphenoid, whilst the base of the cone is in contact with the lateral mass of the ethmoid.

The deposits of earthy matter from which the sphenoidal conchæ are formed appear at the fifth month. At birth each forms a small triangular lamina in the perichondrium of the ethmo-vomerine plate near its junction with the presphenoid, and partially encloses a small recess from the mucous membrane of the nose, which becomes the sphenoidal sinus. By the third year the bone has surrounded the sinus, forming an osseous capsule, conical in shape, the circular orifice which represents the base becoming the sphenoidal foramen. As the cavity enlarges the medial wall is absorbed, and the medial wall of the sinus is then formed by the pre-sphenoid.

Fig. 86.—The Sphenoidal Concha at the Sixth Year.

The bones are subsequently ankylosed in many skulls with the ethmoid, whence they are often regarded as parts of that bone. More frequently they fuse with the pre-sphenoid, and less frequently with the palate bones. After the twelfth year they can rarely be separated from the skull without damage. In many disarticulated skulls they are so broken up that a portion is found on the sphenoid, fragments on the palate bones, and the remainder attached to the ethmoid. Sometimes, even in old skulls, they are represented by a very thin triangular plate on each side of the rostrum of the sphenoid (fig. 87).

Fig. 87.—The Sphenoidal Conchæ from an Old Skull.



THE EPIPTERIC AND WORMIAN BONES

The **epipterics** are scale-like bones which occupy the antero-lateral fontanelles. Each epipteric bone is wedged between the squamo-zygomatic portion of the temporal, frontal, great wing of sphenoid, and the parietal, and is present in most skulls between the second and fifteenth year. After that date it may persist as a separate ossicle, or unite with the sphenoid, the frontal, or the squamo-zygomatic. The epipteric bone is pre-formed in membrane, and appears as a series of bony granules in the course of the first year.

The **Wormian or sutural bones** [ossa suturarum] are small, irregularly shaped ossicles, often found in the sutures of the cranium, especially those in relation with the parietal bones. They sometimes occur in great numbers; as many as a hundred have been counted in one skull. They are rarely present in the sutures of the face.

THE TEMPORAL BONE

The **temporal bone** [os temporale], situated at the side and the base of the cranium, contains the organ of hearing and articulates with the lower jaw. It is usually divided into three parts—viz., the **squamous portion,** forming the anterior and superior part of the bone, thin and expanded and prolonged externally into the zygomatic process; the **mastoid portion,** the thick conical posterior part, behind the external aperture of the ear; and a pyramidal projection named the **petrous portion,** situated in a plane below and to the medial side of the two parts already mentioned, and forming part of the base of the skull.

When it is considered in reference to its mode of development, the temporal bone is found to be built up of three parts (figs. 88, 89, 90), which, however, do not altogether correspond to the arbitrary divisions of the adult bone. The three parts are named **squamosal, petrosal,** and **tympanic,** and a knowledge of their arrangement in the early stages of growth greatly facilitates the study of the fully formed bone.

The more important division of the temporal bone is the petrous portion. It is pyramidal in shape, and contains the essential part of the organ of hearing,

Fig. 88.—The Temporal Bone at Birth.

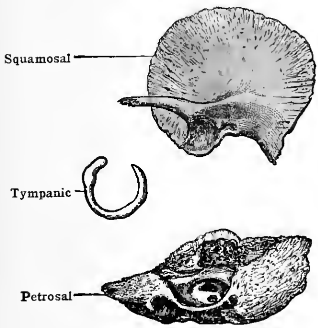


Fig. 89.—Temporal Bone at Birth. (Inner view.)

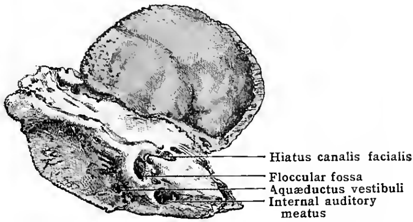

Fig. 90.—The Temporal Bone at Birth. (Outer view.)

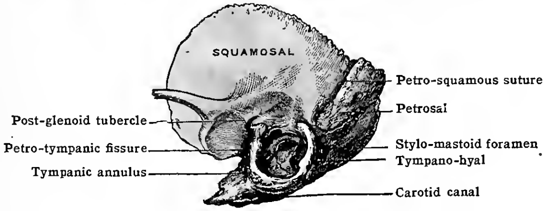

Fig. 91.—Right Temporal Bone at about Six Years.
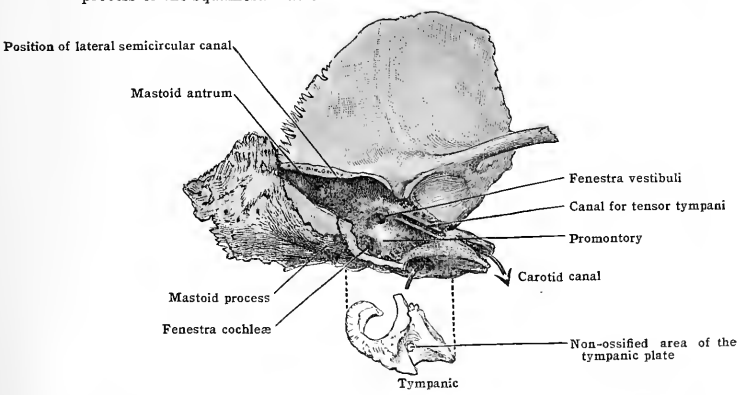
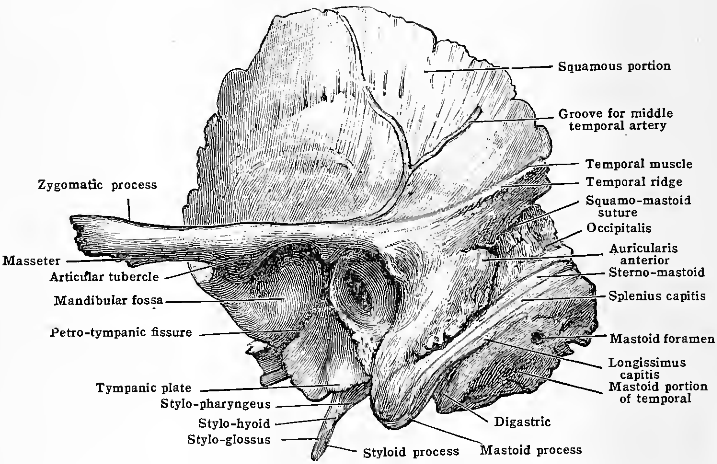
The tympanic plate has been separated and drawn below. A portion of the post-auditory process of the squamosal has been removed to show the mastoid antrum.



around which it is developed as a cartilaginous capsule. This is known as the **periotic capsule or petrosal** element, and its **base** abuts on the outer aspect of the cranium, where it forms a large part of the so-called mastoid portion of the temporal bone. Besides containing the internal ear, it bears on its cranial side a foramen for the seventh and eighth cranial nerves (internal auditory meatus), and on its outer side two openings—the fenestra vestibuli and fenestra cochleæ (fig. 91). The **squamosal** is a superadded element and is formed as a membrane bone in the lateral wall of the cranium. It is especially developed in man in consequence of the large size of the brain, and forms the squamous division of the adult bone, and by a triangular shaped process which is prolonged behind the aperture of the ear it also contributes to the formation of the mastoid portion. It is obvious, therefore, that the mastoid is not an independent element, but belongs in part to the petrous, and in part to the squamous. The **tympanic** portion, also superadded, is a ring of bone developed in connection with the external auditory meatus, and eventually forms a plate constituting part of the bony wall of this passage. These three parts are easily separable at birth, but eventually become firmly united to form a single bone which affords little trace of its complex origin. Lastly a process of bone, developed in the second visceral arch, coalesces with the under surface of the temporal bone and forms the **styloid process.**

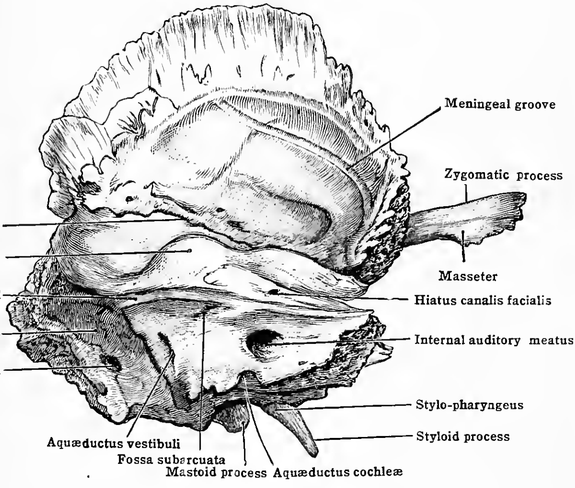
Fig. 92.—The Left Temporal Bone. (Outer view.)



The **squamous portion** [squama temporalis] is flat, scale-like, thin, and translucent. It is attached almost at right angles to the petrous portion, forms part of the side wall of the skull and is limited above by an uneven border which describes about two-thirds of a circle. The outer surface is smooth, slightly convex near the middle, and forms part of the temporal fossa. Above the external auditory meatus it presents a nearly vertical groove for the middle temporal artery. Connected with its lower part is a narrow projecting bar of bone known as the **zygomatic process.** At its base the process is broad, directed laterally, and flattened from above downward. It soon, however, becomes twisted on itself and runs forward, almost parallel with the squamous portion. This part is much narrower and compressed laterally so as to present medial and lateral surfaces with upper and lower margins. The lateral surface is subcutaneous; the medial looks toward the temporal fossa and gives origin to the *masseter* muscle. The lower border is concave and rough for fibres of the same muscle, whilst the upper border, thin and prolonged further forward than the lower, receives the temporal fascia. The extremity of the process is serrated for articulation with the zygomatic bone. At its base the zygomatic process presents three roots—anterior, middle, and posterior.

The anterior, continuous with the lower border, is short, broad, convex, and directed medially to terminate in the **articular tubercle,** which is covered with cartilage in the recent state, for articulation with the condyle of the lower jaw. The middle root, sometimes very prominent, forms the **post-glenoid process.** It separates the articular portion of the mandibular fossa from the external auditory meatus and is situated immediately in front of the **petro-tympanic** (Glaserian) fissure. The posterior root, prolonged from the upper border, is strongly marked and extends backward as a ridge above the external auditory meatus. It is called the **temporal ridge** (supra-mastoid crest), and marks the arbitrary line of division between the squamous and mastoid portions of the adult bone. It forms part of the posterior boundary of the temporal fossa, from which, as well as from the ridge, fibres of the *temporal* muscle arise. Where the anterior root joins the zygomatic process is a slight tubercle—the **preglenoid tubercle**—for the attachment of the temporo-mandibular ligament, and between the anterior and middle roots is a deep oval depression, forming the part of the mandibular fossa for the condyle of the lower jaw. The **mandibular fossa** is a considerable hollow, bounded in front by the articular tubercle and behind by the tympanic plate which separates it from the external auditory meatus. It is divided into two parts by a narrow slit—the **petro-tympanic (Glaserian) fissure.** The anterior part [facies articularis], which belongs to the squamous portion, is articular, and, like the articular tubercle, is coated with cartilage. The posterior

Fig. 93.—The Left Temporal Bone. (Seen from the inner side and above.)



part, formed by the tympanic plate, is non-articular and lodges a lobe of the parotid gland. Immediately in front of the articular tubercle is a small triangular surface which enters into the formation of the roof of the zygomatic fossa.

The inner or *cerebral surface* of the squamous portion is marked by furrows for the convolutions of the brain and grooves for the middle meningeal vessels. At the upper part of the surface the inner table is deficient and the outer table is prolonged some distance upward, forming a thin scale, with the bevelled surface looking inward to overlap the corresponding edge of the parietal. Anteriorly the border is thicker, serrated, and slightly bevelled on the outer side for articulation with the posterior border of the great wing of the sphenoid. Posteriorly it joins the rough serrated margin of the mastoid portion to form the parietal notch. The line separating the squamous from the petrous portion is indicated at the lower part of the inner surface by a narrow cleft, the internal **petro-squamous suture,** the appearance of which varies in different bones according to the degree of persistence of the original line of division.

The **mastoid portion** [pars mastoidea] is rough and convex. It is bounded above by the temporal ridge and the parieto-mastoid suture; in front, by the external auditory meatus and the **tympano-mastoid** fissure; and behind, by the suture between the mastoid and occipital. As already pointed out, it is formed by the squamous portion in front and by the base of the petrosal behind, the line of junction of the two component parts being indicated on the outer surface by the **external petro-squamous suture** (squamo-mastoid). The appearance of the suture varies, being in some bones scarcely distinguishable, in others, a series of irregular depressions, whilst occasionally it is present as a well-marked fissure (fig. 92) directed obliquely downward and forward. The mastoid portion is prolonged downward behind the external acoustic meatus into a nipple-shaped projection, the **mastoid process**, the tip of which points forward as well as downward. The process is marked, on its medial surface, by a deep groove, the **mastoid notch** (digastric fossa), for the origin of the *digastric* muscle, and again medially by the **occipital groove** for the occipital artery.

The outer surface is perforated by numerous foramina, one, of large size, being usually situated near the posterior border and called the **mastoid foramen.** It transmits a vein to the transverse (lateral) sinus and the mastoid branch of the occipital artery. The mastoid portion gives attachment externally to the *auricularis posterior* (*retrahens aurem*) and *occipitalis*, and, along with the mastoid process, to the *sterno-mastoid*, *splenius capitis*, and *longissimus capitis* (*trachelo-mastoid*). Projecting from the postero-superior margin of the external auditory meatus there is frequently a small tubercle—the **supra-meatal spine**—behind which the surface is depressed to form the **mastoid (supra-meatal) fossa.**

The inner surface of the mastoid portion presents a deep curved **sigmoid groove,** in which is lodged a part of the transverse sinus; the mastoid foramen is seen opening into the groove. The interior of the mastoid portion, in the adult, is usually occupied by cavities lined by mucous membrane and known as the **mastoid air-cells** (fig. 97). These open into a small chamber—the **mastoid antrum**—which communicates with the upper part of the tympanic cavity. The mastoid cells are arranged in three groups: (1) antero-superior, (2) middle, and (3) apical. The apical cells, situated at the apex of the mastoid process, are small and usually contain marrow.

Borders.—The superior border is broad and rough for articulation with the hinder part of the inferior border of the parietal bone. The posterior border, very uneven and serrated, articulates with the inferior border of the occipital bone, extending from the lateral angle to the jugular process.

The **petrous portion** [pars petrosa; pyramis] is a pyramid of very dense bone presenting for examination a base, an apex, three (or four) surfaces, and three (or four) borders or angles. Two sides of the pyramid look into the cranial cavity, the posterior into the posterior cranial fossa, and the anterior into the middle cranial fossa. The inferior surface appears on the under surface of the cranium. The medial and posterior walls of the tympanic cavity in the temporal bone are sometimes described as a fourth side of the pyramid. The base forms a part of the lateral surface of the cranium; the apex is placed medially.

The **posterior surface** of the pyramid is triangular in form, bounded above by the superior angle and below by the posterior angle Near the middle is an obliquely directed foramen [porus acusticus internus] leading into a short canal—the **internal auditory meatus**—at the bottom of which is a plate of bone, pierced by numerous foramina, and known as the **lamina cribrosa.** The canal transmits the facial and auditory nerves, the pars intermedia, and the internal auditory artery. The bottom of the internal auditory meatus can be most advantageously studied in a temporal bone at about the time of birth, when the canal is shallow and the openings relatively wide.

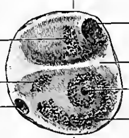
The fundus of the meatus is divided by a transverse ridge of bone, the *transverse crest*, into a superior and inferior fossa. Of these, the superior is the smaller, and presents anteriorly the beginning of the **facial canal** (aqueduct of Fallopius), which transmits the seventh nerve. The rest of the surface above the crest is dotted with small foramina (the superior vestibular area) which transmit nerve-twigs to the recessus ellipticus (fovea hemielliptica) and the ampullæ of the superior and lateral semicircular canals (vestibular division of the auditory nerve). Below the crest there are two depressions and an opening. Of these, an anterior curled tract (the spiral cribriform tract) with a central foramen (foramen centrale cochleare) marks the base of the cochlea; the central foramen indicates the orifice of the canal of the modiolus, and the smaller foramina transmit the cochlear twigs of the auditory nerve. The posterior opening (foramen singulare) is for the nerve to the ampulla of the posterior semicircular canal. The middle depression (inferior vestibular area) is dotted with minute foramina for the nerve-twigs to the saccule, which is lodged in the recessus sphæricus (fovea hemisphærica). The inferior fossa is subdivided by a low vertical crest. The fossa in front of the crest is the *fossula cochlearis*, and the recess behind it is the *fossula vestibularis*.

Behind and lateral to the meatus is a narrow fissure, the **aquæductus vestibuli,** covered by a scale of bone. In the fissure lies the ductus endolymphaticus, a small arteriole and venule, and a process of connective tissue which unites the dura mater to the sheath of the internal ear. Occasionally a bristle can be passed through it into the vestibule. Near the upper margin, and opposite a point about midway between the meatus and the aqueduct of the vestibule, is an irregular opening, the **fossa subarcuata**, the remains of the floccular fossa, a conspicuous depression in the fœtal bone. In the adult the depression usually lodges a process of dura mater and transmits a small vein, though in some bones it is almost obliterated.

The **anterior surface** of the pyramid, sloping downward and forward, forms the back part of the floor of the middle fossa of the cranium.

Upon the anterior surface of the pyramid will be found the following points of interest, proceeding from the apex toward the base of the pyramid:—(1) a shallow **trigeminal impression** for the semilunar (Gasserian) ganglion of the trigeminal nerve; (2) two small grooves running backward and laterally toward two small foramina overhung by a thin osseous lip, the larger and medial of which, known as the **hiatus canalis facialis**, transmits the great superficial petrosal nerve and the petrosal branch of the middle meningeal artery, whilst the smaller and lateral foramen is for the small superficial petrosal nerve; (3) behind and lateral to these is an eminence—the **eminentia arcuata**—best seen in young bones, corresponding to the superior semicircular canal in the interior; (4) still more laterally is a thin transulcent plate of bone, roofing in the tympanic cavity, and named the tegmen tympani.

Fig. 94.—The Foramina in the Fundus of the Left Internal Auditory Meatus of a Child at Birth ($\frac{4}{1}$). (Diagrammatic.)



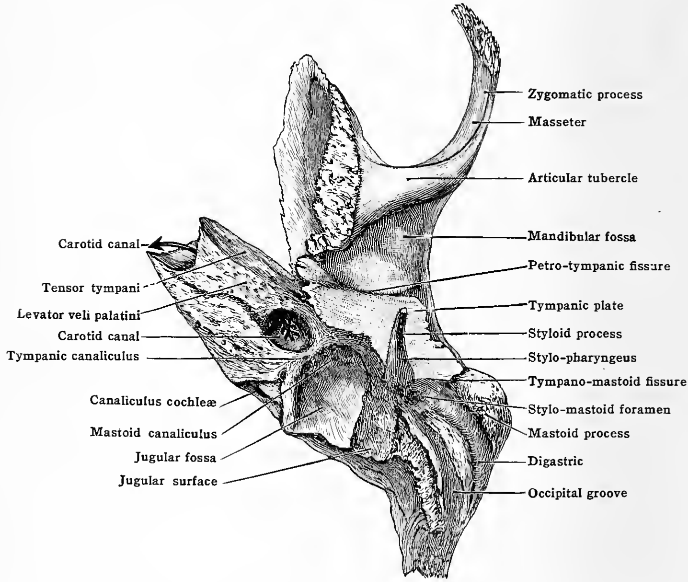
The **inferior or basilar surface** of the pyramid is very irregular. At the apex it is rough, quadrilateral, and gives attachment to the *tensor tympani*, *levator veli palatini*, and the pharyngeal aponeurosis. Behind this are seen the large circular orifice of the **carotid canal** for the transmission of the carotid artery and a plexus of sympathetic nerves, and on the same level, near the posterior border, a small three-sided depression, the **canaliculus cochleæ**, which transmits a small vein from the cochlea to the internal jugular. Behind these two openings is the large elliptical **jugular fossa** which forms the anterior and lateral part of the bony wall of the jugular foramen, in which is contained a dilatation on the commencement of the internal jugular vein; on the lateral wall of the jugular fossa is a minute foramen, the **mastoid canaliculus**, for the entrance of the auricular branch of the vagus (Arnold's nerve) into the interior of the bone. Between the inferior aperture of the carotid canal and the jugular fossa is the sharp **carotid ridge**, on which is a small depression, the **fossula petrosa**, and at the bottom of this a minute opening, the **tympanic canaliculus**, for the tympanic branch of the glosso-pharyngeal or Jacobson's nerve, and the small tympanic branch from the ascending pharyngeal artery. Behind the fossa is the rough **jugular surface** for articulation with the jugular process of the occipital bone, on the lateral side of which is the prominent cylindrical spur known as the **styloid process** with the **stylo-mastoid** foramen at its base. The facial nerve, and sometimes the auricular branch of the vagus, leave the skull, and the stylo-mastoid artery enters it by this foramen. Running backward from the foramen are the mastoid and occipital grooves already described.

The **tympanic surface** of the pyramid, forming the medial and posterior walls [paries labyrinthica] of the tympanic cavity, is shown by removing the tympanic plate (fig. 91). It presents near the base an excavation, known as the **tympanic** or **mastoid antrum**, covered by the triangular part of the squamous below and behind the temporal line. The opening of the antrum into the tympanic cavity is situated immediately above the **fenestra vestibuli**, an oval-shaped opening which receives the base of the stapes; below the fenestra vestibuli is a convex projection or **promontory**, marked by grooves for the tympanic plexus of nerves and containing the commencement of the first turn of the cochlea. In the lower and posterior part of the promontory is the **fenestra cochleæ**, closed in the recent state by the **secondary** membrane of the tympanum. Running downward and forward from the front of the fenestra vestibuli is a thin curved plate of bone [**septum canalis musculotubarii**], separating two grooves converted into canals by the overlying tympanic plate. The lower is the groove for the **Eustachian tube** [semicanalis tubæ auditivæ], the communicating passage between the tympanum and the pharynx; the upper is the **semicanalis m. tensoris tympani,** and the lateral apertures of both canals are visible in the retiring angle, between the petrous and squamous portions of the bone.

The **apex** of the pyramid is truncated and presents the medial opening of the carotid canal. The latter commences on the inferior surface, and, after ascending for a short distance, turns forward and medially, tunnelling the bone as far as the apex, and finally opens into the upper part of the **foramen lacerum** formed between the temporal and sphenoid bones. One or two minute openings in the wall of the carotid canal, known as the **carotico-tympanic canaliculi,** transmit communicating twigs between the carotid and tympanic plexuses. The upper part of the apex is joined by cartilage to the posterior petrosal process of the sphenoid.

The **base** is the part of the pyramid which appears laterally at the side of the cranium and takes part in the formation of the mastoid portion. It is described with that division of the bone.

Fig. 95.—The Left Temporal Bone. (Inferior view.)



Angles.—The **superior angle** (border) of the pyramid is the longest and separates the posterior from the anterior surface. It is grooved for the superior petrosal sinus, gives attachment to the tentorium cerebelli, and presents near the apex a semilunar notch upon which the fifth cranial nerve lies. Near its medial end there is often a small projection for the attachment of the petro-sphenoidal ligament, which arches over the inferior petrosal sinus and the sixth nerve. The **posterior angle** separates the posterior from the inferior surface, and when articulated with the occipital, forms the groove for the inferior petrosal sinus, and completes the **jugular foramen** formed by the temporal in front and on the lateral side, and by the occipital behind and on the medial side. The jugular foramen is divisible into three compartments: an anterior for the inferior petrosal sinus, a middle for the glossopharyngeal, vagus and accessory cranial nerves, and a posterior for the internal jugular vein and some meningeal branches from the occipital and ascending pharyngeal arteries. The **anterior angle** is the shortest and consists of two parts, one joined to the squamous in the petro-squamous suture and a small free part internally which articulates with the sphenoid. A fourth or inferior border may be distinguished, which runs along the line of junction with the tympanic plate and is continued on to the rough area below the apex.

The **tympanic portion** [pars tympanica] is quadrilateral in form, hollowed out above and behind, and nearly flat, or somewhat concave, in front and below. It forms the whole of the anterior and inferior walls, and part of the posterior wall, of the external auditory meatus, and is separated behind from the mastoid process by the **tympano-mastoid** (auricular) fissure through which the auricular branch of the vagus in some cases leaves the bone.

In front it is separated by the **petro-tympanic** fissure from the squamous portion. Through the petro-tympanic fissure the tympanic branch of the internal maxillary artery and the so-called laxator tympani pass. The processus gracilis of the malleus is lodged within it, and a narrow subdivision at its inner end, known as the **canal of Huguier**, transmits the chorda tympani nerve. The tympanic part presents for examination two surfaces and four borders.

The **antero-inferior surface,** directed downward and forward, lodges part of the parotid gland. Near the middle it is usually very thin, and sometimes presents a small foramen (the foramen of Huschke), which represents a non-ossified portion of the plate. The **postero-superior surface** looks into the external auditory meatus and tympanic cavity, and at its medial end is a narrow groove, the **sulcus tympanicus,** deficient above, which receives the membrana tympani.

The **lateral border** is rough and everted, forming the **external auditory process** for the attachment of the cartilage of the pinna; the **superior border** enters into the formation of the petro-tympanic fissure; the **inferior border** is uneven and prolonged into the **vaginal process** [vagina processus styloidei] which surrounds the lateral aspect of the base of the styloid process and gives attachment to the front part of the fascial sheath of the carotid vessels; the **medial border,** short and irregular, lies immediately below and to the lateral side of the opening of the Eustachian tube, and becomes continuous with the rough quadrilateral area on the inferior aspect of the apex.

The **external auditory meatus** is formed partly by the tympanic and partly by the squamous portion. It is an elliptical bony tube leading into the tympanum, the extrance of which is bounded throughout the greater part of its circumference by the external auditory process of the tympanic plate. Above, the entrance is limited by the temporal ridge or posterior root of the zygomatic process.

The **styloid process** is a slender, cylindrical spur of bone fused with the inferior aspect of the temporal immediately in front of the stylo-mastoid foramen. It consists of two parts, **basal** (tympano-hyal), which in the adult lies under cover of the tympanic plate, and a **projecting** portion (stylo-hyal), which varies in length from five to fifty millimetres. When short, it is hidden by the vaginal process, but, on the other hand, it may reach to the hyoid bone. The projecting portion gives attachment to three muscles and two ligaments.

The *stylo-pharyngeus* arises near the base from the medial and slightly from the posterior aspect; the *stylo-hyoid* from the posterior and lateral aspect near the middle; and the *stylo-glossus* from the front near the tip. The tip is continuous with the stylo-hyoid ligament, which runs down to the lesser cornu of the hyoid bone. A band of fibrous tissue—the stylo-mandibular ligament—passes from the process below the origin of the stylo-glossus to the angle of the lower jaw.

Blood-supply.—The arteries supplying the temporal bone are derived from various sources. The chief are:—

Stylo-mastoid from posterior auricular: it enters the stylo-mastoid foramen.

Anterior tympanic from internal maxillary: it passes through the petro-tympanic fissure.

Superficial petrosal from middle meningeal: transmitted by the hiatus canalis facialis.

Carotico-tympanic from internal carotid whilst in the carotid canal.

Internal auditory from the basilar: it enters the internal auditory meatus, and is distributed to the cochlea and vestibule.

Other less important twigs are furnished by the middle meningeal, the meningeal branches of the occipital, and by the ascending pharyngeal artery. The squamous portion is supplied, on its internal surface, by the middle meningeal, and externally by the branches of the deep temporal from the internal maxillary.

Articulations.—The temporal bone articulates with the occipital, parietal, sphenoid, zygomatic, and, by a movable joint, with the mandible. Occasionally the squamous portion presents a process which articulates with the frontal. A **fronto-squamosal** suture is common in the skulls of the lower races of men, and is normal in the skulls of the chimpanzee, gorilla, and gibbon.

Ossification.—Of the three parts which constitute the temporal bone at birth, the squamosal and tympanic develop in membrane and the petrosal in cartilage. The squamosal is formed from one centre, which appears as early as the eighth week, and ossification extends into the zygomatic process, which grows concurrently with the squamosal. At first the tympanic border is nearly straight, but soon assumes its characteristic horseshoe shape. At birth the post-glenoid tubercle is conspicuous, and at the hinder end of the squamosal there is a process which comes into relation with the mastoid antrum The centre for the tympanic element appears about the twelfth week. At birth it forms an incomplete ring, open above, and slightly ankylosed to the lower border of the squamosal. The anterior extremity terminates in a small irregular process, and the medial aspect presents, in the lower half of its circumference, a groove for the reception of the tympanic membrane.

Up to the middle of the fifth month the periotic capsule is cartilaginous; it then ossifies so rapidly that by the end of the sixth month its chief portion is converted into porous bone. The ossific material is deposited in four centres, or groups of centres, named according to their relation to the ear-capsule in its embryonic position.

The nuclei are deposited in the following order:—

1. The **opisthotic** appears at the end of the fifth month. The osseous material is seen first on the promontory, and it quickly surrounds the fenestra cochleæ from above downward, and forms the floor of the vestibule, the lower part of the fenestra vestibuli, and the internal auditory meatus; it also invests the cochlea. Subsequently a plate of bone arises from it to surround the internal carotid artery and form the floor of the tympanum.

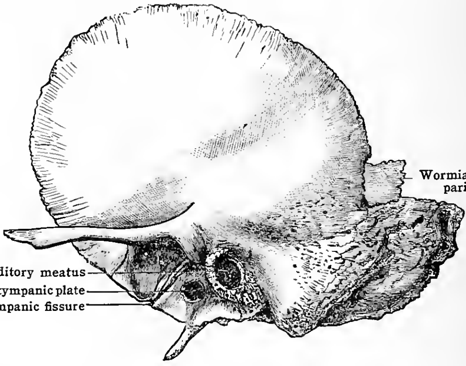
2. The **prootic** nucleus is deposited behind the internal auditory meatus near the medial limb of the superior semicircular canal. It covers in a part of the cochlea, the vestibule, and the internal auditory meatus, completes the fenestra vestibuli, and invests the superior semicircular canal.

3. The **pterotic** nucleus ossifies the tegmen tympani and covers in the lateral semicircular canal; the ossific matter is first deposited over the lateral limb of this canal.

4. The **epiotic**, often double, is the last to appear, and is first seen at the most posterior part of the posterior semicircular canal.

At birth the bone is of loose and open texture, thus offering a striking contrast to the dense and ivory-like petrosal of the adult. It also differs from the adult bone in several other particulars. The floccular fossa is widely open and conspicuous. Voltolini has pointed out that a small canal leads from the floor of the floccular fossa and opens posteriorly on the mastoid surface of the bone; it may open in the mastoid antrum. The hiatus canalis facialis is unclosed

Fig. 96.—Temporal Bone at the Sixth Year.



and the tympanum is filled with gelatinous connective tissue. The mastoid process is not developed, and the jugular fossa is a shallow depression.

After birth the parts grow rapidly. The tympanum becomes permeated with air, the various elements fuse, and the tympanic annulus grows rapidly and forms the tympanic plate. Development of the tympanic plate takes place by an outgrowth of bone from the lateral aspect of the tympanic annulus. This outgrowth takes place most rapidly from the tubercles or spines at its upper extremities, and in consequence of the slow growth of the lower segment a deep notch is formed; gradually the tubercles coalesce, lateral to the notch, so as to enclose a foramen which persists until puberty, and sometimes even in the adult. In most skulls a cleft capable of receiving the nail remains between the tympanic element and the mastoid process; this is the tympano-mastoid fissure. The anterior portion of the tympanic plate forms with the inferior border of the squamosal a cleft known as the petro-tympanic fissure, which is subsequently encroached upon by the growth of the petrosal. As the tympanic plate increases in size it joins the lateral wall of the carotid canal and presents a prominent lower edge, known as the vaginal process (sheath of the styloid).

The **mastoid process** becomes distinct about the first year, coincident with the obliteration of the petro-squamous suture, and increases in thickness by deposit from the periosteum. According to most writers, the process becomes pneumatic about the time of puberty, but it has been shown by Young and Milligan that the mastoid air-cells develop at a much earlier period than is usually supposed. These writers have described specimens in which the air-cells were present, as small pit-like diverticula from the mastoid antrum, in a nine months' fœtus and in an infant one year old. In old skulls the air-cells may extend into the jugular process of the occipital bone.

At birth the mastoid antrum is relatively large and bounded laterally by a thin plate of bone belonging to the squamosal (post-auditory process). As the mastoid increases in thickness the antrum comes to lie at a greater depth from the surface and becomes relatively smaller.

The styloid process is ossified in cartilage from two centres, one of which appears at the base in the tympano-hyal before birth. This soon joins with the temporal bone, and in the second year a centre appears for the stylo-hyal, which, however, remains very small until puberty. In the adult it usually becomes firmly united with the tympano-hyal, but it may remain permanently separate.

THE TYMPANUM

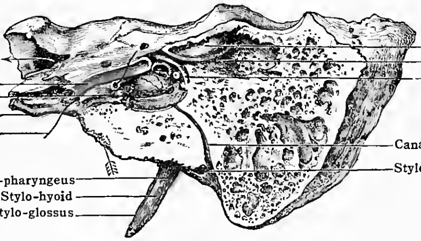
The **tympanum** (middle ear) includes a cavity [cavum tympani] of irregular form in the temporal bone, situated over the jugular fossa, between the petrous portion medially and the tympanic and squamous portions laterally. When fully developed, it is completely surrounded by bone except where it communicates with the external auditory meatus, and presents for examination six walls—lateral, medial, posterior, anterior, superior (roof), and inferior (floor). The lateral and medial walls are flat, but the remainder are curved, so that they run into adjoining surfaces, without their limits being sharply indicated.

The **roof** or tegmen tympani [paries tegmentalis] is a translucent plate of bone, forming part of the superior surface of the petrous portion and separating the tympanum from the middle fossa of the skull. The **floor** [paries jugularis] is the plate of bone which forms the roof of the jugular fossa.

The **medial wall** [paries labyrinthica] is formed by the tympanic surface of the petrous portion. In the angle between it and the roof is a horizontal ridge which extends backward as far as the posterior wall and then turns downward in the angle between the medial and posterior walls. This is the **facial (Fallopian) canal,** and is occupied by the facial nerve. The other features of this surface—viz., the **fenestra vestibuli,** the **fenestra cochleæ,** and the **promontory**—have previously been described with the anterior surface of the petrous portion of the temporal bone.

The **posterior wall** [paries mastoidea] of the tympanum is also formed by the anterior surface of the petrous portion. At the superior and lateral angle of this wall an opening

Fig. 97.—The Medial Wall of the Tympanum.



leads into the **mastoid antrum.** Immediately below this opening there is a small hollow cone, the **pyramidal eminence,** the cavity of which is continuous with the descending limb of the facial canal. The cavity is occupied by the *stapedius* and the tendon of the muscle emerges at the apex. One or more bony spicules often connect the apex of the pyramid with the promontory.

The roof and floor converge toward the **anterior extremity** of the tympanum, which is, in consequence, very low; it is occupied by two semicanals, the lower for the Eustachian tube, the upper for the *tensor tympani* muscle. These channels are sometimes described together as the **canalis musculo-tubarius.** In carefully prepared bones the upper semicanal is a small horizontal hollow cone (anterior pyramid), 12 mm. in length; the apex is just in front of the fenestra vestibuli, and is perforated to permit the passage of the tendon of the muscle. As a rule, the thin walls of the canal are damaged, and represented merely by a thin ridge of bone. The posterior portion of this ridge projects into the tympanum, and is known as the **processus cochleariformis.** The thin septum between the semicanal for the tensor tympani and the tube is pierced by a minute opening which transmits the small deep petrosal nerve.

The **lateral wall** [paries membranacea] is occupied mainly by the external auditory meatus. This opening is closed in the recent state by the tympanic membrane. The rim of bone to which the membrane is attached is incomplete above, and the defect is known as the **tympanic notch (notch of Rivinus).** Anterior to this notch, in the angle between the squamous portion and the tympanic plate, is the **petro-tympanic (Glaserian) fissure,** and the small passage which transmits the chorda tympani nerve, known as the **canal of Huguier.**

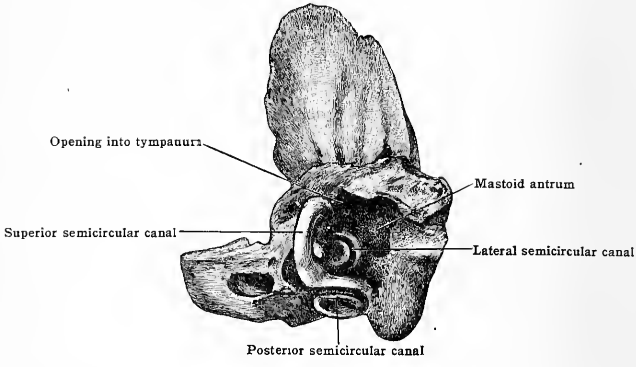
Up to this point the description of the middle ear conforms to that in general usage. But Young and Milligan have laid stress on the fact that the middle ear is really a cleft, named by them the "*middle-ear cleft,*" which intervenes between the periotic capsule, on the one hand, and the squamo-zygomatic and tympanic elements of the temporal bone on the other. This cleft, as development proceeds, gives rise to three cavities:—(1) the mastoid antrum; (2)

tympanum; and (3) the Eustachian tube. They point out that "the cleft is primarily continuous, and however much it may be altered in shape and modified in parts to form these three cavities, that continuity is never lost." It will be clear that the mastoid antrum, according to this view, is not an outgrowth from the tympanum, but is simply the lateral end of the middle-ear cleft.

The tympanic cavity may be divided into three parts. The part below the level of the superior margin of the external auditory meatus is the **tympanum proper**; the portion above this level is the **epitympanic recess** or **attic**; it receives the head of the malleus, the body of the incus, and leads posteriorly into the recess known as the **mastoid antrum.** The third part is the downward extension known as the **hypotympanic recess.**

The tympanic or mastoid antrum.—The air-cells which in the adult are found in the interior of the mastoid portion of the temporal bone open into a small cavity termed the **mastoid antrum.** This is an air-chamber, communicating with the attic of the tympanum, and separated from the middle cranial fossa by the posterior portion of the tegmen tympani. The floor is formed by the mastoid portion of the petrosal, and the lateral wall by the squamosal, below the temporal ridge. In children the outer wall is exceedingly thin, but in the adult it is of considerable thickness. The **lateral semicircular canal** projects into the antrum on its

FIG. 98.—TEMPORAL BONE AT BIRTH DISSECTED FROM ABOVE AND BEHIND TO SHOW THE SEMICIRCULAR CANALS AND THE MASTOID ANTRUM. (Enlarged $\frac{1}{3}$.)



medial wall, and is very conspicuous in the fœtus. Immediately below and in front of the canal is the facial nerve, contained in the facial canal.

The mastoid antrum has somewhat the form of the bulb of a retort (Thane and Godlee) compressed laterally, and opening by its narrowed neck into the attic or epitympanic recess. Its dimensions vary at different periods of life. It is well developed at birth, attains its maximum size about the third year, and diminishes somewhat up to adult life. In the adult the plate of bone which forms the lateral wall of the antrum is 12 to 18 mm. ($\frac{1}{2}$ to $\frac{3}{4}$ in.) in thickness, whereas at birth it is about 1.8 mm. ($\frac{1}{16}$ in.) or less. The deposition of bone laterally occurs, therefore, at average rate of nearly 1 mm. a year in thickness. In the adult the antrum is about 12 mm. ($\frac{1}{2}$ in.) from front to back, 9 mm. ($\frac{3}{8}$ in.) from above downward, and 4.5 mm. ($\frac{3}{16}$ in.) from side to side.

A canal occasionally leads from the mastoid antrum through the petrous bone to open in the recess which indicates the position of the floccular fossa; it is termed the petro-mastoid canal. (Gruber.)

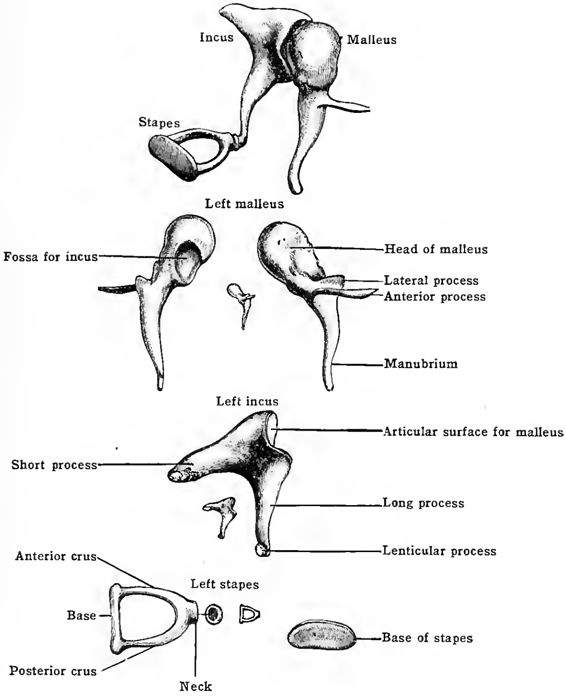
The facial (Fallopian) canal.—This canal begins at the anterior angle of the superior fossa of the internal auditory meatus, and passes forward and laterally above the vestibular portion of the internal ear for a distance of 1.5–2.0 mm. At the lateral end of this portion of its course it becomes dilated to accommodate the geniculate ganglion, and then turns abruptly backward and runs in a horizontal ridge on the medial wall of the tympanum, lying in the angle between it and the tegmen tympani, immediately above the fenestra vestibuli, and extending as far backward as the entrance to the mastoid antrum. Here it comes into contact with the inferior aspect of the projection formed by the lateral semicircular canal, and then turns vertically downward, running in the angle between the medial and posterior walls of the tympanum to terminate at the stylo-mastoid foramen.

The canal is traversed by the facial nerve. Numerous openings exist in the walls of this passage. At its abrupt bend, or **genu,** the greater and smaller superficial petrosal nerves escape from, and a branch from the middle meningeal artery enters, the canal, and in the vertical part of its course the cavity of the pyramid opens into it. There is also a small orifice by which the auricular branch of the vagus joins the facial, and near its termination the **iter chordæ posterius** for the chorda tympani nerve leads from it into the tympanum.

The small bones of the tympanum.—These bones, the malleus, incus and stapes, are contained in the upper part of the tympanic cavity. Together they form a jointed column of bone connecting the membrana tympani with the fenestra vestibuli.

The malleus.—This is the most external of the auditory ossicles, and lies in relation with the tympanic membrane. Its upper portion, or **head**, is lodged in the epitympanic recess. It is of rounded shape, and presents posteriorly an elliptical depression for articulation with the incus. Below the head is a constricted portion or **neck**, from which three processes diverge. The largest is the **handle** or **manubrium**, which is slightly twisted and flattened. It forms an obtuse angle with the head of the bone, and lies between the membrana tympani and the mucous membrane covering its inner surface. The *tensor tympani* tendon is inserted into the manubrium near its junction with the neck on the medial side.

FIG. 99.—THE BONES OF THE EAR. (Modified from Henle.)



The **anterior process** (processus gracilis or Folii) is a long, slender, delicate spiculum of bone (rarely seen of full length except in the fœtus), projecting nearly at right angles to the anterior aspect of the neck, and extending obliquely downward. It lies in the petro-tympanic fissure, and in the adult usually becomes converted into connective tissue, except a small basal stump. The **lateral process** is a conical projection from the lateral aspect of the base of the manubrium. Its apex is connected to the upper part of the tympanic membrane, and its base receives the lateral ligament of the malleus. The malleus also gives attachment to a superior ligament and an anterior ligament, the latter of which was formerly described as the *laxator tympani* muscle.

The incus.—This bone is situated between the malleus externally and the stapes internally. It presents for examination a body and two processes. The **body** is deeply excavated anteriorly for the reception of the head of the malleus. The **short process** projects backward, and is connected by means of ligamentous fibres to the posterior wall of the tympanum, near the entrance to the mastoid antrum. The **long process** is slender, and directed downward and inward, and lies parallel with the manubrium of the malleus. On the medial aspect of the distal extremity of this process is the **lenticular process** (orbicular tubercle), separate in early life, but subsequently joined to the process by a narrow neck. Its free surface articulates with the head of the stapes.

The stapes is the innermost ossicle. It has a head directed horizontally outward, capped at its outer extremity by a disc resembling the head of the radius. The cup-shaped depression receives the lenticular process of the incus. The base occupies the fenestra vestibuli, and like this opening, the inferior border is straight, and the superior curved. The base is connected with the head by means of two **crura**, and a narrow piece of bone called the neck. Of the two crura, the anterior is the shorter and straighter. The crura with the base form a stirrup-shaped arch, of which the inner margin presents a groove for the reception of the membrane stretched across the hollow of the stapes. In the early embryo this hollow is traversed by the stapedial artery. The **neck** is very short, and receives on its posterior border the tendon of the *stapedius* muscle.

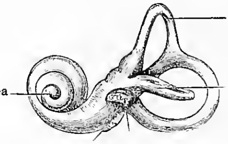
Development.—The tympanic cavity represents the upper extremity of the first endodermal branchial groove, which becomes converted into a blind pouch, the communication of which with the pharyngeal cavity is the tuba auditiva (Eustachian tube). The thin membrane which separates the endodermal from the ectodermal groove becomes the tympanic membrane, and it is from the upper extremities of the axial skeletons of the first and second branchial arches, which bound the groove anteriorly and posteriorly, that the auditory ossicles are formed, the malleus and incus belonging to the first arch and the stapes to the second (Reichert). The ossicles consequently lie originally in the walls of the cavity, but they are surrounded by a loose spongy tissue, which, on the entrance of air into the cavity, becomes compressed, allowing the cavity to enfold the ossicles. These therefore are enclosed within an epithelium which is continuous medially with that lining the posterior tympanic wall, and laterally with that lining the internal surface of the tympanic membrane.

The mastoid cells are outgrowths of the cavity into the adjacent bone, and are therefore lined with an epithelium continuous with that of the cavity.

THE OSSEOUS LABYRINTH

The **osseous labyrinth** [labyrinthus osseus] (fig. 100) is a complex cavity hollowed out of the petrous portion of the temporal bone and containing the membranous labyrinth, the essential part of the organ of hearing. It is incompletely divided into three parts, named the vestibule, the semicircular canals, and the cochlea.

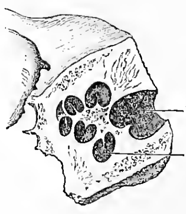
Fig. 100.—The Left Osseous Labyrinth. (After Henle. From a cast.)



The vestibule.—This is an oval chamber situated between the base of the internal auditory meatus and the medial wall of the tympanum, with which it communicates by way of the fenestra vestibuli. Anteriorly, the vestibule leads into the cochlea, and posteriorly it receives the extremities of the semicircular canals. It measures about 3 mm. transversely, and is somewhat longer antero-posteriorly.

Its medial wall presents at the anterior part a circular depression, the **spherical recess** (fovea hemispherica), which is perforated for the passage of nerve-twigs. This recess is separated by a vertical ridge (the **crista vestibuli**) from the vestibular orifice of the **aquæductus**

Fig. 101.—The Cochlea in Sagittal Section. (After Henle.)



vestibuli, which passes obliquely backward to open on the posterior surface of the petrosal. The roof contains an oval depression—the **elliptical recess** (fovea hemielliptica).

The **semicircular canals** are three in number. Arranged in different planes, each forms about two-thirds of a circle. One extremity of each canal is dilated to form an **ampulla.**

The **superior canal** lies transversely to the long axis of the petrosal, and is nearly vertical;

its highest limb makes a projection on the superior surface of the bone. The ampulla is at the lateral end; the medial end opens into the vestibule conjointly with the superior limb of the posterior canal.

The **posterior canal** is nearly vertical and lies in a plane nearly parallel to the posterior surface of the petrosal. It is the longest of the three; its upper extremity joins the medial limb of the superior canal, and opens in common with it into the vestibule. The lower is the ampullated end.

The **lateral canal** is placed horizontally and arches laterally; its lateral limb forms a prominence in the mastoid antrum. This canal is the shortest; its ampulla is at the lateral end near the fenestra vestibuli.

The cochlea.—This is a cone-shaped cavity lying with its base upon the internal auditory meatus, and the apex directed forward and laterally. It measures about five millimetres in length, and the diameter of its base is about the same. The centre of this cavity is occupied by a column of bone—the **modiolus**—around which a canal is wound in a spiral manner, making about two and a half turns. This is the **spiral canal** of the cochlea; its first turn is the largest and forms a bulging, the **promontory,** on the medial wall of the tympanum.

Projecting into the canal throughout its entire length there is a horizontal,shelf-like lamella, the **lamina spiralis,** which terminates at the apex of the cochlea in a hook-like process, the **hamulus.** The free edge of the lamina spiralis gives attachment to the membranous cochlea, a canal having in section the form of a triangle whose base is attached to the lateral wall of the spiral canal. By this the spiral canal is divided into a portion above the lamina spiralis, termed the **scala vestibuli,** which communicates at its lower end with the osseous vestibule, and a portion below, termed the **scala tympani,** which abuts at its lower end upon the fenestra cochleæ. The two scalæ communicate at the apex of the cochlea by the **helicotrema.** Near the commencement of the scala tympani, and close to the fenestra rotunda, is the cochlear orifice of the **canaliculus cochleæ** (ductus perilymphaticus). In the adult this opens below, near the middle of the posterior border of the petrous bone, and transmits a small vein from the cochlea to the jugular fossa.

Measurements of the principal parts connected with the auditory organs:—

Internal auditory meatus.......	Length of anterior wall, 13–14 mm.
	Length of posterior wall, 6.7 mm.
External auditory meatus......	14–16 mm. (Gruber.)
Tympanum..................	Length, 13 mm.
	Height in centre of cavity, 15 mm.
	Width opposite the membrana tympani, 2 mm.
	Width opposite the tubal orifice, 3–4 mm. (Von Tröltsch.)

The capsule of the osseous labyrinth is in length 22 mm. (Schwalbe.)
Superior semicircular canal measures along its convexity 20 mm.
The posterior semicircular canal measures along its convexity 22 mm.
The lateral semicircular canal measures along its convexity 15 mm.
The canal is in diameter 1.5 mm. (Huschke.)
The ampulla of the canal, 2.5 mm.

Development.—The membranous internal ear arises in the embryo as a depression of the ectoderm of the surface of the head opposite the fifth neuromere of the hind-brain and later becomes a sac-like cavity, the otocyst, which separates from its original ectodermal connections and sinks deeply into the subjacent mesoderm, a part of which becomes incorporated with it. The rest of the mesodermal tissue which surrounds the otocyst becomes later the petrous portion of the temporal bone, the perilymph and the internal periosteal layer; the osseous labyrinth is therefore merely the portions of the petrous which enclose the cavity occupied by the membranous internal ear.

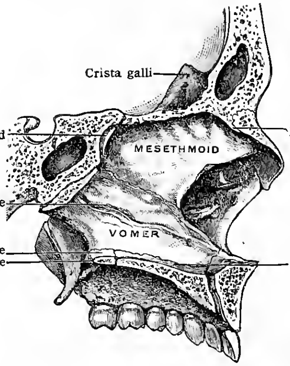
THE ETHMOID

The **ethmoid** [os ethmoidale] is a bone of delicate texture, situated at the anterior part of the base of the cranium (figs. 102, 103, 104). Projecting downward from between the orbital plates of the frontal, it enters into the formation of the orbital and nasal fossæ. It is cubical in form, and its extreme lightness and delicacy are due to an arrangement of very thin plates of bone surrounding irregular spaces known as air-cells. The ethmoid consists of four parts: the horizontal or cribriform plate, the ethmoidal labyrinth on each side, and a perpendicular plate.

The **cribriform plate** [lamina cribrosa] forms part of the anterior cranial fossa, and is received into the ethmoidal notch of the frontal bone. It presents on its upper surface, in the median line, the intra-cranial portion of the perpendicular plate, known as the **crista galli,** a thick, vertical, triangular process with the highest point in front, and a sloping border behind which gives attachment to the falx cerebri. The anterior border is short and in its lower part broadens out to form two **alar processes** which articulate with the frontal bone and complete the **foramen cæcum.** The crista galli is continuous behind with a median ridge, and on each side of the middle line is a groove which lodges the olfactory bulb.

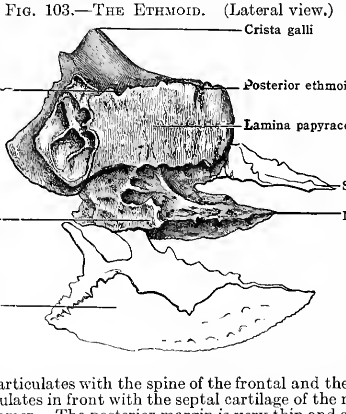
The cribriform plate is pierced, on each side, by numerous foramina, arranged in two or three rows, which transmit the filaments of the olfactory nerves descending from the bulb. Those in the middle of the groove are few and are simple perforations, through which pass the nerves to the roof of the nose; the medial and lateral series are more numerous and constitute the upper ends of small canals, which subdivide as they course downward to the upper parts of the septum and the lateral wall of the nasal fossa. At the front part of the cribriform plate is a narrow longitudinal slit, on each side of the crista galli, which transmits the anterior ethmoidal (nasal) branch of the ophthalmic division of the fifth nerve. The posterior border articulates with the ethmoidal spine of the sphenoid.

Fig. 102.—Section through the Nasal Fossa to show the Mesethmoid (Lamina Perpendicularis).



The **perpendicular plate** (mesethmoid) [lamina perpendicularis is directly continuous with the crista galli on the under aspect of the cribriform plate, so that the two plates cross each other at right angles. The larger part of the perpendicular plate is below the point of intersection and forms the upper third of the septum of the nose. It is quadrangular in form with unequal sides.

Fig. 103.—The Ethmoid. (Lateral view.)

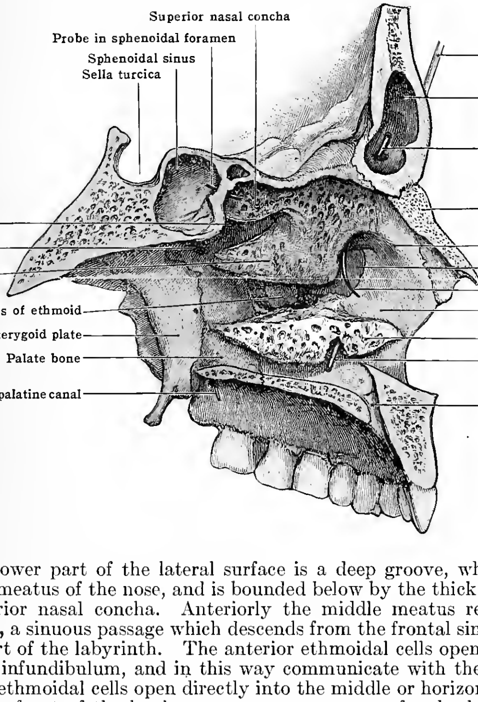


The anterior border articulates with the spine of the frontal and the crest of the nasal bones. The inferior border articulates in front with the septal cartilage of the nose and behind with the anterior margin of the vomer. The posterior margin is very thin and articulates with the crest of the sphenoid. This plate, which is generally deflected a little to one side, presents above a number of grooves and minute canals which lead from the inner set of foramina in the cribriform plate and transmit the olfactory nerves to the septum.

The **labyrinth** (lateral mass) is oblong in shape and suspended from the under aspect of the lateral part of the cribriform plate. It consists of two scroll-like pieces of bone, the **superior** and **middle nasal conchæ** (turbinate bones), and encloses numerous **irregularly** shaped spaces, known as the **ethmoidal cells.** These are arranged in three sets—anterior, middle, and posterior ethmoidal cells —and, in the recent state, are lined with prolongations of the nasal mucous membrane. Laterally the labyrinth presents a thin, smooth, quadrilateral plate of bone—the **lamina papyracea** (os planum)—which closes in the middle and posterior ethmoidal cells and forms a large part of the medial wall of the orbit.

By its anterior border it articulates with the lacrimal, and by its posterior border with the sphenoid; the inferior border articulates with the medial margin of the orbital plate of the maxilla and the orbital process of the palate bone, whilst the superior border articulates with the horizontal plate of the frontal. Two notches in the superior border lead into grooves running horizontally across the lateral mass to the cribriform plate, which complete, with the frontal bone, the **ethmoidal canals.** The anterior canal transmits the anterior ethmoidal vessels and (nasal) nerve; the posterior transmits the posterior ethmoidal vessels and nerve.

FIG. 104.—SECTION THROUGH THE NASAL FOSSA TO SHOW THE LABYRINTH OF THE ETHMOID. It shows also the lateral wall of the left nasal fossa.



At the lower part of the lateral surface is a deep groove, which belongs to the middle meatus of the nose, and is bounded below by the thick curved margin of the inferior nasal concha. Anteriorly the middle meatus receives the **infundibulum,** a sinuous passage which descends from the frontal sinus through the anterior part of the labyrinth. The anterior ethmoidal cells open into the lower part of the infundibulum, and in this way communicate with the nose, whereas the middle ethmoidal cells open directly into the middle or horizontal part of the meatus. In front of the lamina papyracea are seen a few broken cells, which extend under, and are completed by, the lacrimal bone and the frontal process of the maxilla; from this part of the labyrinth an irregular lamina, known as the **uncinate process,** projects downward and backward. The uncinate process articulates with the ethmoidal process of the inferior nasal concha and forms a small part of the medial wall of the maxillary sinus.

Medially the labyrinth takes part in the formation of the lateral wall of the nasal fossa, and presents the **superior** and **middle nasal conchæ** (turbinate processes), continuous anteriorly, but separated behind by a space directed forward from the posterior margin. This channel is the **superior meatus** of the nose and communicates with the posterior ethmoidal cells. The conchæ are covered in the recent state with mucous membrane and present numerous foramina for blood-vessels and, above, grooves for twigs of the olfactory nerves. Each concha has an attached upper border and a free, slightly convoluted, lower border, and in the case of the middle concha, the lower margin has already been noticed on the outer aspect, where it overhangs the middle meatus of the nose. The posterior extremity of the labyrinth articulates with the anterior surface of the body of the sphenoid and is commonly united with the sphenoidal concha.

A rounded prominence on the lateral wall of the middle meatus is known as the **bulla ethmoidalis.** Antero-inferior to the bulla is a large semilunar depression [hiatus semilunaris] which corresponds to the lower aperture of the infundibulum.

Many of the ethmoidal cells are imperfect and are completed by adjacent bones. Those along the superior edge of the lateral mass are the **fronto-ethmoidal;** those at the anterior border, usually two in number, are known as **lacrimo-ethmoidal.** Those along the lower edge of the lamina papyracea are the **maxillo-ethmoidal;** and posteriorly, are the **spheno-ethmoidal,** completed by the sphenoidal concha, and a **palato-ethmoidal** cell. The anterior extremity presents one or two incomplete cells closed by the nasal process of the maxilla.

Blood-supply.—The ethmoid receives its **blood-supply** from the anterior and posterior ethmoidal arteries and from the spheno-palatine branch of the internal maxillary.

Articulations.—With the frontal, sphenoid, two palate bones, two nasals, vomer, two inferior nasal conchæ, two sphenoidal conchæ, two maxillæ, and two lacrimal bones. The posterior surface of each labyrinth is in relation with the sphenoid on each side of the crest and rostrum, and helps to close in the sphenoidal sinus.

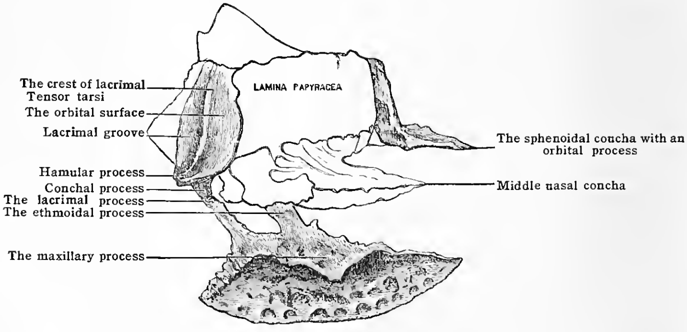
Ossification.—The ethmoid has three centres of ossification. Of these, a nucleus appears in the fourth month of intra-uterine life in each labyrinth, first in the lamina papyracea and afterward extending into the middle concha. At birth each lateral portion is represented by two scroll-like bones, very delicate and covered with irregular depressions, which give it a worm-eaten appearance. Six months after birth a nucleus appears in the ethmo-vomerine cartilage for the vertical plate which gradually extends into the crista galli, and the cribriform plate is formed by ossification extending laterally from this centre, and medially from the labyrinth. The three parts coalesce to form one piece in the fifth or sixth year.

The ethmoidal cells make their appearance about the third year, and gradually invade the labyrinths. In many places there is so much absorption of bone that the cells perforate the ethmoid in situations where it is overlapped by other bones. Along the lower border, near its articulation with the maxilla, the absorption leads to the partial detachment of a narrow strip known as the uncinate process. Sometimes a second but smaller hook-like process is formed, above and anterior to this, so fragile that it is difficult to preserve it in disarticulated bones. The relations of the uncinate process are best studied by removing the lateral wall of the maxillary sinus.

THE INFERIOR NASAL CONCHA

The **inferior nasal concha** (inferior turbinate) (fig. 105) is a slender, scroll-like lamina, attached by its upper margin to the lateral wall of the nasal fossa, and hanging into the cavity in such a way as to separate the middle from the inferior

Fig. 105.—The Inferior Concha, Adult Sphenoidal Turbinate, and Lacrimal Bones.



meatus of the nose. It may be regarded as a dismemberment of the ethmoidal labyrinth, with which it is closely related. It presents for examination two surfaces, two borders, and two extremities.

The **lateral surface** is concave, looks toward the lateral wall of the nasal fossa, and is overhung by the **maxillary process.** The **medial surface** is convex, pitted with depressions, and grooved for vessels, which, for the most part, run longitudinally. The **superior** or **attached border** articulates in front with the conchal crest of the maxilla, then ascends to form the **lacrimal process,** which articulates with the lacrimal bone and forms part of the wall of the lacrimal canal. Behind this, it is turned downward to form the maxillary process, already mentioned, which overhangs the orifice of the maxillary sinus and serves to fix the bone firmly to the lateral wall of the nasal fossa. The projection behind the maxillary process is the **ethmoidal process,** joined in the articulated skull with the uncinate process of the ethmoid across the opening of the maxillary sinus. Posteriorly the upper border articulates with the conchal crest of the palate. The **inferior border** is free, rounded, and somewhat thickened. The **anterior extremity** is blunt and flattened, and broader than the **posterior extremity,** which is elongated, narrow, and pointed.

Articulations.—With the maxilla, lacrimal, palate, and ethmoid.

Ossification.—The inferior nasal concha is ossified in cartilage from a single nucleus which appears in the fifth month of intra-uterine life. At birth it is a relatively large bone and fills up the lower part of the nasal fossa.

THE LACRIMAL

The **lacrimal bone** [os lacrimale] (fig. 105) is extremely thin and delicate, quadrilateral in shape, and situated at the anterior part of the medial wall of the orbit. It is the smallest of the facial bones.

The **orbital surface** is divided by a vertical ridge, the **posterior lacrimal crest,** into two unequal portions. The anterior, smaller portion is deeply grooved to form the **lacrimal groove,** which lodges the lacrimal sac and forms the commencement of the canal for the naso-lacrimal duct. The portion behind the ridge is smooth, and forms part of the medial wall of the orbit. The ridge gives origin to the *orbicularis oculi* (*pars lacrimalis*) muscle and ends below in a hook-like process, the lacrimal hamulus, which curves forward to articulate with the lacrimal tubercle of the maxilla and completes the superior orifice of the naso-lacrimal canal. The **medial surface** is in relation with the two anterior cells of the ethmoid (lacrimo-ethmoidal), forms part of the infundibulum, and inferiorly looks into the middle meatus of the nose. The **superior border** is short, and articulates with the medial angular process of the frontal. The **inferior border** posterior to the crest joins the medial edge of the orbital plate of the maxilla. The narrow piece, anterior to the ridge, is prolonged downward as the **descending process** to join the lacrimal process of the inferior nasal concha. The **anterior border** articulates with the posterior border of the frontal process of the maxilla and the **posterior border** with the lamina papyracea of the ethmoid.

The vessels of the lacrimal bone are derived from the infra-orbital, dorsal nasal branch of the ophthalmic, and anterior ethmoidal arteries.

Articulations.—The lacrimal articulates with the ethmoid, maxilla, frontal, and inferior nasal concha.

Ossification.—This bone arises in the membrane overlying the cartilage of the fronto-nasal plate, and in its mode of ossification is very variable. As a rule, it is formed from a single nucleus which appears in the third or fourth month of intra-uterine life. Not infrequently, the hamulus is a separate element, and occasionally the bone is divided by a horizontal cleft, a process of the lamina papyracea projecting between the two halves to join the frontal process of the maxilla. More rarely the bone is represented by a group of detached ossicles resembling Wormian bones.

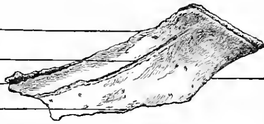
The hamular process is regarded as representing the remains of the facial part of the lacrimal seen in lower animals.

THE VOMER

The **vomer** (fig. 106) (ploughshare bone) is an unpaired flat bone, which lies in the median plane and forms the lower part of the nasal septum. It is thin and irregularly quadrilateral in form, and is usually bent somewhat to one side, though the deflection rarely involves the posterior margin. Each **lateral surface** is covered in the recent state by the mucous membrane of the nasal cavity, and is traversed by a narrow but well-marked groove, which lodges the naso-palatine nerve from the spheno-palatine ganglion.

The **superior border,** by far the thickest part of the bone, is expanded laterally into two **alæ.** The groove between them receives the **rostrum** of the sphenoid, and the margin of each ala comes into contact with the sphenoidal process of the palate and the vaginal process of the medial pterygoid plate. The **inferior border** is uneven and lies in the groove formed by the crests of the maxillary and palate bones of the two sides. The **anterior border** slopes downward and forward and is grooved below for the septal cartilage of the nose; above it is united with the perpendicular plate of the ethmoid. The **posterior border,** smooth, rounded, and covered by mucus membrane, separates the posterior nares. The anterior and inferior borders meet at the anterior extremity of the bone which forms a short vertical ridge behind the incisor crest of the maxillæ. From near the anterior extremity, a small projection passes downward between the incisive foramina.

Fig. 106.—The Vomer. (Side view.)



Blood-supply.—The arterial supply of the vomer is derived from the anterior and posterior ethmoidal and the spheno-palatine arteries. Branches are also derived from the posterior palatine through the foramen incisivum.

Ossification.—The vomer is ossified from two centres which appear about the eighth week in the membrane investing the ethmo-vomerine cartilage. The two lamellæ unite below during the third month and form a shallow bony trough in which the cartilage lies. In the process of growth the lamellæ extend upward and forward and gradually fuse to form a rectangular plate of bone, the cartilage enclosed between them undergoing absorption at the same time. The alæ on the superior margin and the groove in front are evidence of the original bilaminar condition.

THE NASAL

The **nasal** (figs. 107 and 108) are two small oblong bones situated at the upper part of the face and forming the bridge of the nose. Each bone is thicker and narrower above, thinner and broader below, and presents for examination two surfaces and four borders.

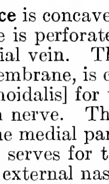


Fig. 107.—The Left Nasal Bone, Facial Surface.

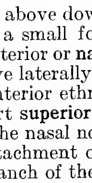

Fig. 108.—The Left Nasal Bone, Nasal Surface.

The **facial surface** is concave from above downward, convex from side to side, and near the centre is perforated by a small foramen, which transmits a small tributary to the facial vein. The posterior or **nasal surface,** covered in the recent state by mucous membrane, is concave laterally, and traversed by a longitudinal groove [sulcus ethmoidalis] for the anterior ethmoidal branch of the ophthalmic division of the fifth nerve. The short **superior border** is thick and serrated for articulation with the medial part of the nasal notch of the frontal. The **inferior border** is thin, and serves for the attachment of the lateral nasal cartilage. It is notched for the external nasal branch of the anterior ethmoidal nerve. The nasal bones of the two sides are united by their **medial borders,** forming the inter-nasal suture. The contiguous borders are prolonged backward to form a crest which rests on the frontal spine and the anterior border of the perpendicular plate of the ethmoid. The **lateral border** articulates with the frontal process of the maxilla.

Blood-supply.—Arteries are supplied to this bone by the nasal branch of the ophthalmic, the frontal, the angular, and the anterior ethmoidal arteries.

Articulations.—With the frontal, maxilla, ethmoid, and its fellow of the opposite side.

Ossification.—Each nasal bone is developed from a single centre which appears about the eighth week in the membrane overlying the fronto-nasal cartilage. The cartilage, which is continuous with the ethmoid cartilage above and the lateral cartilage of the nose below, subsequently undergoes absorption as a result of the pressure caused by the expanding bone. At birth the nasal bones are nearly as wide as they are long, whereas in the adult the length is three times greater than the width.

THE MAXILLA

The **maxilla** or upper jaw-bone (figs. 109, 110, 111) is one of the largest and most important of the bones of the face. It supports the maxillary teeth and takes part in the formation of the orbit, the hard palate, and the nasal fossa. It is divisible into a **body** and four processes, of which two—the **frontal** and **zygomatic**—belong to the upper part, and the **palatine** and **alveolar** to the lower part of the bone.

The **body** is somewhat pyramidal in shape and hollowed by a large cavity known as the **sinus maxillaris** (antrum of Highmore), lined by mucous membrane in the recent state, and opening at the base of the pyramid into the nasal cavity, the zygomatic process forming the apex. The **anterior** (or facial) **surface** looks forward and outward and is marked at its lower part by a series of eminences which indicate the positions of the fangs of the teeth. The eminence produced by the fang of the canine tooth is very prominent and separates two fossæ. That on the medial side is the **incisive fossa,** and gives origin to the *alar* and *transverse portions* of the *nasalis,* and just above the socket of the lateral incisor tooth, to a slip of the *orbicularis oris;* on the lateral side is the **canine fossa,** from which the *caninus* (*levator anguli oris*) arises. Above the canine fossa, and close to the margin of the orbit, is the **infra-orbital foramen,** through which the terminal branches of the infra-orbital nerve and vessels emerge, and from the ridge immediately above the foramen the *quadratus labii superioris* takes origin. The medial margin of the anterior surface is deeply concave, forming the **nasal notch,** and is prolonged below into the **anterior nasal spine.**

A ridge of bone extending upward from the socket of the first molar tooth separates the anterior from the **infratemporal** (zygomatic) **surface.** This latter surface is convex and presents near the middle the orifices of the **posterior alveolar canals,** transmitting the posterior alveolar vessels and nerves. The posterior inferior angle, known as the **tuberosity** [tuber maxillare], is rough and is most prominent after eruption of the wisdom tooth. It gives attachment to a few fibres of the *internal pterygoid* muscle and articulates with the tuberosity of the palate.

The **orbital surface** [planum orbitale] is smooth, irregularly triangular, and forms the greater part of the floor of the orbit.

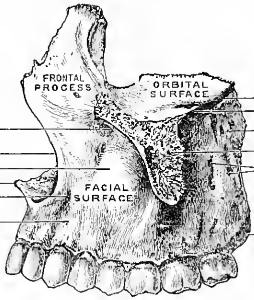
Anteriorly, it is rounded and reaches the orbital circumference for a short distance at the root of the nasal process; laterally is the rough surface for the zygomatic bone. The posterior border, smooth and rounded, forms the inferior boundary of the inferior orbital fissure. The medial border is nearly straight and presents behind the frontal process, a smooth rounded angle forming part of the circumference of the orbital orifice of the naso-lacrimal canal, and a notch which receives the lacrimal bone. The rest of the medial border is rough for articulation with the lamina papyracea of the ethmoid and orbital process of the palate bone.

The orbital surface is traversed by the **infra-orbital groove,** which, commencing at the posterior border, deepens as it passes forward and finally becomes closed in to form the **infra-orbital canal.** It transmits the second division of the fifth nerve and the infra-orbital vessels and terminates on the anterior surface immediately below the margin of the orbit. From the infra-orbital, other canals —the **anterior** and **middle alveolar**—run downward in the wall of the antrum and transmit the anterior and middle alveolar vessels and nerves. Lateral to the commencement of the lacrimal canal is a shallow depression for the origin of the *inferior oblique.*

The **nasal surface** takes part in the formation of the lateral wall of the nasal fossa. It presents a large irregular aperture which leads into the antrum and, immediately in front of this, the **lacrimal groove,** directed downward, backward, and laterally into the inferior meatus of the nose. The groove is converted into a canal by the lacrimal and inferior nasal concha and transmits the naso-lacrimal duct.

In front of the groove is a smooth surface crossed obliquely by a ridge, the **conchal crest**, for articulation with the inferior nasal concha. The surface below the crest is smooth, concave, and belongs to the inferior meatus; the surface above the crest extends on to the lower part of the frontal process and forms the wall of the atrium of the middle meatus. Behind the opening of the antrum the surface is rough for articulation with the vertical plate of the palate bone, and crossing it obliquely is a smooth groove converted by the palate into the **pterygo-palatine canal** for the passage of the (descending) palatine nerves and the descending palatine artery.

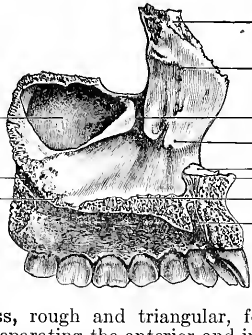
Fig. 109.—The Left Maxilla. (Outer view.)



The **frontal process,** somewhat triangular in shape, rises vertically from the **angle** of the maxilla. Its lateral surface is continuous with the anterior surface of the body, and gives attachment to the *orbicularis oculi*, the medial palpebral ligament and the *quadratus labii superioris* (*caput angulare*). The medial surface forms part of the lateral boundary of the nasal fossa and is crossed obliquely by a low ridge, known as the **agger nasi,** limiting the atrium of the middle meatus.

The hinder part of this surface rests on the anterior extremity of the labyrinth of the ethmoid and completes the maxillo-ethmoidal cells. The superior border articulates with the frontal; the anterior border articulates with the nasal bone; the posterior border is thick and vertically grooved, in continuation with the lacrimal groove, and lodges the lacrimal sac. The medial margin of the groove articulates with the lacrimal bone, and the junction of its lateral margin with the orbital surface is indicated by the **lacrimal tubercle.**

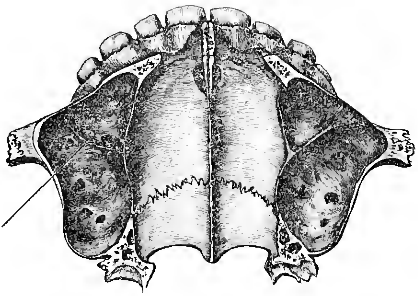
Fig. 110.—The Left Maxilla. (Inner view.)



The **zygomatic process,** rough and triangular, forms the summit of the prominent ridge of bone separating the anterior and infratemporal surfaces. It articulates above with the zygomatic, and from its inferior angle a few fibres of the *masseter* take origin. The anterior and posterior surfaces are continuous with the anterior and infratemporal surfaces of the body.

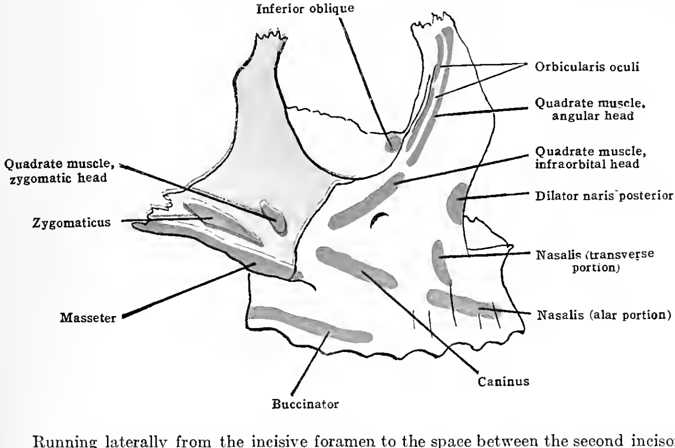
The **palatine process** projects horizontally from the medial surface and, with the corresponding process of the opposite side, forms about three-fourths of the hard palate. The superior surface is smooth, concave from side to side, and constitutes the larger part of the floor of the nasal fossa. The inferior surface is vaulted, rough, and perforated with foramina for nutrient vessels. Near its lateral margin is a longitudinal groove for the transmission of the vessels and nerves which issue at the posterior palatine canal and course along the lower aspect of the palate. When the bones of the two sides are placed in apposition, a large orifice may be seen in the middle line immediately behind the incisor teeth. This is the **incisive foramen,** at the bottom of which are four foramina. Two are small and arranged one behind the other exactly in the **meso-palatine suture.** These are the **foramina of Scarpa** and transmit the naso-palatine nerves, the left

FIG. 111.—SECTION OF MAXILLÆ TO SHOW THE FLOOR OF THE MAXILLARY ANTRUM. (Reduced $\frac{1}{4}$.)



passing through the anterior and the right through the posterior aperture. The lateral and larger orifices are the **foramina of Stenson,** representing the lower apertures of two passages by which the nose communicates with the mouth; they transmit some terminal branches of the descending palatine artery to the nasal fossæ, and lodge recesses of the nasal mucous membrane and remnants of Jacobson's organs.

FIG. 112.—MAXILLA AND ZYGOMATIC BONE, TO SHOW MUSCULAR ATTACHMENTS. (Poirier.)

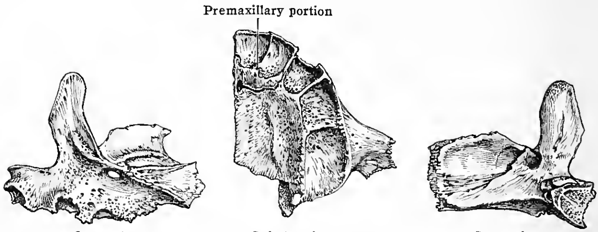


Running laterally from the incisive foramen to the space between the second incisor and canine tooth, an indistinct suture may sometimes be seen, indicating the line of junction of the maxillary and pre-maxillary portions of the bone. The **premaxilla** or incisive bone is the part which bears the incisor teeth and in some animals exists throughout life as an independent element. The posterior border of the palate process is rough and serrated for articulation with the horizontal plate of the palate bone which completes the hard palate. The medial border joins with its fellow to form the **nasal crest** upon which the vomer is received. The more elevated anterior portion of this border is known as the **incisor crest**, and is continued forward into the **anterior nasal spine**. The septal cartilage of the nose rests on its summit and the anterior extremity of the vomer lies immediately behind it. At the side of the incisor crest is seen the upper aperture of the canal leading from the nose to the mouth (Stenson's canal), which in its course downward becomes a groove by a deficiency of its medial wall. Thus when the two bones are articulated a canal is formed (incisive) with the lower ends of two canals opening into it.

The **alevolar process** is crescentic in shape, spongy in texture, and presents cavities [alveoli dentales] in which the upper teeth are lodged. When complete there are eight tooth-cavities (alveoli), with wide mouths, gradually narrowing as they pass into the substance of the bone, and forming exact impressions of the corresponding fangs of the teeth. The pit for the canine tooth is the deepest; those for the molars are the widest, and present subdivisions. Along the lateral aspect of the alveolar process the *buccinator* arises as far forward as the first molar tooth.

The **maxillary sinus** or antrum of Highmore, as the air-chamber occupying the body of the bone is called, is somewhat pyramidal in shape, the **base** being represented by the nasal or medial surface, and the **apex** corresponding to the zygomatic process. In addition it has four walls: the superior is formed by the orbital plate, and the inferior by the alveolar ridge. The anterior wall corresponds to the anterior surface of the maxilla, and the posterior is formed by the infratemporal surface. The medial boundary or base presents a very irregular orifice at its posterior part; this is partially filled in by the vertical plate of the palate bone, the uncinate process of the ethmoid, the maxillary process of the inferior nasal concha, and a small portion of the lacrimal bone. Even when these bones are in their relative positions, the orifice is very irregular in shape, and requires the mucous membrane to form the definite rounded aperture (or apertures, for they are often multiple) known as the **opening of the sinus** through which the cavity communicates with the middle meatus of the nose.

Fig. 113.—The Maxilla at Birth.



The cavity of the sinus varies considerably in size and shape. In the young, it is small and the walls are thick: as life advances it enlarges at the expense of its walls, and in old age they are often extremely thin, so that occasionally the cavity extends even into the substance of the zygomatic bone. The floor of the sinus is usually very uneven, due to prominences corresponding to the roots of the molar teeth. In most cases the bone separating the teeth from the sinus is very thin, and in some cases the roots project into it. The teeth which come into closest relationship with the sinus are the first and second molars, but the sockets of any of the teeth lodged in the maxilla may, under diseased conditions, communicate with it. As a rule, the cavity of the sinus is single, but occasionally specimens are seen in which it is divided by bony septa into chambers, and it is not uncommon to find recesses separated by bony processes. The roof of the sinus presents near its anterior aspect what appears to be a thick rib of bone; this is hollow and corresponds to the infra-orbital canal.

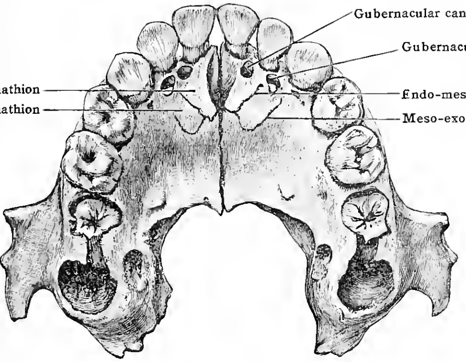
The most satisfactory method of studying the relation of the bones closing in the base of the antrum is to cut away the lateral wall of the cavity (see fig. 128).

Blood-supply.—The maxilla is a very vascular bone and its arteries are numerous and large. They are derived from the infra-orbital, alveolar, descending palatine, spheno-palatine, ethmoidal, frontal, nasal, and facial vessels.

Articulations.—With the frontal, nasal, lacrimal, ethmoid, palate, vomer, zygomatic, inferior nasal concha and its fellow of the opposite side. Occasionally it articulates with the great wing, and the pterygoid process, of the sphenoid.

Ossification.—The maxilla is developed from several centres which are deposited in membrane during the second month of intrauterine life. Several pieces are formed which speedily fuse, so that at birth, with the exception of the incisor fissure separating the maxilla from the premaxilla, there is no trace of the composite character of the bone. The centres of ossification comprise—(1) the **malar**, which gives rise to the portion of bone outside the infra-orbital canal; (2) the **maxillary**, from which the greater part of the body and the frontal process are developed; (3) the **palatine**, forming the hinder three-fourths of the palatal process and adjoining part of the nasal wall; (4) the **premaxillary**, giving rise to the independent premaxillary bone (os incisivum), which lodges the incisor teeth and completes the anterior fourth of the hard palate. In the early stages of growth the premaxilla may consist of two pieces arising from two centres of ossification which Albrecht has named as follows:—the *endognathion*, or medial division for

Fig. 114.—Maxillæ at the end of the First Dentition in both of which the Sutures between Maxilla and Premaxilla, and between the two Parts of the Premaxilla, are seen.



the central incisor, and the *mesognathion*, or lateral division for the lateral incisor; the rest of the maxilla is named the *exognathion;* (5) the **prepalatine**, corresponding to the **infra-vomerine** centre of Rambaud and Renault, forms a portion of bone interposed between the premaxillary in front and the palatine process behind. It gives rise to a part of the nasal surface and completes the medial wall of the incisive canal.

At birth the sinus is narrow from side to side and does not extend laterally to any appreciable extent between the orbit and the alveoli of the teeth. During the early years of life it gradually enlarges, but does not attain its full growth until after the period of the second dentition.

THE PALATE

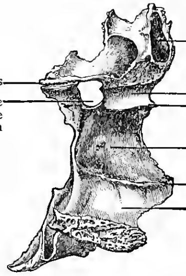
The **palate bone** [os palatinum] (figs. 115, 116) forms the posterior part of the hard palate, the medial wall of the nasal fossa between the maxilla and the medial pterygoid plate, and, by its orbital process, the hinder part of the floor of the orbit. It is somewhat L-shaped and presents for examination a **horizontal** part and a **perpendicular** part; at their point of junction is the **pyramidal process,** and surmounting the top of the vertical plate are the **orbital** and **sphenoidal** processes, separated by the **spheno-palatine notch.**

The **horizontal** part resembles the palatine process ofthe maxilla, but is much shorter. The **superior surface** is smooth, concave from side to side, and forms the back part of the floor of the nasal fossa; the **inferior surface** completes the hard palate behind and presents near its prosterior border a transverse ridge which gives attachment to the *tensor veli palatini* muscle.

The anterior border is rough for articulation with the palatine process of the maxilla; the posterior is free, curved, and sharp, giving attachment to the soft palate. Medially it is thick and broad for articulation with its fellow of the opposite side, forming a continuation of the crest of the palatal processes of the maxillæ and supporting the vomer. The posterior extremity of the crest is the **posterior nasal spine**, from which the *azygos uvulæ* arises. Laterally, at its junction with the perpendicular part, it is grooved by the lower end of the pterygo-palatine canal.

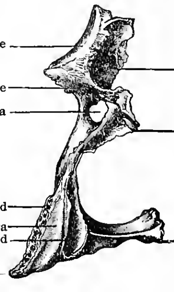
The **perpendicular** part is longer and thinner than the horizontal plate. The **lateral surface** is in relation with the maxilla and is divided into two parts by a vertical groove which forms with the maxilla the **pterygo-palatine canal** for the transmission of the anterior palatine nerve and the descending palatine artery. The part of the surface in front of the groove articulates with the nasal surface of the maxilla and overlaps the orifice of the antrum by the **maxillary process**, a variable projection on the anterior border. Behind the groove the surface is rough for articulation with the maxilla below and the medial pterygoid plate above.

FIG. 115.—PALATE BONE (LEFT). (Medial view.)



The **medial** or **nasal surface** presents two nearly horizontal ridges separating three shallow depressions. Of the depressions, the lower forms part of the inferior meatus of the nose, and the limiting ridge or **conchal (inferior turbinate) crest** articulates with the inferior nasal concha. Above this is the depression forming part of the middle meatus, and the ridge or **ethmoidal (superior turbinate) crest,** constituting its upper boundary, articulates with the middle nasal concha.

FIG. 116.—PALATE BONE. (Posterior view.)



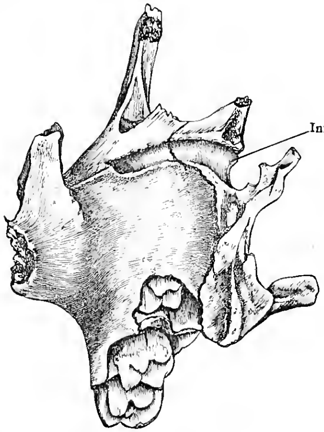
The upper groove is narrower and deeper than the other two and forms a large part of the superior meatus of the nose. The anterior border of the vertical plate is thin and bears the **maxillary process**, a tongue-like piece of bone, which extends over the opening of the maxillary sinus from behind. This border is continuous above with the orbital process. The posterior border is rough and articulates with the anterior border of the medial pterygoid plate. It is continuous superiorly with the sphenoidal process.

The **pyramidal process** or **tuberosity** fits into the notch between the lower extremities of the pterygoid plates and presents posteriorly three grooves. The middle, smooth and concave, completes the pterygoid fossa, and gives origin to a few fibres of the *internal pterygoid;* the medial and lateral grooves are rough for articulation with the anterior border of the corresponding pterygoid plate. Inferiorly, close to its junction with the horizontal plate, are the openings of the **greater palatine** and **smaller palatine canals**, of which the latter are the smaller and less constant; they transmit the palatine nerves. Medially the pyramidal process gives origin to a few fibres of the *superior constrictor* of the pharynx, and laterally a small part appears in the zygomatic fossa between the tuberosity of the maxilla and the pterygoid process of the sphenoid.

The **sphenoidal process**, the smaller of the two processes surmounting the vertical part, curves upward and medially and presents three surfaces and two borders. The **superior surface** is in contact with the body of the sphenoid, and the top of the medial pterygoid plate, where it completes the **pharyngeal** canal. The **medial** or **inferior** surface forms part of the lateral wall and roof of the nasal fossa, and at its medial end touches the ala of the vomer. The **lateral surface** looks forward and laterally into the pterygo-palatine (spheno-maxillary) fossa. Of the two borders, the posterior is thin and articulates with the medial pterygoid plate; the anterior border forms the posterior boundary of the **spheno-palatine** foramen.

The **orbital process** is somewhat pyramidal in shape, and presents for examination five surfaces, three of which—the posterior, anterior, and medial—are articular and the rest non-articular. The **posterior** or **sphenoidal surface** is small and joins the anterior surface of the body of the sphenoid; the **medial** or **ethmoidal** articulates with the labyrinth of the ethmoid; and the **anterior** or **maxillary**, which is continuous with the lateral surface of the perpendicular part, is joined with the maxilla. Of the two non-articular surfaces, the **superior** or **orbital**, directed upward and laterally, is slightly concave, and forms the posterior angle of the floor of the orbit; the **lateral** or **zygomatic**, smooth and directed lateral, looks into the pterygo-palatine (spheno-maxillary) and zygomatic fossæ, and forms the anterior boundary of the spheno-palatine foramen. The process is usually hollow and the cavity completes one of the posterior ethmoidal cells or communicates with the sphenoidal sinus.

FIG. 117.—MAXILLA AND PALATE BONES SHOWING HOW THE INFRA-ORBITAL GROOVE RUNS OUTWARD ALMOST AT RIGHT ANGLES FROM THE NEIGHBOURHOOD OF THE SPHENO-PALATINE FORAMEN ON THE BACK OF THE MAXILLA AND THE ORBITAL PROCESS OF THE PALATE. POSTERIOR VIEW. (E. Fawcett.)



Between the orbital and sphenoidal processes is the **spheno-palatine notch,** converted by the body of the sphenoid, into a complete foramen. It leads from the pterygo-palatine fossa into the back part of the nasal cavity close to its roof, and transmits the medial branches from the spheno-palatine ganglion and the spheno-palatine vessels.

Blood-supply.—The palate bone receives branches from the descending palatine and the spheno-palatine arteries.

Articulations.—With the sphenoid, maxilla, vomer, inferior nasal concha, ethmoid, and its fellow of the opposite side.

Ossification.—The palate is ossified in membrane from a single centre which appears about the eighth week at the angle between the horizontal and perpendicular parts. At birth the two parts are nearly equal in length, but as the nasal fossæ increase in vertical depth, the perpendicular part is lengthened until it becomes about twice as long as the horizontal part.

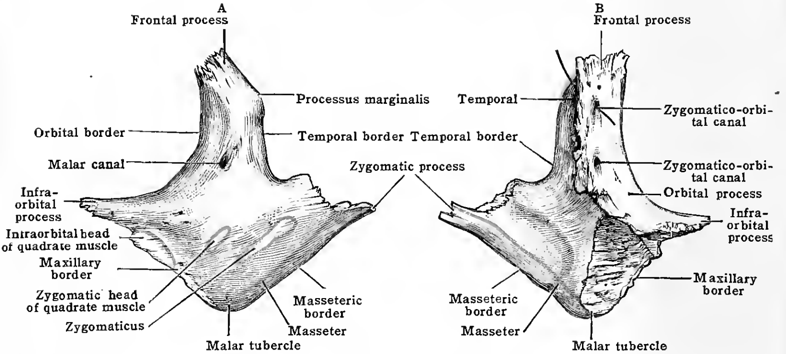
THE ZYGOMATIC

The **zygomatic** [os zygomaticum] or **malar bone** (fig. 118) forms the prominence known as the cheek and joins the zygomatic process of the temporal with the maxilla. It is quadrangular in form with the angles directed vertically and horizontally. The **malar** (or external) **surface** is convex and presents one or two small orifices for the transmission of the zygomatico-facial nerves and vessels. It is largely covered by the *orbicularis oculi* and near the middle is slightly elevated to form the **malar tuberosity,** which gives origin to the *zygomaticus* and *zygomatic head* of quadrate muscle of upper lip.

The **temporal** (or internal) **surface** is concave and looks into the temporal and infratemporal fossæ; it is excluded from the orbit by a prominent curved plate of bone, the **orbital process,** which forms the anterior boundary of the temporal fossa. The upper part gives origin to a few fibres of the *temporal* muscle, while at the lower part is a large rough area for articulation with the zygomatic process of the maxilla.

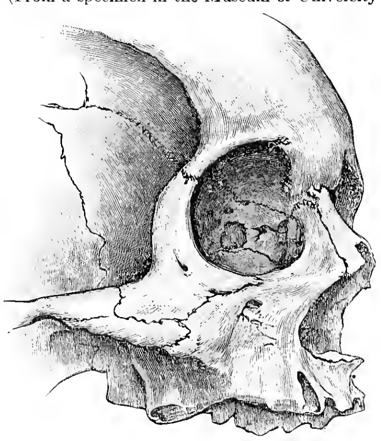
The **orbital process** is placed at right angles to the remaining part of the bone and forms the anterior portion of the lateral wall of the orbit. On the **orbital**

Fig. 118.—The Left Zygomatic Bone.
A, the malar surface. B, the temporal and orbital surfaces.



surface of the process are seen the foramina of two **zygomatico-orbital canals,** which transmit the zygomatico-facial and zygomatico-temporal branches of the zygomatic branch of the fifth, together with two small arteries from the lacrimal. In some cases, however, the canal is single at its commencement on the orbital plate and bifurcates as it traverses the bone. The rough free edge of the

Fig. 119.—Skull showing the Right Malar Bone divided into Two Parts by a Horizontal Suture. (From a specimen in the Museum of University College, London.)



process articulates above with the zygomatic border of the great wing of the sphenoid, and below with the maxilla. When the orbital process is large, it excludes the great wing of the sphenoid from articulation with the maxilla, and the border then presents near the middle a short, non-serrated portion which closes the anterior extremity of the inferior orbital (spheno-maxillary) fissure.

All the four angles of the zygomatic bone have distinguishing features. The superior, forming the **fronto-sphenoidal process**, is the most prominent, and is serrated for articulation with the zygomatic process of the frontal; the anterior or **infra-orbital process**, sharp and pointed, articulates with the maxilla and occasionally forms the superior boundary of the infra-orbital foramen; the posterior or **temporal process** is blunt and serrated mainly on its medial aspect for articulation with the zygomatic process of the temporal; the inferior angle, blunt and rounded, is known as the **malar tubercle.**

Of the four borders, the **orbital** is the longest and extends from the fronto-sphenoidal to the infra-orbital process. It is thick, rounded, and forms more than one-third of the circumference of the orbit; the **temporal border**, extending from the fronto-sphenoidal to the temporal process, is sinuously curved and gives attachment to the temporal fascia. Near the frontal angle is usually seen a slight elevation, the **processus marginalis**, to which a strong slip of the fascia is attached; the **masseteric** border, thick and rough, completes the lower edge of the zygomatic arch and gives origin to the anterior fibres of the *masseter;* the **maxillary** border, rough and concave, is connected by suture with the maxilla, and near the margin of the orbit gives origin to the infra-orbital head of the *quadratus labii superioris.*

Blood-supply.—The arteries of the zygomatic are derived from the infra-orbital, lacrimal, transverse facial, and deep temporal arteries.

Articulations.—With the maxilla, frontal, temporal, and sphenoid.

Ossification.—The zygomatic is ossified in membrane from three centres which appear in the eighth week of intra-uterine life. The three pieces, which have received the names of *premalar, postmalar,* and *hypomalar,* unite about the fifth month. Occasionally the primary nuclei fail to coalesce, and the bone is then represented in the adult by two or three portions separated by sutures. In those cases in which the premalar and postmalar unite and the hypomalar remains distinct, the suture is horizontal; if the independent portion is the premalar, then the suture is vertical. The bipartite zygomatic has been observed in skulls obtained from at least a dozen different races of mankind, but because of the greater frequency in which it occurs in the crania of the Japanese (seven per cent.), the name of *os Japonicum* has been given to it.

THE MANDIBLE

The **mandible** [mandibula] or lower jaw-bone (figs. 120, 121) is the largest and strongest bone of the face. It supports the mandibular teeth, and by means of a pair of condyles, moves on the skull at the mandibular fossæ of the temporal bones. It consists of a horizontal portion—the **body**—strongly curved, so as to somewhat resemble in shape a horseshoe, from the ends of which two branches or **rami** ascend almost at right angles.

The **body** is marked in the middle line in front by a faint groove which indicates the **symphysis** or place of union of the two originally separate halves of the bone. This ends below in the elevation of the chin known as the **mental protuberance,** the lowest part of which is slightly depressed in the centre and raised on each side to form the **mental tubercle.** Each half of the mandible presents two surfaces and two borders. On the **lateral surface,** at the side of the symphysis, and below the incisor teeth, is a shallow depression, the **incisor fossa,** from which the *mentalis* and *the incisivus labii inferioris* muscle arise; and more laterally, opposite the second bicuspid tooth, and midway between the upper and lower margins, is the **mental foramen,** which transmits the mental nerve and vessels. Below the foramen is the **oblique line,** extending backward and upward from the mental tubercle to the anterior border of the ramus; it divides the body into an upper or **alveolar** part and a lower or **basilar** part, and affords attachment to the *quadratus labii inferioris* and the *triangularis oris.*

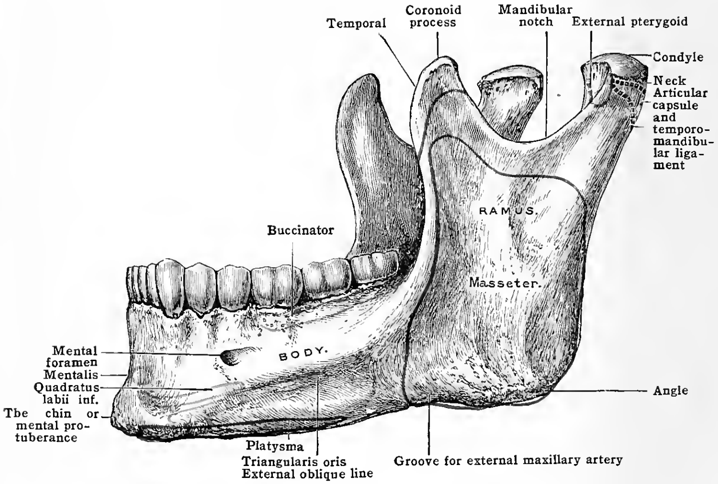
The **medial surface** presents at the back of the symphysis four small projections, called the **mental spine** (genial tubercles). These are usually arranged in two pairs, one above the other; the upper comprising a pair of prominent spines, gives origin to the *genio-glossi,* and the lower, represented in some bones by a median ridge or only a slight roughness, gives origin to the *genio-hyoid* muscles. At the side of the symphysis near the inferior margin is an oval depression, the **digastric fossa,** for the insertion of the *digastric* muscle. Commencing below the mental spine, and extending upward and backward to the ramus, is the **mylo-hyoid line,** which becomes more prominent as it approaches the alveolar border; it gives attachment along its whole length to the *mylo-hyoid* muscle, at its posterior fifth to the *superior constrictor* of the pharynx, and at the posterior extremity to the pterygo-mandibular raphe. Above this line at the side of the symphysis is a smooth depression [fovea sublingualis] for the sublingual gland, and below it, farther back, is another for the submaxillary gland.

The **alveolar part** or superior border is hollowed out into eight sockets or alveoli. These are conical in shape and form an exact counterpart of the roots of the teeth which they contain. From the lateral aspect of the alveolar process, as far forward as the first molar tooth, the *buccinator* muscle takes origin.

The **base** or inferior border is thick and rounded. In the anterior part of its extent it gives attachment to the *platysma*, and near its junction with the ramus is a groove for the external maxillary artery which here turns upward into the face.

The **ramus** is thinner than the body and quadrilateral in shape. The lateral surface is flat, gives insertion to the *masseter*, and at the lower part is marked by several oblique ridges for the attachment of tendinous bundles in the substance of the muscle. The medial surface presents near the middle the **mandibular** (inferior dental) **foramen,** leading into the **mandibular** (inferior dental) **canal** which traverses the bone and terminates at the mental foramen on the lateral surface of the body. From the canal, which in its posterior two-thirds is nearer to the medial, and in its anterior third nearer to the lateral, surface of the mandible,

Fig. 120.—The Mandible. (Lateral view.)



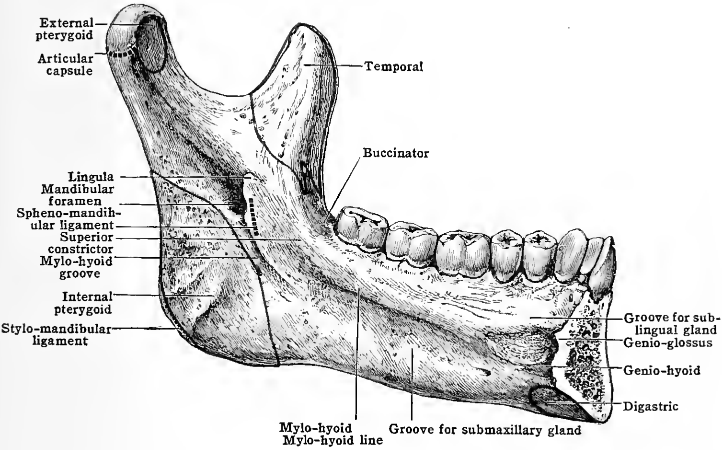
a series of small channels pass upward to the sockets of the posterior teeth and transmit branches of the inferior alveolar (dental) vessels and nerve; in front of the mental foramen a continuation of the canal extends forward and conveys the vessels and nerves to the canine and incisor teeth. The mandibular foramen is bounded medially by a sharp margin forming the **lingula** (mandibular spine), which gives attachment to the spheno-mandibular ligament.

The posterior margin of the lingula is notched. This notch forms the commencement of a groove, the **mylo-hyoid groove** [sulcus mylohyoideus], which runs obliquely downward and forward and lodges the mylo-hyoid nerve and artery, and, in the embryo, Meckel's cartilage. Behind the spine is a rough area for the insertion of the *internal pterygoid* muscle.

The posterior border of the ramus is thick and rounded, and in meeting the inferior border of the ramus forms the **angle** of the jaw, which is rough, obtuse, usually everted, and about 122° in the adult; the angle gives attachment to the stylo-mandibular ligament. The inferior border is thick, rounded, and continuous with the base. The anterior border is continuous with the oblique line, whilst the upper border presents two processes separated by a deep concavity, the **mandibular** (sigmoid) **notch.** Of the processes, the anterior is the **coronoid;** the posterior, the **condylar.**

The **condylar process** consists of the **condyle** [capitulum mandibulæ] and the narrowed portion by which it is supported, the **neck.** The **condyle** is oval in shape, with its long axis transverse to the upper border of the ramus, but oblique with regard to the median axis of the skull, so that the lateral extremity, which presents the **condylar tubercle** for the temporo-mandibular ligament of the temporo-mandibular articulation, is a little more forward than the medial extremity. The convex surface of the condyle is covered with cartilage in the recent

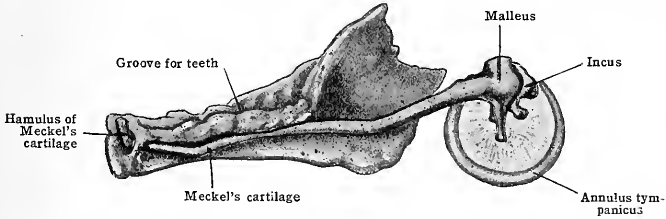
FIG. 121.—THE MANDIBLE. (Medial view.)



state, and rests in the mandibular fossa; the **neck** is flattened from before backward, and presents, in front, a depression [fovea pterygoidea] for the insertion of the *external pterygoid* muscle.

The **coronoid process,** flattened and triangular, is continued upward from the anterior part of the ramus. The lateral surface is smooth and gives insertion to the *temporal* and *masseter* muscles; the medial surface is marked by a ridge which descends from the tip and becomes continuous with the posterior part of the mylo-hyoid line. On the medial surface, as well as on the tip of the coronoid

FIG 122—MANDIBLE SHOWING RELATIONS OF MECKEL'S CARTILAGE IN HUMAN FŒTUS OF 8 CM. CROWN-RUMP LENGTH. (After Kollmann, Handatlas der Entwickelungsgeschichte.)



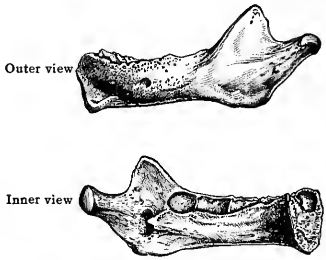
process, the *temporal* muscle is inserted. The **mandibular notch,** the deep semilunar excavation separating the coronoid from the condylar process, is crossed by the masseteric nerve and vessels.

Blood-supply.—Compared with other bones, the superficial parts of the mandible are not so freely supplied with blood. The chief artery is the inferior alveolar which runs in the mandibular canal, and hence, as the bone is exposed to injury and sometimes actually laid bare in its alveolar portion, it often necroses, especially if the artery is involved at the same time.

Ossification.—The mandible is mainly formed by ossification in the fibrous tissue investing the cartilage of the first branchial arch or Meckel's cartilage, although a small portion of the cartilage itself is directly converted into bone.

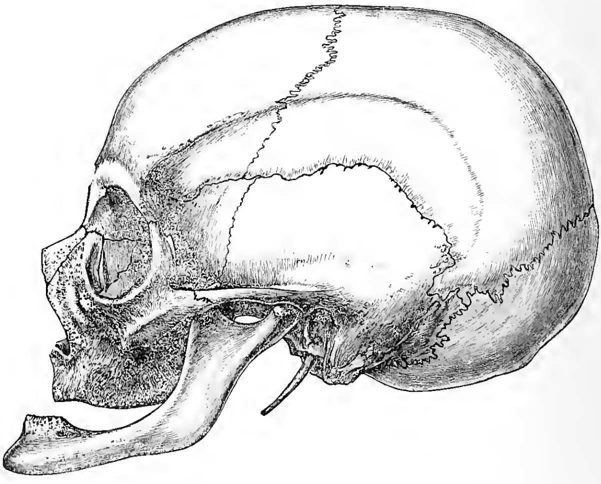
It is now generally admitted that the lower jaw is developed in membrane as a single skeletal element. The centre of ossification appears in the outer aspect of Meckel's cartilage and gives rise to the bony plate known as the *dentary*. This plate extends forward right up to the middle line in front, and from it a shelf grows upward for the support of the tooth germs.

Fig. 123.—The Mandible at Birth.



Meckel's cartilage lies below and medial to the dentary plate, and the inferior alveolar nerve passes forward between the two structures. Meckel's cartilage itself takes some small part in the formation of the lower jaw. Ossification from the primary nucleus invades the cartilage at a point opposite the interval between the first and second tooth germs, and the resulting bone contributes to the formation of the alveolar margin opposite these two teeth. Behind this point the cartilage atrophies except in so far as it helps to form the spheno-mandibular ligament and the malleus and incus. Behind the symphysis the anterior extremity of the cartilage does not enter into the formation of the jaw, but it usually persists throughout fœtal

Fig. 124.—The Skull of a Woman Eighty-three Years Old, to show the Changes in the Mandible and Maxilla.



life as one or two small, rounded, cartilaginous masses. Occasionally they become ossified and give rise to accessory ossicles in this situation. The lamella of bone situated on the medial side of Meckel's cartilage, corresponding to the distinct splenial element in some animals, arises in man as an extension from the dentary element.

In connection with the condylar and coronoid processes, cartilaginous masses are developed. These do not, however, indicate separate elements, but are adaptations to the growth of the lower jaw. They are ossified by an extension from the surrounding membrane bone.

The process of ossification of the lower jaw commences very early, between the sixth and eighth week, and proceeds rapidly, so that by the fourth month the various parts are formed.

Age-changes.—At birth the mandible is represented by two nearly horizontal troughs of bone, lodging unerupted teeth, and joined at the symphysis by fibrous tissue. The body is mainly alveolar, the basal part being but little developed; the condyle and the upper edge of the symphysis are nearly on a level; the mental foramen is nearer the lower than the upper margin, and the angle is about 175°. The inferior alveolar nerve lies in a shallow groove between the splenial and dentary plates.

During the first year osseous union of the two halves takes place from below upward, but is not complete until the second year. After the first dentition, the ramus forms with the body of the mandible an angle of about 140°, and the mental foramen is situated midway between the upper and lower borders of the bone opposite the second milk-molar. In the adult, the angle formed by the ramus and body is nearer to a right angle, and the mental foramen is opposite the second bicuspid, so that its relative position remains unaltered after the first dentition. In old age, after the fall of the teeth, the alveolar margin is absorbed, the angle formed by the ramus and body is again increased, and the mental foramen approaches the alveolar margin. In a young and vigorous adult the mandible is, with the exception of the petrous portion of the temporal, the densest bone in the skeleton; in old age it becomes exceedingly porous, and often so soft that it may easily be broken.

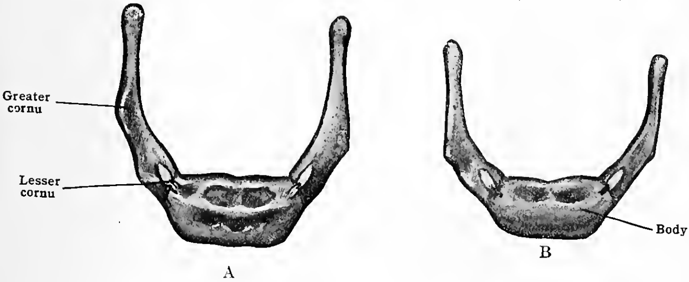
THE HYOID BONE

The **hyoid bone** [os hyoideum] or os linguæ (fig. 125), situated in the anterior part of the neck between the chin and the thyreoid cartilage, supports the tongue and gives attachment to numerous muscles. It is suspended from the lower extremities of the styloid processes of the temporal bones by two slender bands known as the **stylo-hyoid ligaments,** and is divisible into a **body** and two pairs of processes, the **greater** and **lesser cornua.**

The **body,** constituting the central portion of the bone, is transversely placed and quadrilateral in form. It is compressed from before backward and lies obliquely so that the anterior surface looks upward and forward and the posterior surface in the opposite direction.

The **anterior surface** is convex and divided by a horizontal ridge into a superior and an inferior portion. Frequently it also presents a vertical ridge crossing the former at right angles, and just above the point of intersection is the **glosso-hyal**

Fig. 125.—The Hyoid Bone. A, Male, B, Female (Natural Size)

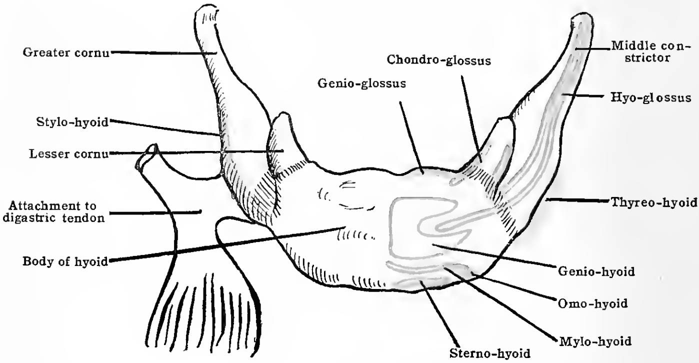


process, the vestige of a well-developed process in this situation in the hyoid bone of some of the lower animals (reptiles and the horse). In this way four spaces or depressions for muscular attachments are marked off, two on either side of the middle line. The **posterior surface** is deeply concave and separated from the epiglottis by the thyreo-hyoid membrane, and by some loose areolar tissue. The membrane passes upward from the thyreoid cartilage to be attached to the **superior border,** and interposed between it and the concavity on the back of the body is a small synovial bursa. The **inferior border,** thicker than the upper, gives insertion to muscles. The **lateral borders** are partly in relation with the greater cornua, with which they are connected, up to middle life, by synchondrosis, but after this period, usually by bone.

The **greater cornua** projects upward and backward from the sides of the body. They are flattened from above downward, thicker near their origin, and terminate posteriorly in a rounded tubercle to which the thyreo-hyoid ligament is attached.

The **lesser cornua** are small conical processes projecting upward and backward opposite the lines of junction between the body and the greater cornua, and by their apices give attachment to the stylo-hyoid ligaments; they are connected to the body by fibrous tissue. Professor Parsons has shown that a joint with a synovial cavity is common between the smaller and geater cornua. The lesser cornua are sometimes partly or even completely cartilaginous in the adult.

Fig. 126.—Hyoid Bone Enlarged to show Muscular Attachments. (After F. G. Parsons.)



The muscles attached to each half of the hyoid bone may be enumerated as follows:—

Body............ Genio-hyoid, genio-glossus, mylo-hyoid, sterno-hyoid, omo-hyoid, stylo-hyoid, thyreo-hyoid and hyo-glossus.
Greater cornu.....Thyreo-hyoid, middle constrictor, hyo-glossus, and digastric.
Lesser cornu...... Chondro-glossus, and middle constrictor.

Ossification.—In the early months of intra-uterine life the hyoid bone is composed of hyaline cartilage and is directly continuous with the styloid processes of the temporal bones. Ossification takes place from six centres, of which two appear in the central piece of cartilage, one on either side of the middle line, either just before or just after birth; soon after their appearance, however, they coalesce to form the body of the bone (basi-hyal). The centre for each of the greater cornua (thyreo-hyals) appears just about the time of birth, and for each of the lesser cornua (cerato-hyals) some years after birth, even as late as puberty. (F. G. Parsons.) The greater cornua and the body unite in middle life; the lesser cornua rarely ankylose with the body and only in advanced age. Professor Parsons has shown, however, that the lesser cornua more frequently unite with the greater cornua.

THE SKULL AS A WHOLE

The skull, formed by the union of the cranial and facial bones already described, may now be considered as a whole. Taking a general view, it is spheroidal in shape, smooth above, compressed from side to side, flattened and uneven below, and divisible into six regions: a superior region or vertex, a posterior or occipital region, an anterior or frontal region, an inferior region or base, and two lateral regions.

(1) The Superior Region

Viewed from above (*norma verticalis*) the skull presents an oval outline with the broader end behind, and includes the **frontal, parietals,** and the **interparietal** portion of the **occipital.** In a skull of average width the zygomatic arches are visible, but in very broad skulls they are obscured.

The sutures of the vertex are:—

The **metopic**, which is, in most skulls, merely a median fissure in the frontal bone just above the glabella; occasionally it involves the whole length of the bone. It is due to the persistence of the fissure normally separating the two halves of the bone in the infant.

The **sagittal** is situated between the two parietals, and extends from the bregma to the lambda.

The **coronal** lies between the frontal and parietals, and extends from pterion to pterion.

The **lambdoid** is formed by the parietals and interparietal portion of the occipital. It extends from asterion to asterion.

The **occipital** suture is only present when the interparietal exists as a separate element (figs. 70 and 71).

The more important points are:—

The **bregma**, which indicates the situation of the frontal (greater) fontanelle, and marks the confluence of the coronal, the sagittal, and, when present, the metopic sutures.

The **lambda**, where the sagittal enters the lambdoid suture; it marks the situation of the occipital (lesser) fontanelle.

The **obelion**, a little anterior to the lambda, is usually indicated by a median or two lateral foramina.

(2) The Posterior Region

Viewed from behind (*norma occipitalis*) the skull is somewhat pentagonal in form. Of the five angles, the superior or median is situated in the line of the sagittal suture; the two upper lateral angles coincide with the parietal eminences and the two lower with the mastoid processes of the temporal bones. Of the sides, four are somewhat rounded, and one, forming the basal line, running between the mastoid processes, is flattened.

The centre is occupied by the lambda, and radiating from this point are three sutures, the **sagittal**, and the two parts of the **lambdoid**. Each half of the lambdoid suture bifurcates at the mastoid portion of the temporal bone, the two divisions constituting the **parieto-mastoid** and **occipito-mastoid** sutures; the point of bifurcation is known as the **asterion.**

In the lower part of the view is seen the **external occipital protuberance** (inion), the occipital crest, and the three pairs of nuchal lines, which give it a rough and uneven appearance. The **occipital point** is the point of the occiput furthest from the glabella in the median plane. It is situated above the external occipital protuberance.

(3) The Lateral Region

The **lateral region** (*norma lateralis*) (fig. 127) is somewhat triangular in shape, being bounded above by a line extending from the zygomatic process of the frontal, along the temporal line to the lateral extremity of the superior nuchal line of the occipital bone; this forms the base of the triangle. The two sides are represented by lines drawn from the extremities of the base to the angle of the jaw. It is divisible into two portions, one in front, the other behind, the eminentia articularis [tuberculum articulare]. The posterior portion presents, in a horizontal line from behind forward, the mastoid portion of the temporal, with its process and foramen, the external auditory meatus, the centre of which is known as the **auricular point,** the mandibular fossa, and the condyle of the mandible.

In the anterior portion are three fossæ, (a) temporal, (b) infratemporal, (c) pterygo-palatine (spheno-maxillary), and two fissures, the inferior orbital (spheno-maxillary) and pterygo-palatine.

(a) The **temporal fossa**, somewhat semilunar in shape, is bounded *above* and *behind* by the temporal line, in *front* by the frontal, zygomatic, and great wing of sphenoid, and *laterally* by the zygomatic arch, by which it is separated superficially from the infratemporal fossa; more deeply the infratemporal ridge separates the two fossæ.

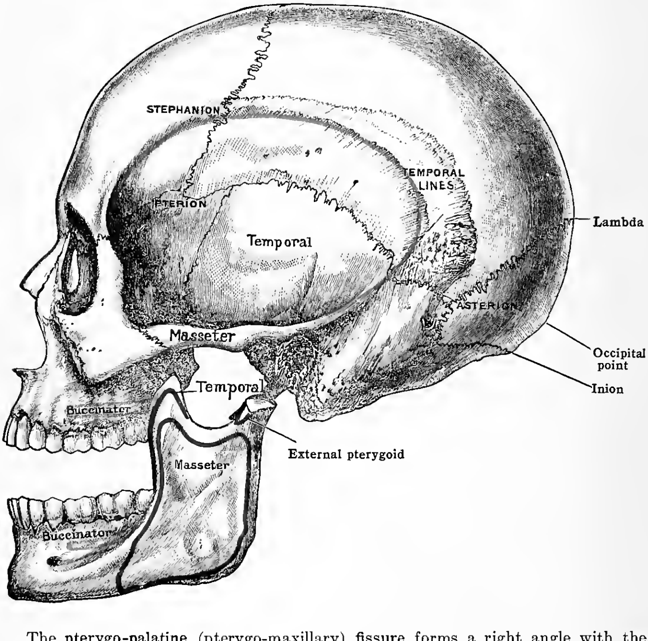
The fossa is formed by parts of five bones, the zygomatic, temporal, parietal, frontal, great wing of sphenoid, and is traversed by six sutures, coronal, spheno-zygomatic, spheno-squamosal, spheno-parietal, squamosal, and spheno-frontal. The point where the temporal ridge is crossed by the coronal suture is the **stephanion,** and the region where the frontal, sphenoid, temporal, and parietal meet is the **pterion.** The latter is frequently occupied in the adult by the epipteric bone.

The temporal fossa is concave in front, convex behind, filled by the temporal muscle, and roofed in by a strong glistening aponeurosis, the **temporal fascia,** which serves to bind down the muscle.

(b) The **infratemporal fossa** (zygomatic fossa), irregular in shape, is situated below and to the medial side of the zygoma, covered in part by the ramus of the mandible. It is bounded *in front* by the lower part of the medial surface of the zygomatic, and by the infratemporal surface of the maxilla, on which are seen the orifices of the posterior superior alveolar canals; *behind* by the posterior border of the lateral pterygoid plate, the spine of the sphenoid, and the articular tubercle; *above* by the infratemporal ridge, a small part of the squamous portion of the temporal, the great wing of the sphenoid perforated by the foramen ovale and foramen spinosum; *below* by the alveolar border of the maxilla; *laterally* by the ramus of the mandible and the zygoma formed by zygomatic and temporal; *medially* by the lateral pterygoid plate, a line from which to the spine of the sphenoid separates the infratemporal fossa from the base of the skull. It contains the lower part of the temporal muscle and the coronoid process of the mandible, the external and internal pterygoids, the internal maxillary vessels, and the mandibular division of the fifth nerve with numerous branches. At its upper and medial part are seen the inferior orbital and pterygo-palatine fissures.

The **inferior orbital** (or spheno-maxillary) **fissure** is horizontal in position, and lies between the maxilla and the great wing of the sphenoid; laterally it is usually completed by the zygomatic, though in some cases the sphenoid joins the maxilla, and in this way excludes the zygomatic bone from the fissure; medially it is terminated by the infratemporal surface of the orbital process of the palate bone. Through this fissure the orbit communicates with the pterygo-palatine (spheno-maxillary), infratemporal, and temporal fossæ. It transmits the infra-orbital nerve and vessels, the zygomatic nerve, ascending branches from the spheno-palatine ganglion to the orbit, and a communicating vein from the ophthalmic to the pterygoid plexus.

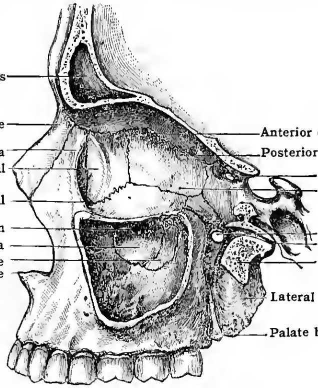
Fig. 127.—The Skull. (Norma lateralis.)



The **pterygo-palatine** (pterygo-maxillary) **fissure** forms a right angle with the inferior orbital fissure and is situated between the maxilla and the anterior border of the pterygoid process of the sphenoid. At its lower angle, where the two lips of the fissure approximate, the lateral pterygoid plate occasionally articulates with the maxilla, but they are usually separated by a thin portion of the pyramidal process of the palate. The pterygo-palatine fissure, which serves to connect the infratemporal fossa with the pterygo-palatine fossa, is bounded medially by the perpendicular part of the palate; it transmits branches of the internal maxillary artery, and the corresponding veins, to and from the pterygo-palatine fossa.

(c) The **pterygo-palatine** (spheno-maxillary) **fossa** is a small space, of the form of an inverted pyramid, situated at the angle of junction of the inferior orbital (spheno-maxillary) with the pterygo-palatine (pterygo-maxillary) fissure, below the apex of the orbit. It is bounded *in front* by the infratemporal surface of the maxilla; *behind*, by the base of the pterygoid process and the lower part of the anterior surface of the great wing of the sphenoid; medially by the perpendicular part of the palate with its orbital and sphenoidal processes; *above* by the lower surface of the body of the sphenoid. Three fissures terminate in it—viz., the superior orbital, pterygo-palatine, and inferior orbital; through the superior orbital fissure it communicates with the cranium, through the pterygo-palatine fissure with the infratemporal fossa, through the inferior orbital fissure with the orbit, and through the spheno-palatine foramen on the medial wall it communicates with the upper and back part of the nasal fossa. Including the spheno-palatine foramen six foramina open into the fossa. Of these, three are on the posterior wall: enumerated from without inward, and from above downward, they are the **foramen rotundum,** the **pterygoid** (Vidian) **canal,** and the **pharyngeal** (pterygo-palatine) **canal.** The apex of the pyramid leads below into the **pterygo-palatine canal** and the **accessory palatine canals** which branch from it; and anteriorly is the orifice of the **infra-orbital canal.** The fossa contains the spheno-palatine ganglion, the maxillary nerve, and the terminal part of the internal maxillary artery, and the various foramina and canals in relation with the fossa serve for the transmission of the numerous branches which these vessels and nerves give off.

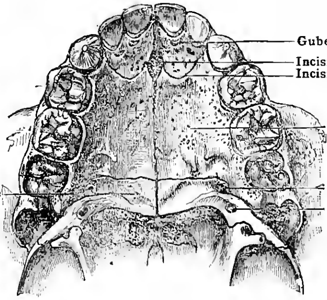
Fig. 128.—A Section of the Skull showing the Medial Wall of the Orbit, the Medial Wall of the Antrum, and the Pterygo-palatine Fossa.



(4) Inferior Region or External Base of Skull

The **external base** of the skull (*norma basilaris*) (figs. 130, 131) extends from the incisor teeth to the occipital protuberance, and is bounded on each side by the alveolar arch, the zygomatic, the zygoma, the temporal, and the superior nuchal line of the occipital bone. It is very uneven and, excluding the lower jaw, divisible into three portions: (a) anterior, (b) middle or subcranial, and (c) posterior or suboccipital.

Fig. 129.—Hard Palate of a Child Five Years Old.



(a) The **anterior division** consists of the hard palate, the alveolar arch, and the choanæ (posterior nares).

When the skull is inverted, the hard palate stands at a higher level than the rest, and is bounded anteriorly and laterally by the alveolar ridges containing the teeth. The bones appearing in the intermediate space are the premaxillary and palatine portions of the maxillæ and the horizontal parts of the palate bones.

FIG. 130.—THE SKULL. (Norma basilaris.)

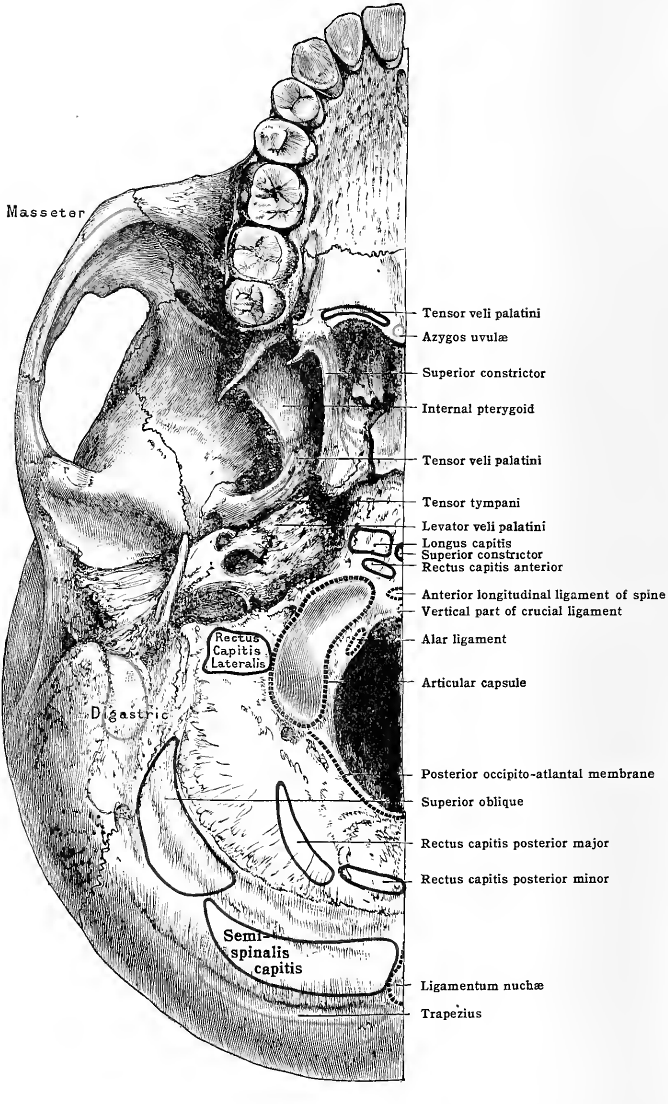


Fig. 131.—The Skull. (Norma basilaris.)

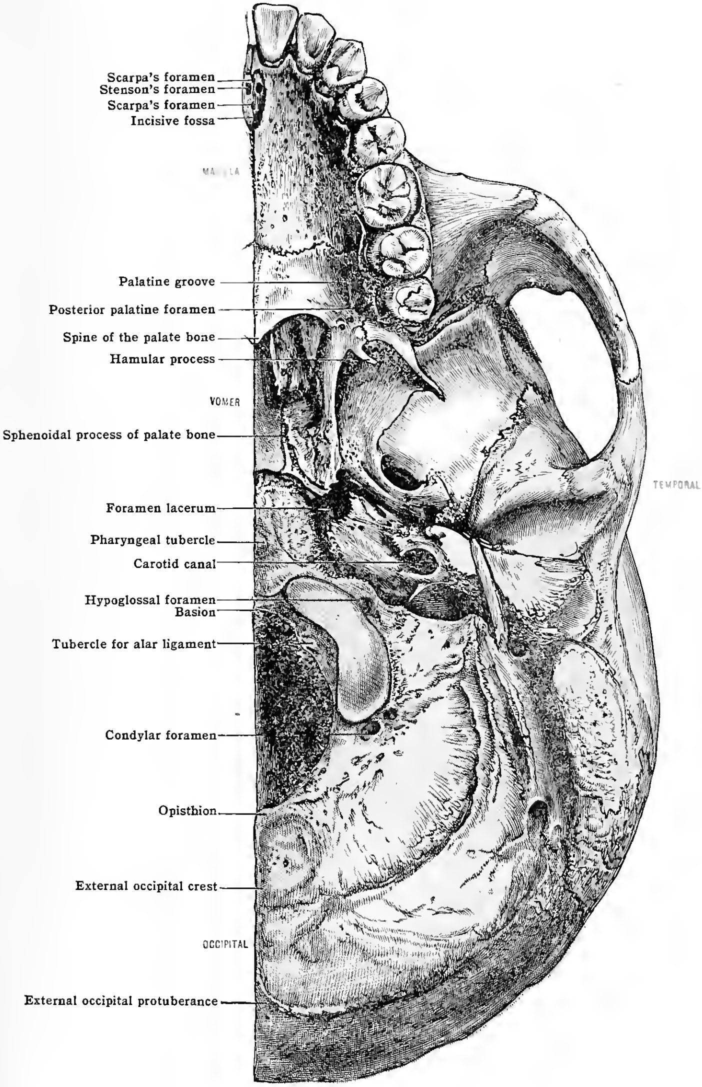


They are rough for the attachment of the muco-periosteum, and near the posterior margin is the ridge for the fibrous expansion of the *tensor veli palatini*. The following points are readily recognised (fig. 129):—

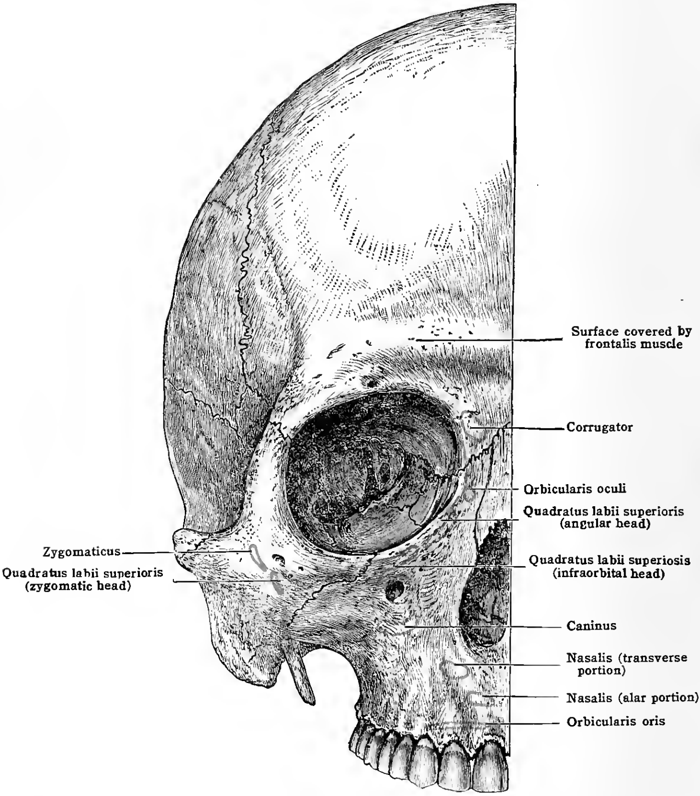
The **meso-palatine suture** commences at the alveolar point, traverses the incisive fossa, and terminates at the posterior nasal spine.

The **transverse palatine suture,** between the palate bones and palatine processes of the maxillæ.

In young skulls the **incisive sutures**, and behind the incisor teeth four small openings known as the **gubernacular canals** (see figs. 114 and 129).

The incisive fossa containing the termination of four canals: two small orifices, **foramina of**

FIG. 132.—THE SKULL. (Norma facialis.)



Scarpa, situated one behind the other in the meso-palatine suture; and two larger openings, the **foramina of Stenson.** The foramina of Scarpa transmit the naso-palatine nerves, and those of Stenson are in relation (embryonic) with the organs of Jacobson.

At the posterior angles of the hard palate are the **greater palatine foramina**, through which the descending palatine vessels and the anterior palatine nerves emerge on to the palate; a thin lip of bone separates them from the **lesser palatine foramen** in the tuberosity of the palate bone on each side, for the posterior palatine nerve.

The **hamular process** of the medial pterygoid plate is the most posterior limit of the hard palate.

At the posterior extremity of each alveolar ridge is the **tuberosity** of the maxilla, and between it and the palate bone is a foramen (variable in size and sometimes absent), the **middle palatine foramen,** for the middle palatine nerve. This foramen is often included under the lesser palatine foramina (BNA).

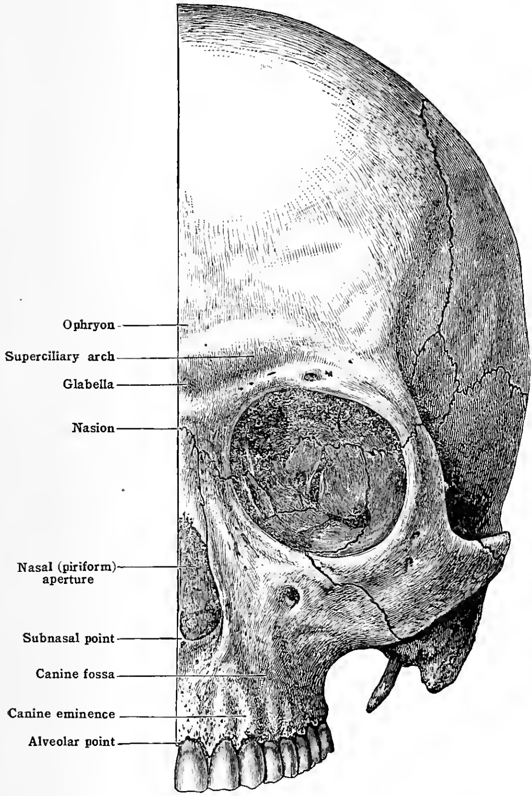
Behind the hard palate are the **choanæ** (posterior nares), separated from each other by the vomer. Each is bounded laterally by the medial pterygoid plate; below by the horizontal plate of the palate bone; above by the under surface of the body of the sphenoid, with the ala of the vomer and a portion of the sphenoidal process of the palate bone.

Lateral to the choanæ there is on each side a vertical fossa lying between the pterygoid plates. It extends upward to the under surface of the great wings of the sphenoid; it is completed anteriorly by the coalescence of the pterygoid plates and below by the pyramidal process of the palate bone. It contains the following points of interest:—

An elongated furrow, the **scaphoid fossa,** for the *tensor veli palatini* muscle and the cartilage of the Eustachian tube.

The general cavity of the **pterygoid** fossa which lodges the *tensor veli palatini* and *internal pterygoid* muscles.

Fig. 133.—The Skull. (Norma facialis.)



Frequently there is a notch in the lateral pterygoid plate close beside the foramen ovale.

The posterior termination of the **pterygoid** (Vidian) **canal.**

If a line be drawn across the base of the skull from one preglenoid tubercle to the other, it will fall immediately behind the lateral pterygoid plate and bisect the foramen spinosum on each side. A second transverse line, drawn across the **opisthion** or posterior margin of the foramen magnum, will fall behind the mastoid processes. The space between these arbitrary lines may be called the *subcranial region;* that behind the second line, the *suboccipital region.*

(b) The **subcranial region** is separated from the infratemporal fossa by a line drawn from the posterior margin of the lateral pterygoid plate to the spine of the sphenoid. It is formed by the inferior surface of the basilar process of the occipital and the body of the sphenoid, the petrous portion of the temporal bone, a small piece of the squamosal portion, the posterior part of the great wing of the sphenoid, and the condylar portions of the occipital bone. It presents the following points for examination (Figs. 95, 131):—

The **pharyngeal tubercle.**

The **foramen magnum** and the **occipital condyles.** The most anterior point of the foramen is termed the **basion,** and the most posterior point the **opisthion.**

On each side will be seen:—The **hypoglossal foramen** for the hypoglossal nerve and a meningeal branch of the ascending pharyngeal artery.

The **condylar fossa** with the condylar foramen (this foramen is not constant).

The under aspect of the **jugular process,** from which the *rectus capitis lateralis* takes origin.

The **foramen lacerum** and the orifice of the **pterygoid (Vidian) canal.**

The **canalis musculo-tubarius** for the *tensor tympani* muscle and Eustachian tube.

The **carotid canal.**

The quadrilateral area for the origin of the *levator veli palatini* and *tensor tympani* muscles.

The **canaliculus cochleæ,** or ductus perilymphaticus.

The **jugular foramen** and **fossa** for the glosso-pharyngeal, vagus, and spinal accessory nerves, the internal jugular vein, and a meningeal branch of the ascending pharyngeal artery.

The **tympanic canaliculus** for Jacobson's nerve (tympanic branch of glossopharyngeal).

The **spine** of the sphenoid; this is sometimes fifteen millimetres in length.

The **mandibular fossa** with the **petro-tympanic fissure.** This lodges the anterior process of the malleus, the tympanic twig of the internal maxillary artery. A small passage beside it, the **canal of Huguier,** conducts the chorda tympani nerve from the tympanum.

The **external auditory meatus.**

The **auricular** or **tympano-mastoid fissure.**

The **tympanic** plate and vaginal process.

The **styloid process.**

The **stylo-mastoid foramen** for the stylo-mastoid artery and the exit of the facial nerve and, in some cases, the auricular branch of the vagus.

The **mastoid process** with the digastric and occipital grooves.

(c) The **suboccipital region** is largely formed by the tabular portion of the occipital bone with its ridges and areas for muscular attachment. Laterally a small part of the mastoid portion of the temporal is seen, pierced by a small foramen, of variable size, the **mastoid foramen,** which transmits a vein from the transverse (lateral) sinus and a meningeal branch of the occipital artery.

(5) The Anterior Region

The **anterior region** (*norma facialis*) (figs. 132, 133) comprises the anterior end of the cranium or forehead, and the skeleton of the face; also the cavities known as the **orbits,** formed by the junction of the two parts of this region, and the **nasal fossæ,** situated on either side of the septum of the nose.

The upper part or forehead, narrowest between the temporal crests about half an inch above the zygomatic processes of the frontal, presents at this level the two **transverse sulci;** above are the **frontal eminences,** below the **superciliary arches,** and still lower the supra-orbital margins, interrupted near their medial ends by the supra-orbital notches.

Below the forehead are the openings of the **orbits,** bounded laterally by the zygomatic bones constituting the prominences of the cheeks, and between them the bridge of the nose, formed by the nasal bones and the frontal processes of the maxillæ. Below the nasal bones is the **apertura piriformis** or **anterior nasal aperture,** leading into the nasal fossæ. The teeth form a conspicuous feature in this view of the skull, the outline of which is completed below by the mandible.

The **bones** entering into formation of the *norma facialis* are:—the frontal, nasals, lacrimals, orbital surfaces of the small and the great wings, and a portion of the body of the sphenoid, the laminæ papyraceæ of the ethmoids, the orbital processes of the palate bones, the zygomatics, maxillæ, inferior nasal conchæ, and the mandible.

The **sutures** are numerous, and for the most part unimportant:—

The **transverse** suture (fig. 133) extends from one zygomatic process of the frontal to the other. The upper part of the suture is formed by the frontal bone; below are the zygomatic, great and small wings of the sphenoid, lamina papyracea, lacrimal, maxillary, and nasal bones. A portion of this complex suture, lying between the sphenoidal and frontal bones, appears in the anterior cranial fossa.

Other fissures are the internasal, naso-maxillary, inter-maxillary and zygomatico-maxillary. The small sutures seen in the orbit are described with that cavity.

The **foramina** are:—the supra-orbital, infra-orbital, optic, zygomatico-facial, and mental; the naso-lacrimal canal; the ethmoidal canals; and the inferior and superior orbital fissures.

The following points may also be noticed:—

The **glabella**, a smooth space between the converging superciliary arches.

The **ophryon**, the most anterior point of the metopic suture.

The **nasion**, the middle of the naso-frontal suture.

The **subnasal point**, the middle of the inferior border of the pyriform aperture at the base of the nasal spine.

The **alveolar point**, the centre of the anterior margin of the upper alveolar arch.

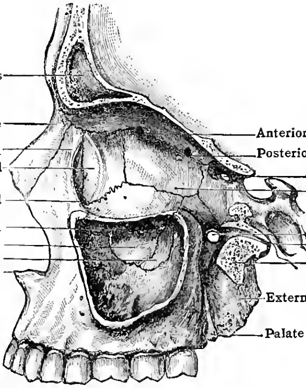
THE ORBITS

The **orbits** [orbitæ] (fig. 134) are two cavities of pyramidal shape, with their bases directed forward and laterally and their apices backward and medially; their medial walls are nearly parallel, but their lateral walls diverge so as to be nearly at right angles to each other. Each cavity forms a socket for the eyeball and the muscles, nerves, and vessels associated with it.

Seven bones enter into formation of its walls, viz., the frontal, zygomatic, sphenoid, ethmoid, lacrimal, palate, and maxilla; but as three of these—the frontal, sphenoid, and ethmoid—are single median bones which form parts of each cavity, there are only eleven bones represented in the two orbits. Each orbit presents for examination four walls, a circumference or base, and an apex.

The **superior wall** or **roof**, vaulted and smooth, is formed mainly by the orbital plate of the frontal and is completed posteriorly by the small wing of the sphenoid. At the lateral angle it presents the **lacrimal** fossa for the lacrimal gland, and at the medial angle a depression or a spine for the pulley of the *superior oblique* muscle.

Fig. 134.—The Medial Wall of the Orbit.



The **inferior** wall or **floor** is directed upward and laterally and is not so large as the roof. It is formed by the orbital plate of the maxilla, the orbital process of the zygomatic, and the orbital process of the palate bone. At its medial angle it presents the naso-lacrimal canal, and near this, a depression for the origin of the *inferior oblique* muscle. It is marked near the middle by a furrow for the infra-orbital artery and the second division of the fifth nerve, terminating anteriorly in the infra-orbital canal, through which the nerve and artery emerge on the face. Near the commencement of the canal a narrow passage, the anterior alveolar canal, runs forward and downward in the anterior wall of the antrum, transmitting nerves and vessels to the incisor and canine teeth.

The **lateral wall**, directed forward and medially, is formed by the orbital surface of the great wing of the sphenoid, and the zygomatic. Between it and the roof, near the apex, is the **superior orbital** (sphenoidal) **fissure**, by means of which the third, fourth, ophthalmic division of the fifth, and sixth nerves enter the orbit from the cranial cavity; it also transmits some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, recurrent branches of the lacrimal artery, and an ophthalmic vein. The lower margin of the fissure presents near the middle a small tubercle, from which the inferior head of the *lateral rectus* muscle arises. Between the lateral wall and the floor, near the apex, is the **inferior orbital** (spheno-maxillary) **fissure,** through which the second division of the fifth and the infra-orbital vessels pass from the pterygo-palatine fossa to enter the infra-orbital groove. At the anterior margin of the fissure the sphenoid occasionally articulates with the maxilla, but the two are usually separated by the orbital plate of the zygomatic, and on the latter are seen the orifices of the zygomatico-temporal and zygomatico-facial canals, which traverse the zygomatic bone. The commencement of the zygomatico-temporal canal is sometimes seen in the spheno-zygomatic suture connecting the sphenoid and zygomatic bones.

The **medial wall,** narrow and nearly vertical, is formed from before backward by the frontal process of the maxilla, the lacrimal, the lamina papyracea of the ethmoid, and the body of the sphenoid. At the junction of the medial wall with the roof, and in the suture between the ethmoid and frontal, are seen the orifices of the **anterior** and **posterior ethmoidal canals,** the anterior, transmitting the anterior ethmoidal vessels and nerve; and the posterior, the posterior vessels and nerve. Anteriorly is the **lacrimal groove** for the lacrimal sac, and behind this the **lacrimal crest,** from which the *tensor tarsi* arises. The medial wall, which is the smallest of the four, is traversed by three vertical sutures:—one between the frontal process of the maxilla and the lacrimal, a second between lacrimal and lamina papyracea, and a third between the lamina papyracea and the sphenoid. Occasionally the sphenoidal concha appears in the orbit between the ethmoid and the body of the sphenoid.

The **apex** of each orbit corresponds to the **optic foramen,** a circular orifice which transmits the optic nerve and ophthalmic artery. The **base** or circumference is quadrilateral in form and is bounded by the frontal bone above, the frontal process of the maxilla and the medial angular process of the frontal on the medial side, the zygomatic bone and the zygomatic process of the frontal on the lateral side, and by the zygomatic and the body of the maxilla below. The following points may also be noted:—The suture between the zygomatic process of the frontal bone and the zygomatic; the supra-orbital notch (sometimes a complete foramen); the suture between the frontal bone and the frontal process of the maxilla; and in the lower segment, the zygomatico-maxillary suture.

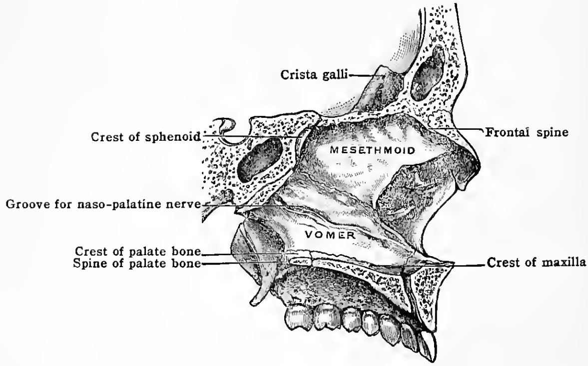
The orbit communicates with the cranial cavity by the optic foramen and superior orbital fissure; with the nasal fossa, by means of the naso-lacrimal canal; with the zygomatic and pterygo-palatine fossæ, by the inferior orbital fissure. In addition to these large openings, the orbit has five other foramina—the infra-orbital, zygomatico-orbital, and the anterior and posterior ethmoidal canals—opening into it or leading from it.

The following **muscles** arise within the **orbit:**—the *four recti*, the *superior oblique*, and *levator palpebræ superioris*, near the apex; the *inferior oblique* on the floor of the orbit lateral to the naso-lacrimal canal; and the *tensor tarsi* from the lacrimal crest. The margins of the inferior orbital fissure give attachment to the *orbitalis* muscle.

THE NASAL FOSSÆ

The **nasal fossæ** (figs. 135, 136) are two irregular cavities situated on each side of a median vertical septum. They open in front by the piriform aperture and communicate behind with the pharynx by the choanæ. They are somewhat

Fig. 135.—Section through the Nasal Fossa to show the Septum. Left Half, with Septum looking toward Right Nasal Fossa.



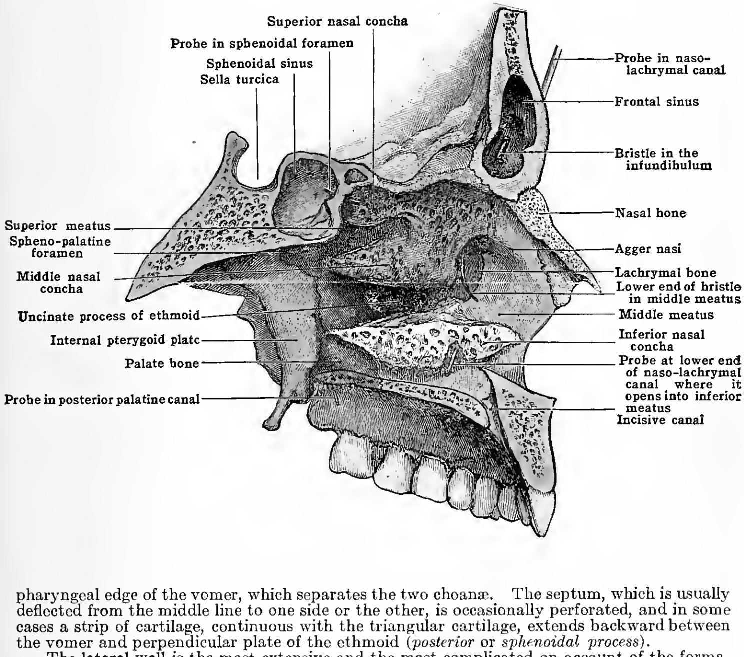
oblong in transverse section, and extend vertically from the anterior part of the base of the cranium above to the superior surface of the hard palate below. Their transverse extent is very limited, especially in the upper part. Each fossa presents for examination a roof, floor, medial and lateral walls, and communicates with the sinuses of the frontal, sphenoid, maxilla, and ethmoid bones.

The **roof** is horizontal in the middle, but sloped downward in front and behind. The anterior slope is formed by the posterior surface of the nasal bone and the nasal process of the frontal; the horizontal portion corresponds to the cribriform plate of the ethmoid and the sphenoidal concha; the posterior slope is formed by the inferior surface of the body of the sphenoid, the ala of the vomer, and a small portion of the sphenoidal process of the palate. The sphenoidal sinus opens at the upper and back part of the roof into the spheno-ethmoidal recess, above the superior meatus.

The **floor** is concave from side to side, and in the transverse diameter wider than the roof. It is formed mainly by the palatine process of the maxilla and completed posteriorly by the horizontal part of the palate bone. Near its anterior extremity, close to the septum, is the **incisive canal.**

The **septum** or medial wall is formed by the perpendicular plate of the ethmoid, the vomer, the rostrum of the sphenoid, the crest of the nasal bones, the frontal spine, and the median crest formed by the apposition of the palatine processes of the maxillæ and the horizontal parts of the palate bones. The anterior border has a triangular outline limited above by the perpendicular plate of the ethmoid and below by the vomer, and in the recent state the deficiency is filled up by the septal cartilage of the nose. The posterior border is formed by the

FIG. 136.—SECTION THROUGH THE NASAL FOSSA TO SHOW THE LATERAL WALL WITH THE MEATUSES.



pharyngeal edge of the vomer, which separates the two choanæ. The septum, which is usually deflected from the middle line to one side or the other, is occasionally perforated, and in some cases a strip of cartilage, continuous with the triangular cartilage, extends backward between the vomer and perpendicular plate of the ethmoid (*posterior* or *sphenoidal process*).

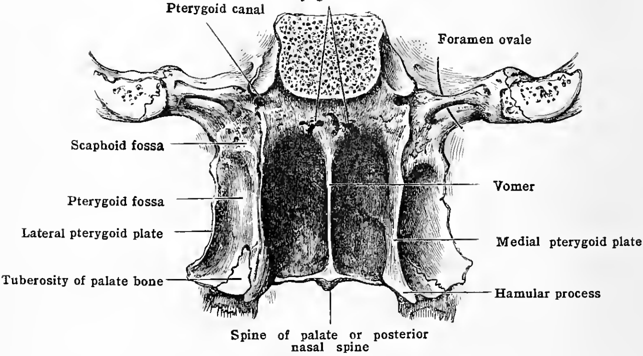
The **lateral wall** is the most extensive and the most complicated on account of the formation of the meatuses of the nose. It is formed by the frontal process and the medial surface of the maxilla, the lacrimal, the superior and inferior conchæ of the ethmoid, the inferior nasal concha, the vertical part of the palate bone, and the medial surface of the medial pterygoid plate. The three conchæ, which project medially, overhang the three recesses known as the **meatuses** of the nose. The **superior meatus,** the shortest of the three, is situated between the superior and middle nasal conchæ, and into it open the orifice of the **posterior ethmoidal cells** and the **spheno-palatine foramen.** The **middle meatus** lies between the middle and inferior conchæ. At its fore part it communicates with the frontal sinus by means of the **infundibulum,** and near the middle with the **maxillary sinus (antrum)**; the communication with the sinus is very irregular and sometimes represented by more than one opening (fig. 136). Two sets of **ethmoidal cells**—the **middle** and anterior—also open into the middle meatus, the anterior in common with the infundibulum, the middle on an elevation known as the **bulla ethmoidalis.** The **inferior meatus,** longer than either of the preceding, is situated between the inferior nasal concha and the floor of the fossa, and presents, near the anterior part, the lower orifice of the canal for the **naso-lacrimal duct.**

The nasal fossæ open on the face by means of the **apertura piriformis**, a heart-shaped or piriform opening whose long axis is vertical and whose broad end is below. The orifice is bounded above by the lower borders of the nasal bones, laterally by the maxillæ, inferiorly by the premaxillary portions of the maxillæ, and in the recent state the orifice is divided by the septal cartilage. Below, where the lateral margins slope inward to meet in the middle line, is the **anterior nasal spine.**

The **choanæ** (posterior nares) are bounded superiorly by the alæ of the vomer, the sphenoidal processes of the palate, and the inferior surface of the body of the sphenoid; laterally by the lateral pterygoid plates; and inferiorly by the posterior edge of the horizontal plates of the palate bones. They are separated from each other by the posterior border of the vomer.

The nasal fossæ communicate with all the more important fossæ and the air-sinuses of the skull. By means of the foramina in the roof they are in connection with the cranial cavity;

Fig. 137.—The Choanæ. Veiwed from behind.



by the infundibulum each fossa is in communication with the frontal and anterior ethmoidal cells; the posterior ethmoidal cells open into the superior meatuses and the sphenoidal sinuses into the recesses above; the spheno-palatine foramina connect them with the pterygo-palatine fossæ, and by means of an irregular orifice in each lateral wall they communicate with the maxillary sinuses. The canals for the naso-lacrimal ducts connect them with the orbits, and the incisive canals with the oral cavity.

THE INTERIOR OF THE SKULL

In order to study the interior of the skull it is necessary to make sections in three directions—sagittal, coronal, and horizontal. This enables the student to examine the various points with facility, and displays the great proportion the brain cavity bears to the rest of the skull. The **sagittal section** (fig. 138) should be made slightly to one side of the median line, in order to preserve the nasal septum. The black line (fig. 138) drawn from the **basion** (anterior margin of the foramen magnum) to the **gonion** (the anterior extremity of the sphenoid) represents the **basi-cranial axis**; whilst the line drawn from the **gonion** to the **subnasal point** lies in the **basi-facial axis.** These two axes form an angle termed the **cranio-facial,** which is useful in making comparative measurements of crania. A line prolonged vertically upward from the **basion** will strike the **bregma.** This is the **basi-bregmatic** axis, and gives the greatest height of the cranial cavity. A line drawn from the **ophryon** to the **occipital point** indicates the greatest length of the cranium.

Near its middle, the cranial cavity is encroached upon by the petrous portion of the temporal bone on each side; the walls are channelled vertically by narrow grooves for the middle and small meningeal vessels, and toward the base and at the vertex are broader furrows for the venous sinuses.

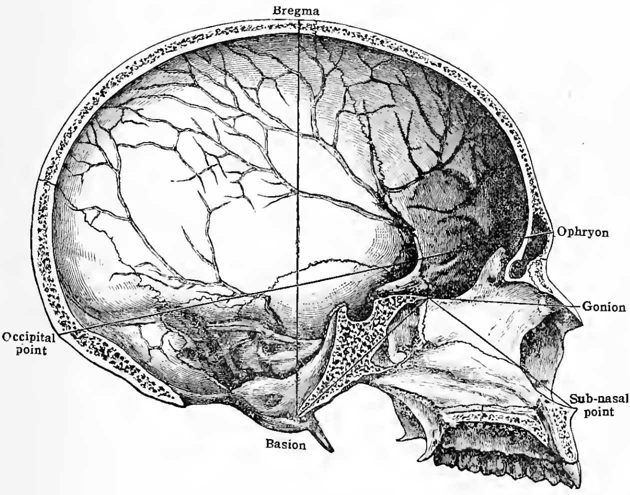
The **coronal** section is most instructive when made in the **basi-bregmatic axis.** The section will pass through the petrous portion on each side in such a way as to traverse the external auditory passage and expose the tympanum and vestibule, and will also partially traverse the internal auditory meatus. Such a section will divide the parietal bones slightly posterior to the parietal eminences, and a line drawn transversely across the section at the mid-point will give the greatest transverse measurement of the cranial cavity. A skull divided in this way facilitates the examination of the parts about the choanæ (posterior nares).

The **horizontal section** (figs. 139, 140) of the skull should be made through a line extending from the **ophryon** to the **occipital point,** passing laterally a few millimetres above the **pterion** on each side. It is of great advantage to study the various parts on the floor of the cranial cavity in a second skull in which the dura mater and its various processes have not been removed.

The **floor** [basis cranii interna] of the cranial cavity presents three irregular depressions termed the anterior, middle, and posterior fossæ (figs. 139 and 140).

The Anterior Cranial Fossa.—The floor of this fossa is on a higher level than the rest of the cranial floor. It is formed by the horizontal plate of the frontal bone, the cribriform plate of the ethmoid, and the lesser wings of the

Fig. 138.—The Skull in Sagittal Section.



sphenoid, which meet and exclude the body of the sphenoid from the anterior fossa. The free margins of the lesser wings and the anterior margin of the optic groove mark the limits of this fossa posteriorly. The central portion is depressed on each side of the crista galli, presents the numerous apertures of the cribriform plate, and takes part in the formation of the roof of the nasal fossæ; laterally, the floor of the anterior cranial fossa is convex; it forms the roof of the orbits, and is marked by irregular furrows. It supports the frontal lobes of the cerebrum. The **sutures** traversing the floor of the fossa are the fronto-ethmoidal, forming three sides of a rectangle, that portion of the transverse facial suture which traverses the roof of the orbit, and the ethmo-sphenoidal suture, the centre of which corresponds to the **gonion.** The other points of interest in the fossa are:—

A groove for the superior sagittal sinus.
The **foramen cæcum** which frequently transmits a small vein to the nasal cavity.
The **crista galli.**
The **ethmoidal fissure** for the anterior ethmoidal branch of the fifth nerve.
The cranial orifice of the **anterior ethmoidal canal,** transmitting the anterior ethmoidal branch of the fifth nerve, and a meningeal branch of the anterior ethmoidal artery.
The cranial orifice of the **posterior ethmoidal canal,** transmitting a meningeal branch of the posterior ethmoidal artery.
The **ethmoidal spine** of the sphenoid.
Furrows for meningeal vessels.

Fig. 139.—The Skull in Horizontal Section.

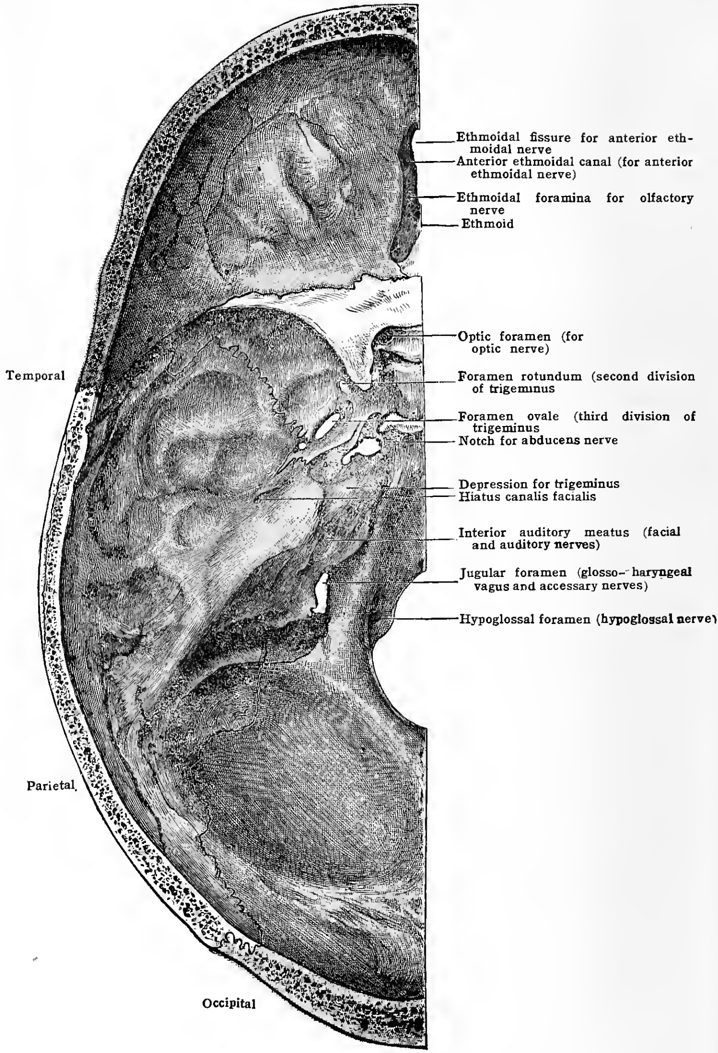


FIG. 140.—THE SKULL IN HORIZONTAL SECTION.

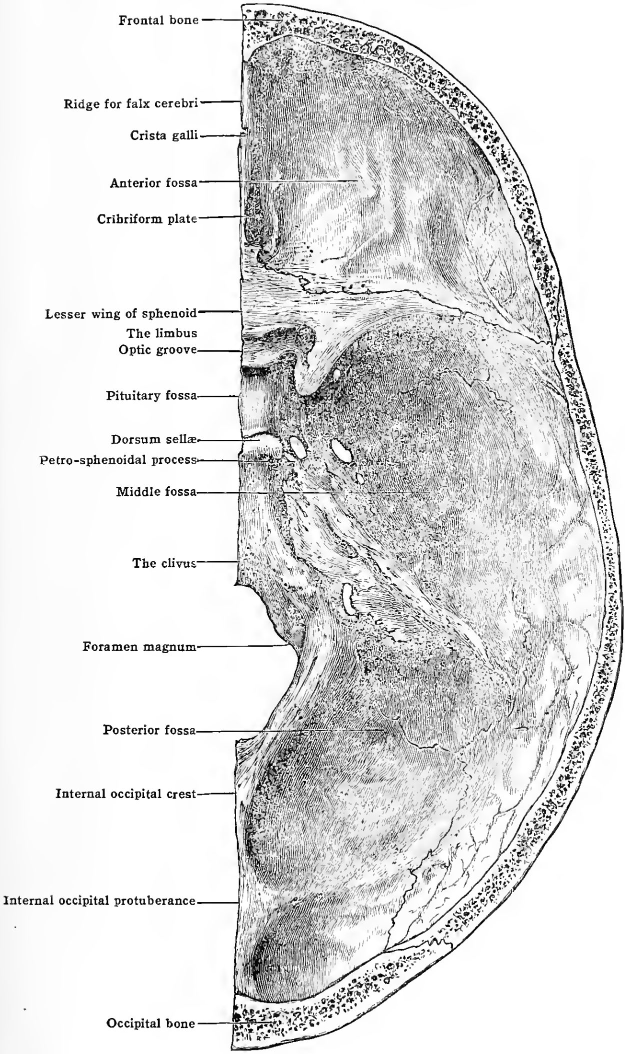

The Middle Cranial Fossa, situated on a lower level than the anterior, consists of a central and two lateral portions. In front it is limited by the posterior borders of the lesser wings of the sphenoid and the anterior margin of the optic groove, behind by the dorsum sellæ and the upper angle of the petrous portion of both temporal bones. Laterally it is bounded on each side by the squamous portion of the temporal, the great wing of the sphenoid, and the parietal bone, whilst the floor is formed by the body and great wings of the sphenoid and the anterior surface of the petrous portion of the temporals. It contains the following sutures:—spheno-parietal, petro-sphenoidal, squamo-sphenoidal, squamous, and a part of the transverse suture. The central portion of the fossa presents from before backward:

The **optic groove,** above and behind which is the optic chiasma.

The **optic foramen** on each side, transmitting the optic nerve and ophthalmic artery.

The **tuberculum sellæ,** indicating the line of junction of pre- and post-sphenoid elements.

The **anterior clinoid processes.**

The **fossa hypophyseos or sella turcica,** with the **middle clinoid processes,** and grooves for the internal carotid arteries. The **dorsum sellæ,** with the **posterior clinoid processes,** and notches for the sixth pair of cranial nerves.

The central portion is in direct relation with the parts of the brain within the circle of Willis.

The lateral portions are of considerable depth and marked by numerous elevations and depressions corresponding to the convolutions of the temporal lobes of the brain, and by grooves for the branches of the middle and small meningeal vessels. The following foramina are seen on each side:—

The **superior orbital** (sphenoidal) **fissure,** leading into the orbit and transmitting the third, fourth, three branches of the ophthalmic division of the fifth and sixth cranial nerves, some filaments from the cavernous plexus of the sympathetic, an ophthalmic vein, the orbital branch of the middle meningeal, and a recurrent branch of the lacrimal artery.

The **foramen rotundum,** for the passage of the second division of the fifth nerve into the pterygo-palatine fossa.

The **foramen ovale,** which transmits the third division of the fifth nerve with its motor root (mandibular nerve), the small meningeal artery, and the small superficial petrosal nerve.

The **foramen Vesalii** (not always present) for a small vein.

The **foramen spinosum,** for the middle meningeal artery and its venæ comitantes; also the N. spinosus.

The **foramen lacerum** is the irregular aperture between the body and great wing of the sphenoid, and the apex of the petrous portion of the temporal. In the recent state it is closed below by a layer of fibro-cartilage which is perforated by the Vidian nerve, a meningeal branch of the ascending pharyngeal artery, and an emissary vein. The carotid canal opens on its lateral wall and the pterygoid (Vidian) canal in front.

On the anterior surface of the petrous portion of the temporal bone are seen:—

A depression which lodges the semilunar (Gasserian) ganglion.

The **hiatus canalis facialis** for the great superficial petrosal nerve and the petrosal branch of the middle meningeal artery.

The **accessory hiatus** for the small superficial petrosal nerve.

A minute foramen for the external superficial petrosal nerve.

The **eminentia arcuata,** formed by the superior semicircular canal.

Anterior and slightly lateral to the eminentia arcuata the bone is exceedingly thin and translucent, forming the roof of the tympanum (tegmen tympani). When the dura mater is *in situ*, the depression lodging the semilunar ganglion is converted into a foramen, traversed by the fifth nerve, and in the same way the notch on the side of the dorsum sellæ is converted into a foramen for the sixth nerve. In many skulls the middle clinoid process is prolonged toward the anterior clinoid process, with which it may be joined to complete a foramen for the internal carotid artery. The grooves for the middle meningeal vessels are sometimes converted into canals or tunnels for a short distance, especially in old skulls. The bones most deeply marked are the squamous portion of temporal, the great wing of the sphenoid, and the parietal.

The Posterior Cranial Fossa is the deepest and largest of the series. It is bounded in front by the dorsum sellæ of the sphenoid and on each side by the superior border of the petrosal, and the mastoid portion of the temporal bone, the posterior inferior angle of the parietal, and the groove on the occipital bone for the transverse sinus; each of the bones mentioned takes part in the formation of its floor.

In the recent state the fossa lodges the cerebellum, pons, and medulla, and is roofed in by the tentorium cerebelli, a tent-like process of the dura mater attached to the ridges limiting the fossa above. It communicates with the general cranial cavity by means of the **foramen ovale of Pacchionius,** a large opening bounded in front by the clivus (basilar groove) and behind by the anterior free edge of the tentorium.

The posterior fossa is marked by several **sutures**, viz., petro-occipital, occipito-mastoid, parieto-mastoid, and in young skulls the basilar (occipito-sphenoidal). In addition, the following points may be noted:—

The **clivus**, extending from the dorsum sellæ to the anterior margin of the foramen magnum, and in relation with the basilar artery, the pons, the medulla, the sixth nerves, and the basilar sinus.

The **foramen magnum**, occupied in the recent state by the lower end of the medulla oblongata and its membranes, the vertebral, anterior spinal and posterior spinal arteries, the accessory (eleventh) cranial nerves, and the tectorial membrane.

The **hypoglossal canal** (foramen), sometimes divided by a spicule of bone into two divisions, for the two parts of the hypoglossal nerve and a meningeal branch of the ascending pharyngeal artery.

The **internal occipital crest**, behind the foramen magnum, for the attachment of the falx cerebelli. It sometimes presents a depression known as the **vermiform fossa.**

The **internal auditory meatus**, for the seventh and eighth cranial nerves, the pars intermedia, and the internal auditory vessels.

The **jugular foramen** (foramen lacerum posterius), somewhat pyriform in shape, and divisible into three compartments. The anterior division, placed somewhat medially, transmits the inferior petrosal sinus and is sometimes completely separated by an intra-jugular process of bone; the middle division transmits three cranial nerves, the ninth, tenth, and eleventh; and, in the posterior division, placed somewhat laterally, the transverse sinus becomes continuous with the internal jugular vein. A meningeal branch of the ascending pharyngeal or occipital artery enters the cranium through this division of the foramen.

The termination of the groove for the transverse sinus with the internal orifice of the **mastoid foramen.**

The **aquæductus vestibuli** and the **fossa subarcuata**, on the posterior surface of the petrous portion of the temporal.

The cranium of an average European has a *capacity* of 1450 c.c. The *circumference*, taken in a plane passing through the ophryon in front, the occipital point behind, and the pterion at the side, is 52 cm. The *length* from the ophryon to the occipital point is 17 cm., and the width between the parietals at the level of the zygomata is 12.5 cm. The proportion of the greatest width to the length is known as the *cephalic index*, i. e., index of breadth. A skull with an average cephalic index is *mesaticephalic*. When the index is above the average, it is *brachycephalic* (short and broad), and when below the average, *dolichocephalic* (long and narrow). The *height* from the basion to the bregma is nearly the same as the width at the level of the zygomata. The cranio-facial angle is about 96°.

THE MORPHOLOGY OF THE SKULL

In man the skull during development passes through three stages. At first the brain vesicles are enclosed in a sac of indifferent tissue which ultimately becomes tough and fibrous to form the **membranous cranium.** This, in turn, is partly converted into the membrane or roof bones of the cranium, whilst the remainder is represented in the adult by the dura mater. At the sides and base of the membranous cranium, however, cartilage is deposited, **chondro-cranium,** in which, as well as in the membranous tracts, osseous tissue appears in due course. Eventually, as **osseous box** is formed, consisting of membrane bones and cartilage bones intricately interwoven.

A study of the skull in the chondral stage is very instructive. It consists of two parts: (1) The skull proper and (2) the appendicular elements.

(1) The **skull proper** consists of three regions:—

(*a*) The **notochordal** region, which ultimately gives rise to the chief parts of the occipital bone and a part of the sphenoid. It is named notochordal because the notochord runs in it as far as the anterior extremity, i. e., the level of the fossa hypophyseos (sella turcica.)

(*b*) Anterior to the notochordal is the **trabecular region,** from which the remainder of the sphenoid is developed.

(*c*) The most anterior part of the prechordal portion of the base is the **ethmo-vomerine region,** from which the nasal septum and its cartilages arise. These three parts continue forward the line of the vertebral axis, and constitute a *cranio-facial axis* terminating, in front, in the premaxillæ. Finally, wedged in on each side, between the notochordal and trabecular regions, is the complicated **periotic capsule.**

The **chondro-cranium** at the third month presents the following parts. Seen from above, the cartilage extends from the cranial base to a spot midway between the base and the vertex, shading off indefinitely on the membranous wall. The oval masses on each side are the **periotic cartilages,** in which the fossæ subarcuatæ are conspicuous objects. Each periotic cartilage is joined to the sphenoid by a strip, termed the **sphenotic cartilage,** which usually persists in the adult skull. The cartilage for the orbito-sphenoid (the small wing) is co-extensive with the ali-sphenoid, and forms part of the lateral wall of the skull. The snout-like appearance of the anterior part of the skull is caused by the **fronto-nasal** plate. On each side of the ethmo-vomerine plate, near its anterior termination, are two small concave pieces of cartilage for Jacobson's organs. They are sometimes referred to as the ploughshare cartilages, owing to their shape. Further details are given in fig. 141.

(2) The **appendicular elements** of the skull are a number of cartilaginous rods surrounding the visceral cavity—i. e., nose, mouth, and pharynx—which undergo a remarkable metamorphosis, and are represented in the adult by the *ear bones*, the *styloid process*, and the *hyoid bone.*

Fig. 141.—Model of the Chondro-cranium of a Human Fœtus 8 cm. in Length. Cartilage in Blue. Viewed from Above. (After O. Hertwig.)

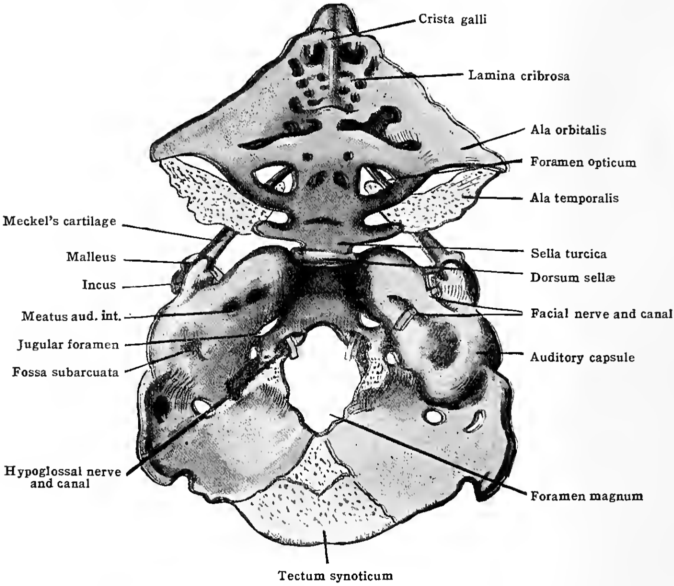

Fig. 142.—An Enlarged Portion of the Same Model of the Chondro-cranium as Shown in Fig. 141. Viewed From the Right Side, Showing the Skeleton of the Auditory Region. Cartilage in Blue. (After O. Hertwig.)

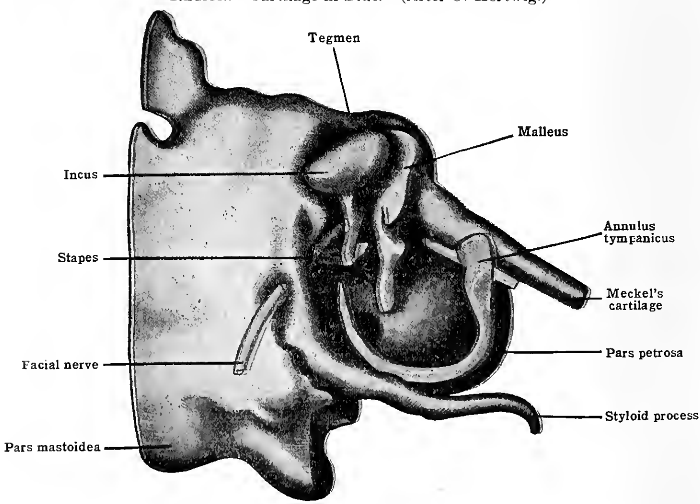


Metamorphosis of the Branchial or Visceral Bars

These rods of cartilage are named, f om before backward, the **mandibular**, **hyoid**, and **thyreoid** bars. They may with care be easily dissected in the fœtus between the third and fourth months. Their metamorphosis is as follows:—

The two extremities of the **mandibular bar** (cartilago Meckelii) ossify; the distal end ultimately forms a portion of the mandible near to the symphysis (see p. 98); the proximal end ossifies as the **malleus** and **incus**. The intermediate portion disappears; the only vestige is a band of fibrous tissue, the spheno-mandibular ligament, extending from the spine of the sphenoid to the spine of the mandible.

In the connective tissue surrounding the bar there appear, however, ossifications, one of which invests the bar to form the dentary plate; while a second, situated more proximally, forms the tympanic bone.

The **hyoid bar** fuses distally with the thyreoid bar, and forms part of the **hyoid bone**. Its proximal end becomes the **stapes**, the **tympano-hyal** portion of the styloid process (fused with the petro-mastoid), and the **stylo-hyal** or free portion of the process. The succeeding portion (**epi-hyal segment**) is represented in the adult by the stylo-hyoid ligament, and the lowest segment, or **cerato-hyal**, by the small cornu of the hyoid.

The **thyreoid bar** forms the great cornu of the hyoid bone (**thyreo-hyal**). The body of the hyoid (**basi-hyal**) is regarded as representing the fused ventral ends of the hyoidean and thyreoidean arches.

In addition to these structures ossifications occur in the connective tissue of the maxillary process, a structure which may be regarded as forming the anterior part of the first branchial arch, and in the fronto-nasal process. The ossifications in the maxillary process give rise to the pterygoid (medial pterygoid process of the sphenoid), the palate, the maxilla, and the zygomatic, while that in the fronto-nasal process forms the premaxilla.

The bony elements of the head may therefore be arranged, according to their origin, in the following table:—

I. Basilar Bones Developed in the Cartilaginous Cranium

Basi-occipital	Basilar portion of the occipital bone.
Exoccipitals	Condylar parts of the occipital bone.
Supra-occipital	Lower part of the squamous portion of the occipital.
Basi-sphenoid **Pre-sphenoid**	Constituting the body of the sphenoid.
Ali-sphenoids	Greater wings and lateral pterygoid plates.
Orbito-sphenoids	Lesser wings.
Petro-mastoids	Petrous and mastoid portions (excepting post-auditory processes) of the temporal bones.

II. Roof Bones Developed in the Membranous Cranium

Squamosals	Squamous portions of temporals.
Parietals	The two parietal bones.
Frontals	United to form a median frontal bone.
Interparietal	Upper part of squamous portion of occipital.
Epipterics	The epipteric bones.

III. Bones of the Nasal Region

Mesethmoid	Vertical plate of ethmoid developed in the cartilage of the cranio-facial axis.
Ethmo-turbinals	Superior and inferior conchal processes of ethmoid.
Maxillo-turbinals	The inferior nasal conchæ.
Cribriform lamina	Cribriform plate of ethmoid.
These elements are developed in the cartilage of the lateral nasal process.	
Sphenoidal turbinals	Sphenoidal conchæ. These are derivatives of the ethmo-turbinals.
Lacrimals **Nasals**	The lacrimal bones The nasal bones — Developed in the membrane over the lateral nasal process.
Vomer	The vomer. Ossified in the membrane investing the cartilage of the cranio-facial axis.

IV. Facial Bones

Maxillæ **Zygomatics**	The maxillæ The zygomatic bones — Developed in the connective tissue of the maxillary process.
Premaxillæ	The incisor parts of the maxillæ. Formed at the anterior extremity of the cranio-facial axis in the tissue of the fronto-nasal process (proc. globulares).

V. Appendicular Elements (Bones of the Visceral Arches)

(A) *Cartilaginous*

Malleus, Incus, and Stapes	The ossicula auditus.
Mento-Meckelian portion of the lower jaw	Small part on either side near to the symphysis menti.
Tympano-hyals and Stylo-hyals	Styloid processes of the temporal bones.
Epihyals	Stylo-hyoid ligaments.
Cerato-hyals	Lesser cornua of hyoid bone.
Thyreo-hyals	Greater cornua of hyoid bone.
Basi-hyals	Body of hyoid bone.

(B) *Membranous*

Mandible	The lower jaw excluding a small portion near symphysis.
Tympanics	The tympanic plates.
Pterygoids	The medial pterygoid plates.
Palatals	The palate bones.

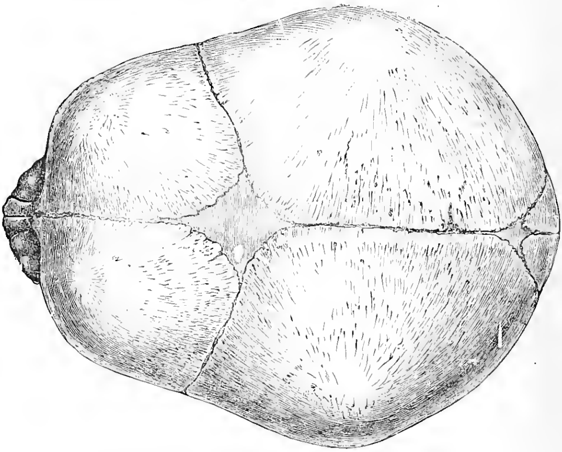
The Skull at Birth

The skull at birth presents, when compared with the adult skull, several important and interesting features. Its peculiarities may be considered under three headings:—The peculiarities of the fœtal skull as a whole; the construction of the individual bones; the remnants of the chondral skull.

(1) *The General Characters of the Fœtal Skull*

The most striking features of the skull at birth are, its relatively large size in comparison with the body, and the predominance of the cranial over the facial portion of the skull (8 to 1); the latter is, in fact, very small.

Fig. 143.—The Cranium at Birth. (Viewed from above.)

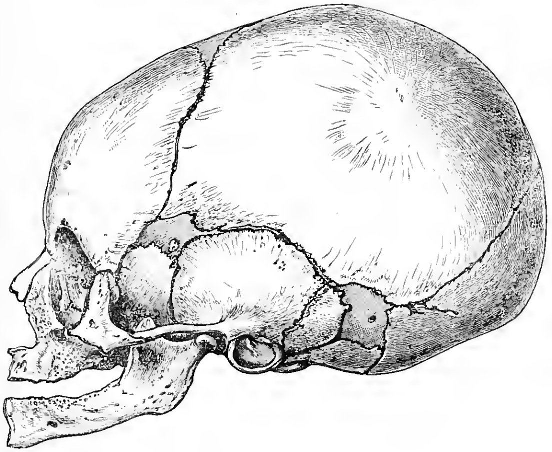


The frontal and parietal eminences are large and conspicuous; the sutures are absent; the adjacent margins of the bones of the vault are separated by septa of fibrous tissue continuous with the dura mater internally and the pericranium externally; hence it is difficult to separate the roof bones from the underlying dura mater, each being lodged, as it were, in a dense membranous sac. The bones of the vault consist of a single layer without any diploë, and their cranial surfaces present no digital impressions. Six membranous spaces exist, named fontanelles: two are median, the frontal [fonticulus frontalis; major] being anterior and the occipital [fonticulus occipitalis; minor] posterior. Two exist on each side, termed anterior [fonticulus sphenoidalis] and posterior [fonticulus mastoideus] lateral fontanelles. Each angle of the parietal bones is in relation with a fontanelle. The anterior fontanelle is lozenge-shaped, the posterior triangular. The lateral fontanelles are irregular in outline. The lateral fontanelles close soon after birth; the occipital fontanelle closes in the first year, and the frontal during the second year.

Turning to the base of the skull, the most striking points are the absence of the mastoid processes, and the large angle which the pterygoid plates form with the skull-base, whereas in the adult it is almost a right angle. The base of the skull is relatively short, and the lower border of the mental symphysis is on a level with the occipital condyles.

The facial skeleton is relatively small in consequence of the small size of the nasal fossæ, the small size of the maxillary sinus, and the rudimentary condition of the alveolar borders

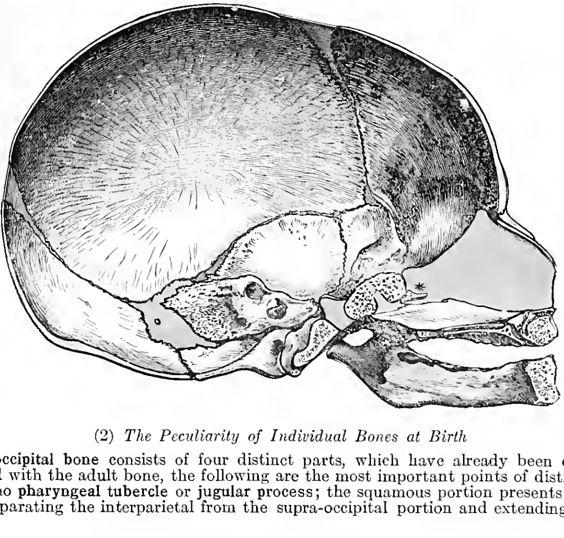
FIG. 144.—THE CRANIUM AT BIRTH. (Lateral view.)



of the maxillæ and mandible; the nasal fossæ are as wide as they are high, and are almost filled with the conchæ.

Growth takes place rapidly in the first seven years after birth. There is a second period of rapid growth at puberty, when the air sinuses develop, and this affects especially the face and frontal portion of the cranium.

FIG. 145.—THE CRANIUM AT BIRTH IN SAGITTAL SECTION. (Sphenoidal concha indicated by a *)

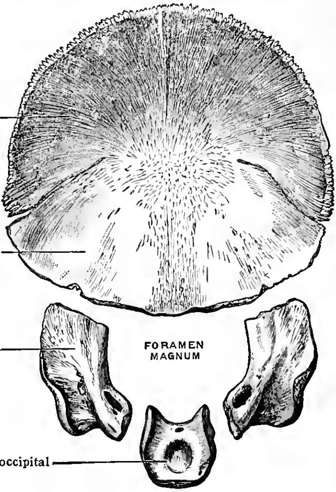


(2) *The Peculiarity of Individual Bones at Birth*

The **occipital bone** consists of four distinct parts, which have already been described. Compared with the adult bone, the following are the most important points of distinction:—There is no **pharyngeal tubercle** or **jugular process**; the squamous portion presents two deep fissures separating the interparietal from the supra-occipital portion and extending medially as far as the occipital protuberance. The grooves for the transverse (lateral) sinuses are absent.

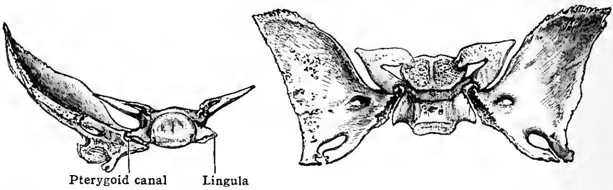
The **sphenoid** in a macerated fœtal skull falls into three pieces: (1) united **pre-** and **post-sphenoids, orbito-sphenoids,** and **lingulæ,** and (2 and 3) the **ali-sphenoids.** The **pre-sphenoid** is quite solid and connected with the ethmo-vomerine cartilage, and presents no traces of the air sinuses which occupy this part in the adult skull. The pre-sphenoid by its upper surface forms part of the anterior cranial fossa, from which it is subsequently excluded by the growth of the orbito-sphenoids. The optic foramina are large and triangular in shape. The **lingulæ**

Fig. 146.—The Occipital at Birth.



stand out from the basi-sphenoid as two lateral buttresses, and at the tuberculum sellæ is the **basi-pharyngeal canal,** which in the recent bone is occupied by fibrous tissue. The **dorsum sellæ** is still cartilaginous. The **ali-sphenoids** with the pterygoid processes are separated from the rest of the bone by cartilage. The foramen rotundum is complete, but the future foramen ovale is merely a deep notch in the posterior border of the great wing, and there is no foramen spinosum. The pterygoid processes are short, and each medial pterygoid plate presents a broad surface for articulation with the lingula. The **pterygoid canal** is a groove between the medial pterygoid plate, the lingula, and great wing.

Fig. 147.—The Sphenoid at Birth.



The **temporal bone** at birth consists of three elements, the **petrosal, squamosal,** and **tympanic.** The **petrosal** presents a large and conspicuous floccular fossa; the hiatus Fallopii is a shallow bay lodging the geniculate ganglion of the facial nerve. There is a relatively large mastoid antrum, but no mastoid process. The styloid process is unossified, but the **tympano-hyal** may be detected as a minute rounded nodule of bone near the stylo-mastoid foramen.

The squamosal has a very shallow mandibular fossa and a relatively large post-glenoid tubercle. The posterior part of the inferior border is prolonged downward into an uncinate process (*post-auditory process*) which closes the mastoid antrum laterally.

The **tympanic** bone or annulus is a delicate, horseshoe-shaped ossicle, attached by its anterior and posterior extremities to the inferior border of the squamosal

The **ear-bones** are chiefly of interest from their size, for they are as large at birth as in the adult. The anterior process (Folian process) may be 2 cm. in length.

FIG 148.—THE TEMPORAL BONE AT BIRTH.

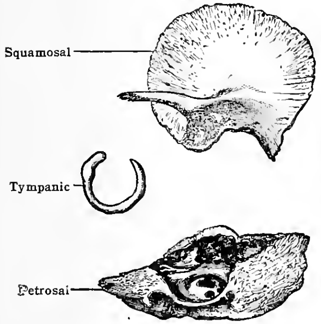


FIG. 149.—TEMPORAL BONE AT BIRTH. (Medial view.)

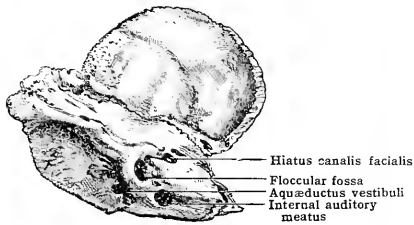

FIG. 150.—THE TEMPORAL BONE AT BIRTH. (Lateral view.)

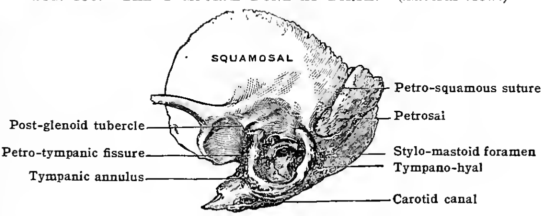
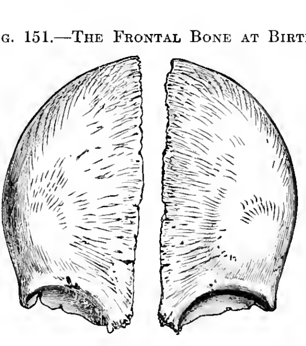


The **frontal** consists of two bones separated by a median vertical (metopic) suture. The frontal eminence is very pronounced, but the superciliary arches and frontal sinuses are wanting. The frontal spine, which later becomes one of the most conspicuous features of this bone, is absent. There is no temporal line.

FIG. 151.—THE FRONTAL BONE AT BIRTH.



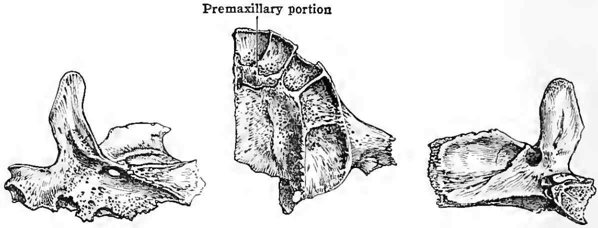
The **parietal** is simply a quadrilateral lamina of bone, concave on its inner and convex on the outer surface. The parietal eminence, which indicates the spot in which the ossification of the bone commenced, is large and prominent. The grooves for blood-sinuses, as in other cranial bones, are absent. Each angle of the parietal is in relation with a fontanelle. As in the adult, the anterior inferior angle of the bone is prolonged downward toward the ali-sphenoid.

The **ethmoid** consists of two lateral portions separated by the still cartilaginous ethmo-vomerine plate. The ethmoid cells are represented by shallow depressions, and the uncinate process is undeveloped.

The **sphenoidal conchæ** are two small triangular pieces of bone lying in the perichondrium on each side of the ethmo-vomerine plate near its junction with the pre-sphenoid. (Indicated by the * in fig. 145.)

The **maxilla** presents the following characters:—The incisive suture is visible on the palatine aspect of the bone. The alveolar border presents five sockets for teeth. The infra-orbital

Fig. 152.—The Maxilla at Birth.



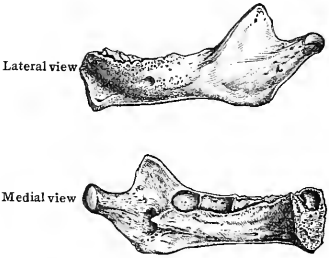
foramen communicates with the floor of the orbit by a deep fissure; this fissure sometimes persists in the adult. The sinus is a shallow depression.

The **mandible** at birth consists of two halves united by fibrous tissue in the line of the future symphysis. Each half is a bony trough lodging teeth. The trough is divided by thin osseous partitions into five compartments: of these, the fifth is the largest, and is often subdivided by a ridge of bone. The floor is traversed by a furrow as far forward as the fourth socket (that for the first milk molar), where it turns outward at the mental foramen. This furrow lodges the inferior alveolar nerve and artery, which enter by the large mandibular foramen. The condyle is on a level with the upper border of the anterior extremity of the bone.

The **palate bones** differ mainly from those in the adult in that the vertical and horizontal plates are of the same length; thus the nasal fossæ in the fœtus are as wide as they are high, whereas in the adult the height of each nasal fossa greatly exceeds the width.

Concerning the remaining bones little need be said. The vomer is a delicate trough of bone for the reception of the inferior border of the ethmo-vomerine plate; its inferior border,

Fig. 153.—The Mandible at Birth.



which rests upon the hard palate, is broad, and the bone presents quite a different appearance from that in the adult. The **nasal bones** are short and broad; the **zygomatics** and **inferior conchæ** are relatively very large; and the **lacrimals** are thin, frail, and delicate lamellæ.

The **hyoid** consists of five parts. There is a median nucleus for the basi-hyal, and one on each side for the greater cornua (thyreo-hyals). The lesser cornua are cartilaginous.

(3) *Remnants of the Cartilaginous Cranium*

It has already been pointed out that at an early date the base of the skull and the face are represented by hyaline cartilage, which for the most part is replaced by bone before birth. Even at birth remnants of this primitive chondral skull are abundant. In the cranium, cartilaginous tracts exist between the various portions of the occipital bone, as well as at the line of junction of the occipital with the petrosal and sphenoid. The dorsum sellæ is entirely cartilaginous at birth, and the last portion of this cartilage disappears with the ankylosis of the basi-occipital and basi-sphenoid about the twentieth year. A strip of cartilage unites the alisphenoids with the lingulæ, and for at least a year after birth this cartilage is continuous with that which throughout life occupies the foramen lacerum. A strip of cartilage exists along the posterior border of the orbito-sphenoid, and not unfrequently extends lateralward to the pterion. In the adult skull it is replaced by ligamentous tissue.

The ethmo-vomerine plate is entirely cartilaginous, and near the end of the nose supports the lateral nasal cartilages, remnants of the fronto-nasal plate. The fate of the ethmo-vomerine plate is instructive. The upper part is ossified to form the mesethmoid; the lower part atrophies from the pressure exerted by the vomer; the anterior end remains as the septal cartilage. The lateral snout-like extremities of the fronto-nasal plate persist as the lateral cartilages of the nose.

Among the appendicular elements of the skull, the styloid process and a large portion of the hyoid are cartilaginous at birth.

The Nerve-foramina of the Skull

The various foramina and canals in the skull which give passage to nerves may be arranged in two groups, **primary** and **secondary. Primary** foramina indicate the spots where the nerves leave the general cavity of the dura mater, and as this membrane indicates the limit of the primitive cranium, a cranial nerve, in a morphological sense, becomes extra-cranial at the point where it pierces this membrane. In consequence of the complicated and extraordinary modifications the vertebrate skull has undergone, many nerves traverse, in the adult skull, bony tunnels and canals which are not represented in the less complex skulls of low vertebrates, such as sharks and rays. To such foramina and canals the terms **secondary** or **adventitious** may be applied.

Nerve-foramina are further interesting in that they occupy sutures, or indicate the points of union of two or more ossific centres. To this rule the foramen rotundum is the only exception in the human skull.

The Primary Foramina

1. **Foramen magnum.**—This is bounded by four distinct centres, the supra-, basi-, and two ex-occipitals. It transmits the accessory (eleventh) pair of cranial nerves, the vertebral arteries and their anterior and posterior spinal branches, the medulla oblongata and its membranes, and the membrana tectoria.

2. **The hypoglossal.**—At birth this is a deep notch in the anterior extremity of the ex-occipital, and becomes a complete foramen when the basi- and ex-occipitals fuse. Occasionally it may be complete in the ex-occipital, but it indicates accurately the line of union of these two elements of the occipital bone. It transmits the hypoglossal nerve, the meningeal branch of the ascending pharyngeal artery, and its venæ comitantes.

3. **Jugular foramen.**—This occupies the petro-occipital suture, and is formed by the basi- and ex-occipital in conjunction with the petrosal. It transmits the glosso-pharyngeal, vagus, and accessory nerves, a meningeal branch of the ascending pharyngeal artery, and receives the transverse and inferior petrosal sinuses.

4. **Auditory.**—This marks the point of confluence of the groups of centres termed pro-otic and opisthotic. It transmits the facial and auditory nerves, the pars intermedia, and the auditory twig of the basilar artery.

5. **Trigeminal.**—This is only a foramen when the dura mater is present in the skull. It is a notch at the apex of the petrosal converted into a foramen by the tentorium. The main trunk of the trigeminal nerve, with the small motor root (masticator nerve), traverses it.

6. **Petro-sphenoidal.**—This is a notch between the side of the dorsum sellæ and apex of the petrosal which becomes converted into a foramen by dura mater.

7. **Optic.**—This foramen is formed by the confluence of the orbito- and pre-sphenoidal centres. It opens into the orbit and transmits the optic nerve and ophthalmic artery.

The Secondary Nerve-foramina

Foramina transmitting the various subdivisions of the trigeminal nerve.—The primary foramen of exit for the trigeminal nerve is formed partly of bone and partly of membrane at the apex of the petrosal. The three divisions of the nerve issue through secondary foramina.

(*a*) The **superior orbital** (sphenoidal) fissure is an elongated chink, bounded above by the orbital wing and below by the great wing of the sphenoid, medially by the body of the sphenoid, and laterally by the frontal. It opens into the orbit, and transmits the third, fourth, first (ophthalmic) division of the trigeminal and abducens nerves, also the ophthalmic vein or veins.

(*b*) The **foramen rotundum** is the only exception to the rule relating to the formation of nerve-foramina; it is probably a segment of the superior orbital fissure. The foramen is really a canal running from the middle cranial fossa to the pterygo-palatine fossa, and transmits the second or maxillary division of the trigeminal.

(*c*) The **foramen ovale** at birth is a gap in the hinder border of the great wing (ali-sphenoid) of the sphenoid, and is converted into a foramen by the petrosal; subsequently it becomes complete in the sphenoid. It transmits the third or mandibular division of the trigeminal and the small or motor root, the small superficial petrosal nerve (which occasionally passes through a separate foramen), and the small meningeal artery with its venæ comitantes.

The ethmoidal canals.—These commence in the suture between the lamina papyracea and the frontal bone, and traverse the space between the upper surface of the lateral mass of the ethmoid and the horizontal plate of the frontal, to emerge on the cribriform plate; they are situated outside the dura mater. The anterior foramen transmits the anterior ethmoidal branch of the ophthalmic, which subsequently gains the nasal cavity by passing through the ethmoidal fissure by the side of the crista galli.

The **infra-orbital canal** indicates the line of confluence of the maxillary and malar centres of the maxilla; occasionally it is completed by the zygomatic; rarely it is incomplete above, and communicates by a narrow fissure with the orbit. It lodges the infra-orbital nerve and artery.

The **zygomatico-temporal foramen** is situated in the suture between the zygomatic and the greater wing of the sphenoid (ali-sphenoid); it transmits the temporal branch of the zygomatic nerve and a branch of the lacrimal artery. In the adult this foramen may be wholly confined to the zygomatic bone.

The **zygomatico-facial canals** traverse the zygomatic bone, and indicate the line of confluence of the two chief centres for this bone. The facial twigs of the zygomatic nerve issue from them accompanied by arterial twigs.

The **spheno-palatine foramen** is a deep groove between the orbital and sphenoidal processes of the palate bone, converted into a foramen by the sphenoidal concha. It is traversed by the naso-palatine nerve and artery as they enter the nasal from the pterygo-palatine fossa.

Scarpa's foramina are two minute openings in the meso-palatine suture where it is in relation with the incisive fossa. They are traversed by the naso-palatine nerves.

The **pharyngeal foramen** is situated between the sphenoidal process of the palate bone, the medial pterygoid plate of the sphenoid, and the sphenoidal concha. The pharyngeal branch of the spheno-palatine ganglion and a branch of the spheno-palatine artery pass through it.

The **pterygoid** (Vidian) **canal** is trumpet-shaped: the narrower end is situated in the foramen lacerum; the broader orifice opens on the posterior wall of the pteryo-palatine fossa. The canal is 10 mm. long; in the fœtal skull it is a chink between the base of the medial pterygoid plate, the ali-sphenoid, and the lingula of the sphenoid. The canal is traversed by the Vidian branch of the spheno-palatine ganglion and the Vidian artery.

The **posterior** (greater) **palatine canal** is a passage left between the maxilla, the vertical plate and tuberosity of the palate bone and the medial pterygoid plate; it commences on the hard palate by the greater palatine foramen. The descending palatine nerve and artery traverse this canal. Several foramina open from it. In the suture between the vertical plate of the palate bone and the maxilla, two small openings allow minute nerves to issue for the middle and inferior nasal conchæ. In the fissures between the tuberosities of the palate and maxillæ, and the pterygoid plates, the posterior and middle palatine nerves issue. These are sometimes called the posterior and middle (smaller) palatine canals.

The **mandibular or inferior dental canal** runs in the mandible between the dentary and Meckel's cartilage of the mandible. The posterior orifice of the canal is the mandibular (inferior dental) foramen; the anterior orifice is the mental foramen. The inferior alveolar nerve and artery enter the canal at its posterior orifice; the mental foramen allows the mental nerve to escape from the canal accompanied by the mental artery.

Foramina transmitting the facial nerve and its branches.—The main trunk of the facial enters the internal auditory meatus and traverses the facial canal. In the early embryo the nerve lies on the petrosal, and is not covered in with bone until the fifth month of fœtal life. The terminal orifice, the **stylo-mastoid foramen,** is situated between the tympanic, tympanohyal, and epiotic elements of the complex temporal bone.

The **'iter chordæ posterius'** is a chink between the squamosal and the tympanic elements, and allows the chorda tympani nerve to enter the tympanum. The fissure of exit for this nerve is the subdivision of the petro-tympanic fissure termed the canal of Huguier, or **'iter chordæ anterius.'** The **petro-tympanic fissure** lies between the tympanic plate and the squamosal. It transmits the tympanic branch of the internal maxillary artery, and lodges the anterior process of the malleus.

The **inferior orbital** (spheno-maxillary) fissure is situated between the posterior border of the orbital plate of the maxilla and a smooth ridge on the orbital surface of the great wing of the sphenoid. It transmits the superior maxillary division (second) of the fifth nerve, the zygomatic nerve, branches of the spheno-palatine ganglion to the orbit, and a communicating vein from the ophthalmic to the pterygoid plexus.

C. THE THORAX

The **thorax** is a bony cage formed by the thoracic vertebræ already described, the ribs with their costal cartilages, and the sternum.

THE RIBS

The **ribs** [costæ] (figs. 154, 155) twelve in number on each side, constitute a series of narrow, flattened bones, extending from the sides of the thoracic vertebræ toward the median line on the anterior aspect of the trunk. The anterior ends of the first seven pairs are connected, by means of their costal cartilages, with the sides of the sternum, and on this account the first seven ribs on each side are termed **true** or sternal ribs. The remaining five pairs, known as **false** or asternal ribs, may be arranged in two sets:—one, including the eighth, ninth, and tenth ribs, in which the cartilages of the anterior extremities are connected together, and the other, including the eleventh and twelfth, in which the anterior extremities, tipped with cartilage, are free. The eleventh and twelfth are known, in consequence, as the **floating** ribs. Thus, the first seven are **vertebro-sternal;** the eighth, ninth, and tenth, **vertebro-chondral;** the eleventh and twelfth, **vertebral** ribs.

The ribs increase in length from the first to the seventh, and decrease from the seventh to the twelfth. They also vary in their direction, the upper ones being less oblique than the lower. The obliquity is greatest at the ninth rib and gradually decreases from the ninth to the twelfth.

Typical characters of a rib (fig. 154).—The seventh is regarded as the most typical rib. It presents for examination a vertebral extremity or **head;** a narrow portion or **neck;** a **sternal** extremity; and an intermediate portion, the **body** or **shaft.**

The **head** [capitulum costæ] presents an **articular surface** made up of two articular facets separated by a horizontal crest [crista capituli]. The crest is connected by an interarticular ligament with an intervertebral disc, and the facets articulate with the costal pits on the sides of the bodies of two vertebræ (sixth and seventh). As a rule, the lower facet is the larger, and articulates with the thoracic vertebra, to which the rib corresponds in number. This is the primary facet, and is the one represented in those ribs which possess only a single facet on the rib-head. The anterior margin is lipped for the attachment of the radiate ligament.

The **neck** [collum costæ] is that portion of the rib extending from the head to the **tubercle.** It is flattened from before backward and the posterior surface is in relation with the transverse process of the lower of the two vertebræ with which the head articulates; it forms the anterior boundary of the **costo-transverse foramen,** and is rough where it is attached to the neck (middle costo-transverse) ligament. The anterior surface is flat and smooth. The superior border of the neck, continuous with the corresponding border of the shaft, presents a rough crest [crista colli] for the anterior costo-transverse ligament. The inferior border of the neck is rounded and continuous with the ridge of the **costal groove.** This difference in the relation of the neck, to the upper and lower borders of the rib-shaft, is useful in determining to which side a rib belongs.

The **tubercle,** situated behind at the junction of the neck with the shaft, consists of an upper and lateral part, rough for the attachment of the posterior costo-transverse ligament, and a lower and medial part, bearing a facet for articulation with a pit near the tip of the transverse process. The tubercle projects below the lower edge of the rib to form a crest, marking the beginning of the costal groove.

The **body** is strongly curved and presents for examination two surfaces and two borders. At first the curve is in the same plane as the neck, but it quickly turns forward at a spot on the posterior surface of the shaft known as the **angle,** where it gives attachment to the *ilio-costalis* muscle and some of its subdivisions. The rib has also a second or upward curve, beginning at the angle. These curves are expressed by describing the main curve as disposed around a vertical, and the second or upward curve around a second transverse axis.

When a rib, except the first, second, and twelfth, is laid with its lower border upon the table, the rib-head rises and the rib touches the table at two places, viz., at the anterior end, and in the neighbourhood of the angle.

Besides the two curves now described, the rib is slightly twisted on itself, so that the surfaces which look medially and laterally behind are placed obliquely in front and look downward as well as medially, and upward as well as laterally.

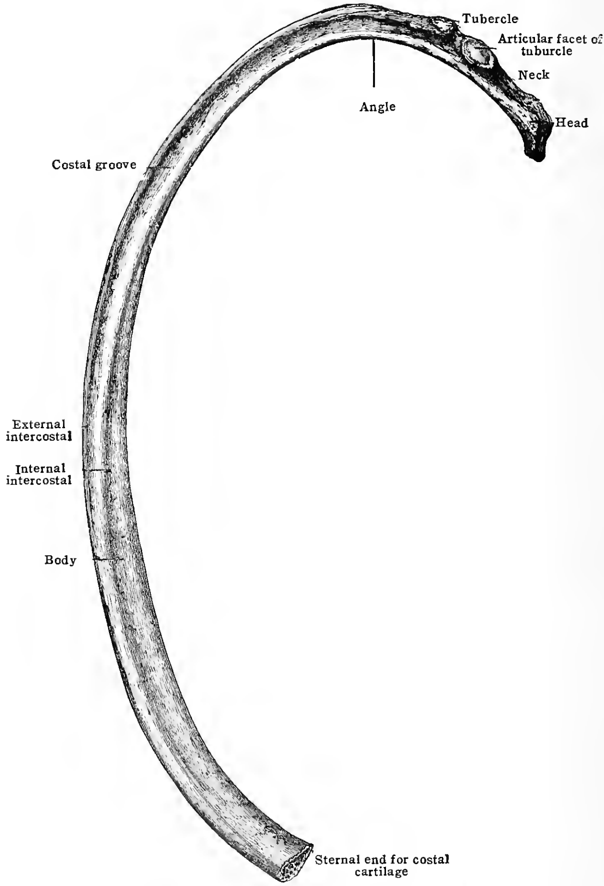
The external surface of the rib is convex, and gives attachment to muscles. Near its anterior extremity it forms a somewhat abrupt curve, indicated by a ridge on the bone, which gives attachment to the *serratus anterior* (*magnus*) muscle, and is sometimes called the **anterior angle.**

The internal surface is concave and presents near its inferior border the **costal groove** [sulcus costæ]. The groove is best marked near the angle, and gradually becomes shallower toward the anterior extremity of the rib, where it is finally lost; it lodges the intercostal vessels and nerve. The ridge limiting the groove above is continuous with the inferior border of the neck of the rib, and gives attachment to the *internal intercostal* muscle.

The superior border is rounded, and affords attachment to the *internal* and *external intercostal* muscles. The inferior border commences abruptly near the angle, and gives attachment to the *external intercostal* muscle.

The **sternal** end of the shaft is cupped for the reception of the costal cartilage.

FIG. 154.—THE SEVENTH RIB OF THE LEFT SIDE. (Seen from below.)

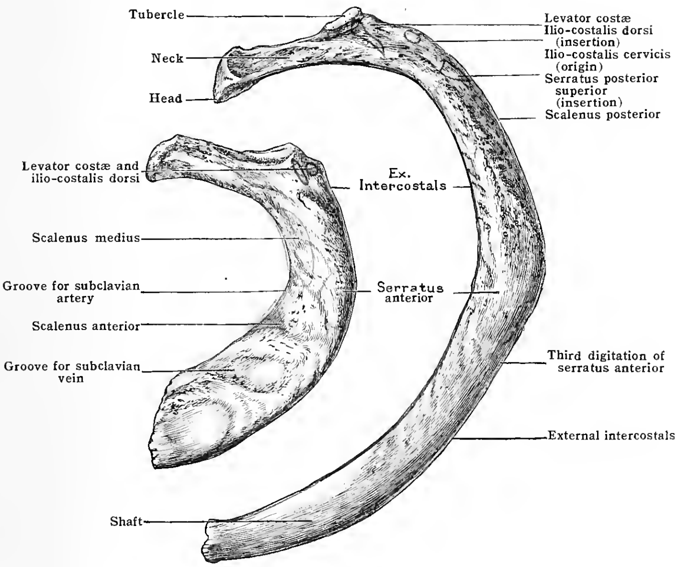


Blood-supply.—The ribs are very vascular and derive numerous branches from the intercostal arteries. The branches in the shaft run toward the vertebral end, whilst those in the head and neck run, as a rule, toward the shaft. In the neighbourhood of the tuberosity the vessels do not seem to have any constant arrangement.

Peculiar ribs(figs. 155, 156).—Several of the ribs present certain peculiarities and differ in many particulars from the general description given above. These are the first, second, tenth, eleventh, and twelfth.

The **first rib** is the broadest, flattest, strongest, shortest, and most curved of all the series. It is not twisted, and is so placed that its superior surface looks forward as well as upward, and its inferior surface backward as well as downward. The head is small, and as a rule is furnished with only one articular facet. The neck, longer than that of most of the ribs, is slender and rounded. The tubercle is large and prominent. The shaft lies for its whole extent nearly in one plane, has no angle, and is curved in one direction only, i. e., around a vertical axis. The superior surface presents two shallow grooves, separated near the inner border by a rough surface (**scalene tubercle** or tubercle of Lisfranc) for the *scalenus anterior* muscle. The groove in front of this surface is for the subclavian vein, and the groove behind it is for the subclavian artery and a nerve trunk passing to the brachial plexus. Between the groove for the artery and the tubercle is a rough surface for the insertion of the *scalenus medius*, and between the groove and the outer margin is an area for the origin of the *serratus anterior* (*magnus*). The inferior surface is uniformly flat and lacks a subcostal groove. By the lateral portion, which is rough, it gives attachment to the internal intercostal muscle; the remainder of the inferior surface is in relation to pleura and lung. The lateral border is thick and rounded, and gives attachment to the *external intercostal* muscle, whilst the medial border, thin, sharp, and concave, receives the attachment of the fascia (Sibson's) covering the dome of the pleura. The anterior extremity is thick and broad, and its upper margin, as well as the cartilage to which it is joined, afford attachment to the costo-clavicular ligament and the *subclavius* muscle. The costal cartilage of this rib is directly united to the manubrium sterni, and occasionally the cartilage and the adjoining part of the anterior extremity of the rib are replaced by fibrous tissue.

FIG. 155.—FIRST AND SECOND RIBS. (Viewed from above.)



The rib derives its nutrition mainly from the superior intercostal branch of the subclavian artery.

The **second rib** is much longer than the first, and although like it in being strongly curved round a vertical axis, in its form and general characters there is a closer resemblance to the ribs lower down in the series. The head is round and presents two facets, the costal groove is present, though faintly marked, and an angle is situated near the tubercle. The specially distinguishing feature of the rib, however, is a well-marked tuberosity on its outer surface somewhat near the middle, for the origin of a part of the first digitation, and the whole of the second digitation of the *serratus anterior* (*magnus*). Between the tuberosity and the tubercle the outer surface is smooth and rounded and gives attachment to the *scalenus posterior*, the *serratus posterior superior*, the *ilio-costalis cervicis* (*cervicalis ascendens*), and the *ilio-costalis dorsi* (*accessorius*). The internal surface is smooth and in relation to the pleura. The borders give attachment to the *intercostal* muscles, the upper, to those of the first space, the lower, to those of the second. The shaft of the second rib is not twisted on its own axis, so that both ends can lie flat on the table. The second rib receives vessels from the superior intercostal branch of the subclavian artery and the first aortic intercostal.

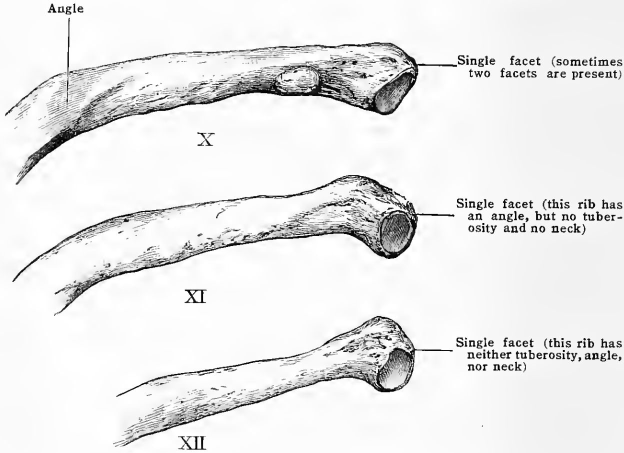
The **tenth rib** is distinguished by a single facet on the head for articulation with the body of the tenth thoracic vertebra. Occasionally there are two facets, in which case the rib articulates also with the ninth thoracic vertebra. The tenth rib, like the ribs immediately above, is long, curved, presents a deep costal groove, a well-marked tuberosity and an angle. It may be noted, however, that the distance between the tubercle and the angle in this rib is greater than in the ribs above. Speaking generally, the distance between these points increases from above downward—a disposition which is useful in at once determining if any given rib belongs to the upper or lower end of the series.

The eleventh **rib** is peculiar in that it has a single facet on the head, a feebly marked angle some distance from the head, a shallow costal groove, no tubercle, and no neck. The tubercle is sometimes represented by a slight elevation or roughness without any articular facet. The anterior extremity is pointed.

The **twelfth rib** has a large head furnished with one facet for articulation with the root (pedicle) of the twelfth thoracic vertebra. The shaft is narrow and extremely variable in length (3 to 20 cm.). It is usually somewhat longer than the first rib, but it may be shorter. There is no tubercle, no angle, no neck, no costal groove. The anterior extremity is pointed. Posteriorly, the upper border is smooth and somewhat rounded; the lower border is sharp and rough.

The **costal cartilages** are bars of hyaline cartilage attached to the anterior extremities of the ribs, and may be regarded as representing **unossified epiphyses.** Like the shaft of a rib, each cartilage has an outer and inner surface. The outer surfaces give origin and insertion to large muscles, and the inner surfaces, from the second to the sixth inclusive, are in relation with the *transversus thoracis* (*triangularis sterni*). The upper and lower borders serve for the attachment of the *internal intercostal* muscles. The upper seven cartilages, and occasionally the eighth, are connected with the sternum. Of these, the first fuses with the manubrium sterni and the remaining six are received into small articular concavities, and retained by means of ligaments.

Fig. 156.—The Vertebral Ends of Tenth, Eleventh, and Twelfth Ribs.



The cartilages of the vertebro-chondral ribs are united to one another and to the seventh costal cartilage by ligaments (sometimes by short vertical bars of cartilage), while those of the vertebral ribs form no such attachment, but lie between the abdominal muscles. The inner surfaces of the lower six costal cartilages afford attachment to the *diaphragm* and the *transversalis* muscle.

Each of the second, third, fourth, and fifth costal cartilages articulates with the side of the sternum, at a point corresponding to the junction of two sternebræ. The sixth and seventh (and eighth when this reaches the sternum) are arranged irregularly. As a rule, the sixth lies in a recess at the side of the fifth sternebra; the seventh corresponds to the line of junction of the meso- and metasternum; and the eighth articulates with the metasternum (see figs. 158, 161).

Blood-supply.—The costal cartilages derive their blood-supply from the terminal twigs of the aortic intercostals and from the internal mammary arteries.

Ossification.—At the eighth week of intra-uterine life the ribs are cartilaginous. About this date a nucleus appears near the angle of each rib, and spreads with great rapidity along the shaft, and by the fourth month reaches as far as the costal cartilage. At this date the length of rib-shaft bears the same proportion to that of the costal cartilage as in adult life. Whilst the ribs are in a cartilaginous condition, the first eight reach to the side of the sternum, and even after ossification has taken place, the costal cartilage of the eighth rib, in many instances, retains its articulation with the sternum up to as late as the eighth month (fig. 158). This relationship may persist through life, but usually the cartilage retrogresses, and is replaced by ligamentous tissue. About the fifteenth year a secondary centre appears for the head of each rib, and a little later one makes its appearance for the tubercle, except in the eleventh and twelfth ribs. Frequently epiphyses are developed on both parts of the tubercle (see figs. 159 and 160). The epiphyses fuse with the ribs about the twenty-third year. The rib-shaft increases in length mainly at its line of junction with the costal cartilage.

Variations in the Number and Shape of the Ribs

The ribs may be increased in number by addition either at the cervical or lumbar end of the series, but it is extremely rare to find an additional rib or pair of ribs in both the cervical and lumbar regions in the same subject.

Fig. 157.—Rib at Puberty.

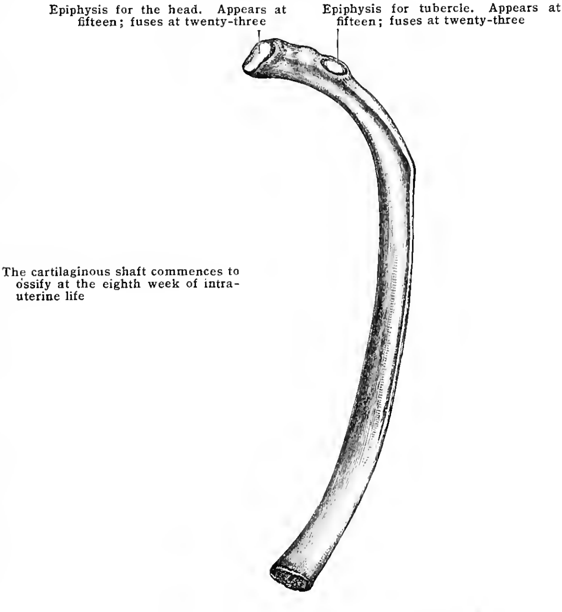


Fig. 158.—The Thorax at the Eighth Fœtal Month. (On the left side eight cartilages reach the sternum.)

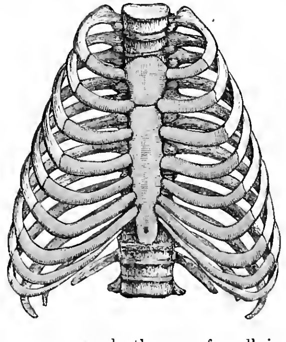
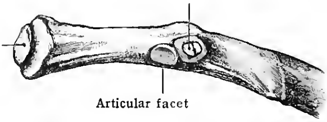


Cervical ribs are fairly common; as a rule, they are of small size and rarely extend more than a few millimeters beyond the extremity of the transverse process (see p. 35). Rarely they exceed such insignificant proportions and reach as far as the sternum; between these two extremes many varieties occur. In one case Turner was able to make a thorough dissection of a specimen in which a complete cervical rib existed. Its head articulated with the body of the seventh cervical vertebra and had a radiate ligament. The tubercle was well developed, and articulated with the transverse process. The costal cartilage blended with that of the first thoracic rib, and gave attachment to the costo-clavicular ligament. Between it and the first thoracic rib there was a well-marked intercostal space occupied by intercostal muscles. It received the attachment of the *scalenus anterior* and *medius* muscles, and it was crossed by the subclavian artery and vein. The nerves of the intercostal space were supplied by the eighth cervical and first thoracic. The artery of the space was derived from the deep cervical, which, with the superior intercostal, arose from the root of the vertebral. The head of the first thoracic rib in this specimen articulated with the seventh cervical, as well as with the first thoracic vertebra. An interesting fact is also recorded in the careful account of this specimen. There was no movable twelfth thoracic rib on the same side as this well-developed cervical rib, and the twelfth thoracic vertebra had mammillary and accessory processes, and a strong elongated costal process, and was in linear series with the lumbar transverse processes.

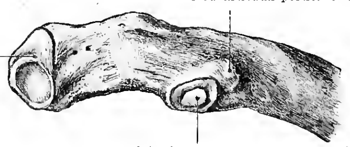
Fig. 159.—Posterior Portion of the Sixth Rib in the Fifteenth Year. (After Toldt.)



Gruber and Turner, from a careful and elaborate study of this question, summarise the variations in the cervical rib thus:—It may be very short and possess only a head, neck, and tubercle. When it extends beyond the transverse process, its shaft may end freely or join the first thoracic rib: this union may be effected by bone, cartilage, or ligament. In very rare instances it may have a costal cartilage and join the manubrium of the sternum. Not unfrequently a process, or eminence, exists on the first thoracic rib at the spot where it articulates with a cervical rib.

Lumbar ribs are of less significance than cervical ribs and rarely attain a great length. Their presence is easily accounted for, as they are the differentiated costal elements of the transverse processes. They are never so complete as the cervical ribs, and articulate only with the transverse processes; the head never reaches as far as the body of the vertebra, and there is no neck or tubercle. An extra *levator costæ* muscle is associated with a lumbar rib.

Fig. 160.—Posterior Portion of the Sixth Rib in the Eighteenth Year. (After Toldt.)



Not the least interesting variation of a rib is that known as the **bicipital rib.** This condition is seen exclusively in connection with the **first thoracic rib.** The vertebral end consists of two limbs which lie in different transverse planes. These bicipital ribs have been especially studied in whales and man. This abnormality is due to the fusion of two ribs, either of a cervical rib with the shaft of the first thoracic; or the more common form, the fusion of the first and second true ribs.

Among unusual variations of ribs should be mentioned the replacement of the costal cartilage and a portion of the rib-shaft by fibrous tissue, a process which occurs normally in the case of the eighth rib during its development.

Sometimes the shafts of two or more ribs may become united by small quadrilateral plates of bone extending across the intercostal spaces.

THE STERNUM

The **sternum** (figs. 161, 162) is a flat, oblong plate of bone, situated in the anterior wall of the thorax, and divisible into three parts, called respectively—(1) the **manubrium sterni** (presternum), (2) the **gladiolus** (mesosternum), constituting the **body** of the bone, and (3) the **xiphoid** (or ensiform) **process** (metasternum). In the young subject it consists of six pieces or segment (sternebræ). Of these, the first remains separate throughout life and forms the manubrium; the succeeding four segments fuse together, forming the body; whilst the lowest segment, also distinct until middle life, is represented by the xiphoid process.

In its natural position the sternum is inclined obliquely from above downward and forward, and corresponds in length to the spine from the third to the ninth thoracic vertebra. It is not of equal width throughout, being broader above at the manubrium and narrow at the junction of this piece with the body. Toward the lower part of the body the sternum again widens, and then suddenly contracts at its junction with the xiphoid process which constitutes the narrowest part.

The **manubrium** or first piece of the sternum forms the broadest and thickest part of the bone, and is of a somewhat triangular form with the base directed upward and the apex downward. It presents for examination two surfaces and four borders. The **anterior surface** [planum sternale] is largely subcutaneous. It is slightly convex and directed obliquely upward and forward, is smooth and gives origin on each side to the sternal head of the *sterno-mastoid* and the *pectoralis major*. The **posterior surface,** almost flat, and directed downward and backward, affords origin near the lateral margins on each side, to the *sterno-hyoid* muscle above and the *sterno-thyreoid* muscle below. Of the four borders, the **superior** is the longest and much the thickest. In the middle is a curved, non-articular depression, called the **jugular** (interclavicular) **notch,** to which the fibres of the interclavicular ligament are attached, and at either end is an oval articular surface [incisura clavicularis], somewhat saddle-shaped and directed upward, backward, and laterally for the reception of the medial end of the clavicle. The circumference of the articular surface gives attachment to the sterno-clavicular ligaments. The **lateral borders** slope from above downward and medially and each presents an irregular surface above for the first costal cartilage and a small facet below, which, with an adjoining facet on the body, forms a notch for the second costal cartilage. The two articular surfaces are separated by a narrow curved edge in relation with the *internal intercostal* muscle of the first space. The **lower border** is thick and short and presents an oval rough surface which articulates with the upper border of the body, forming the **sternal synchondrosis.** The two opposed surfaces are separated by a fibro-cartilaginous disc, which may, however, become partially ossified in advanced age, and at the position of the joint there is usually an angle—the **angle of the sternum**—which can be felt as a transverse ridge beneath the skin. This is useful in locating the position of the second rib in the living subject.

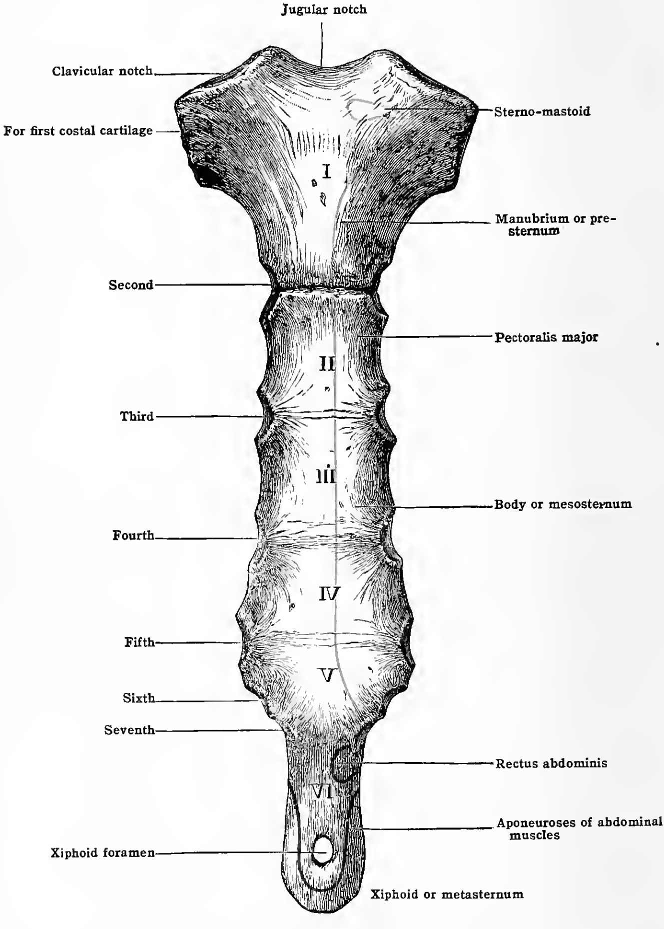
The **body** (gladiolus) or second piece of the sternum is longer, narrower, and thinner than the manubrium. It is widest opposite the notches for the fifth costal cartilages and becomes narrower above and below. The **anterior surface** is flat, directed upward and forward, and marked by three transverse elevations which indicate the lines of junction of its four component parts. It gives attachment on each side to fibres of the *pectoralis major*, and occasionally presents a foramen—the **sternal foramen**—situated at the junction of the third and fourth pieces of the bone. The **posterior surface** is slightly concave, marked by lines corresponding to those on the anterior surface, and below gives attachment on each side to fibres of the *transversus thoracis* (*triangularis sterni*). The **lateral borders** present four whole notches [incisuræ costæ] and two half-notches on each side, which articulate with the costal cartilages of the second to the seventh ribs inclusive; the two half-notches are completed by corresponding notches on the manubrium and the xiphoid process. Between the articular depressions the lateral border is curved and in relation to the *internal intercostal* muscles.

In order to appreciate the nature of these articular notches, it is advantageous to study the sternum in a young subject. Each typical **sternebra** presents four angles at each of which is a demi-notch. Between every two sternebræ there is an intersternebral disc so that when in position, each notch for a costal cartilage is formed by a sternebra above and below and an intersternebral disc in the middle, thus repeating the relation of the rib-head to the vertebral centre. Later in life these fuse more or less together, except in the case of the first and second sternebræ, which usually remain separate to the end of life. The first (pre-sternum) is the most modified of all the sternebræ, and differs from them in the fact that the costal cartilage of the first rib is continuous with it, and in fact that it supports the clavicles. Occasionally a rounded pisiform bone is seen on each side, medial to the articular notch for the clavicle; these are the **supra-sternal** bones.

The **superior border** of the sternal body presents an oval facet for articulation (synchondrosis) with the manubrium. The **inferior border** is short and articulated with the xiphoid process, forming the meso-metasternal joint, the two opposed surfaces being separated by a layer of cartilage so long as they are not united by bone.

The **xiphoid** (ensiform) **process** is the thin, elongated process projecting downward between the cartilages of the seventh ribs. It is the least developed

Fig. 161.—The Sternum. (Anterior view.)

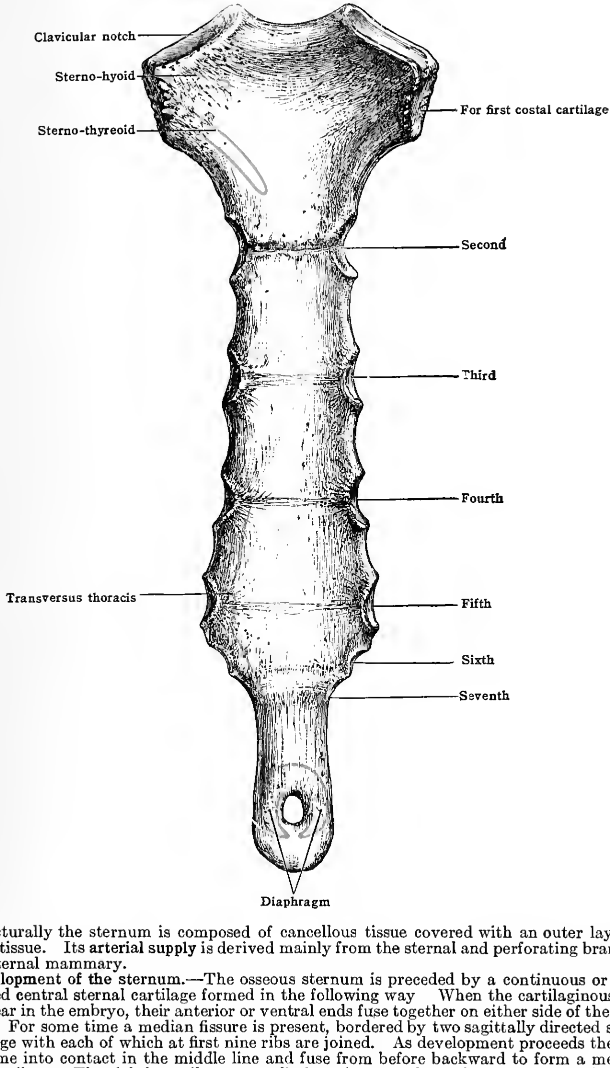


part of the sternum and is subject to many variations in form, being sometimes pointed, broad and thin, occasionally bifid or perforated by a foramen, and sometimes bent forward, backward, or deflected to one side. In structure it is cartilaginous in early life, partially ossified in the adult, but in old age it tends to become ossified throughout and to fuse with the body.

The **anterior surface** of the xiphoid process gives attachment to a few fibres of the *rectus abdominis* muscle and the chondro-xiphoid ligament, the **posterior surface** to the sternal fibres of the *diaphragm*, and the lowest fibres of the *transversus thoracis* (*triangularis sterni*), whilst the lateral margins receive the aponeuroses of the abdominal muscles. Its tip is directly continuous with the linea alba.

Differences according to sex.—The sternum differs somewhat in the two sexes. The female sternum is relatively shorter, the diminution being almost confined to the body. In the male the body is more than twice as long as the manubrium, whereas in the female it is usually less than twice the length of the first piece.

Fig. 162.—The Sternum. (Posterior view.)

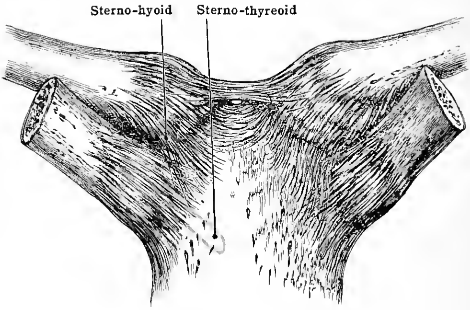


Structurally the sternum is composed of cancellous tissue covered with an outer layer of compact tissue. Its **arterial supply** is derived mainly from the sternal and perforating branches of the internal mammary.

Development of the sternum.—The osseous sternum is preceded by a continuous or non-segmented central sternal cartilage formed in the following way When the cartilaginous ribs first appear in the embryo, their anterior or ventral ends fuse together on either side of the middle line. For some time a median fissure is present, bordered by two sagittally directed strips of cartilage with each of which at first nine ribs are joined. As development proceeds the two strips come into contact in the middle line and fuse from before backward to form a median sternal cartilage. The eighth cartilage generally loses its sternal attachment, although in some cases it remains permanently articulated with the side of the ensiform process. The ninth costal cartilage becomes subdivided, one part remaining attached to the sternum and forming the xiphoid process, whilst the end still continuous with the rib acquires a new attachment to the eighth cartilage. The ends adherent to the sternum may remain separate and give rise to a bifid xiphoid process, though much more frequently they unite, leaving a small foramen.

At first, therefore, the sternum and costal cartilages are continuous. A joint soon forms between the presternum and mesosternum, and others between the costal cartilages and the sternum (except in the case of the first) quickly follow. The division of the mesosternum into segments is a still later formation and arises during the process of ossification.

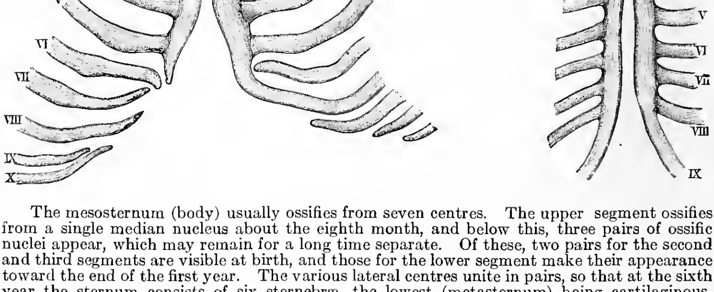
Fig. 163.—Posterior Surface of the Manubrium (Pre-sternum), with Sternal Ends of Clavicles and the First Costal Cartilages.



On the other hand, a view has been advanced by Professor A. M. Paterson that the sternum is not a bilateral structure, but is laid down, as shown in human sterna of the third month, as a simple median band of hyaline cartilage, in complete fusion with the costal cartilages on each side and presenting no differentiation of its component parts. From a study of the earliest stages of the development of the sternum, its comparative anatomy and structure, Professor Paterson has, moreover, brought forward evidence which indicates its independence in the first instance of costal elements and its genetic association with the shoulder girdle.

Ossification.—The ossification of the sternum is slow and irregular. The process begins in the presternum (manubrium) by a single centre about the sixth month of intra-uterine life, though occasionally other accessory centres are superadded.

Fig. 164.—Two Stages in the Formation of the Cartilaginous Sternum. (After Ruge.)



The mesosternum (body) usually ossifies from seven centres. The upper segment ossifies from a single median nucleus about the eighth month, and below this, three pairs of ossific nuclei appear, which may remain for a long time separate. Of these, two pairs for the second and third segments are visible at birth, and those for the lower segment make their appearance toward the end of the first year. The various lateral centres unite in pairs, so that at the sixth year the sternum consists of six sternebræ, the lowest (metasternum) being cartilaginous. Very often, however, there are only four centres of ossification in the gladiolus, as shown in fig. 165. Gradually the four pieces representing the mesosternum fuse with one another, and

FIG. 165.—OSSIFICATION OF THE STERNUM.

A, common arrangement of the ossific centres. B, showing accessory centre in the manubrium sterni, and bilateral centres in the second, third, and fourth pieces of the body.

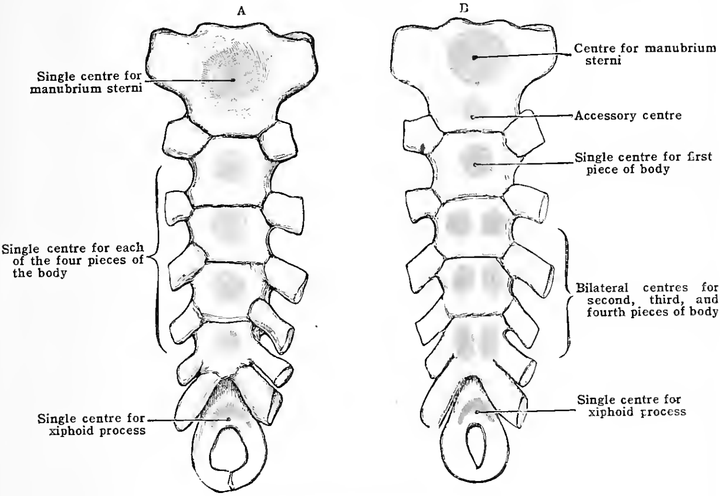


FIG. 166.—THE THORAX. (Front view.)

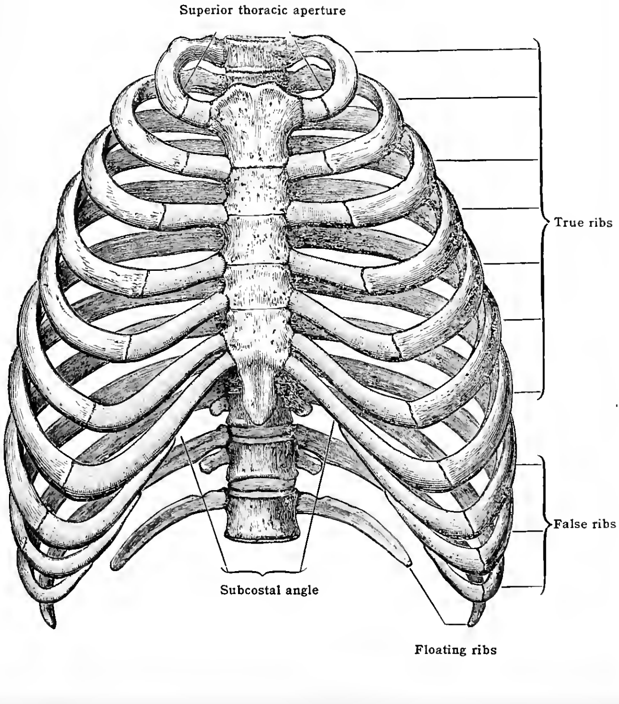


at twenty-five they form a single piece, but exhibit, even in advanced life, traces of their original separation. A sternal foramen is usually the result of non-union across the middle line or a defect of ossification.

The metasternum is always imperfectly ossified, and does not join with the mesosternum till after middle life. The presternum and mesosternum rarely fuse. The dates given above for the various nuclei, and for the union of the various segments, are merely approximate, hence the sternum affords very uncertain data as to age.

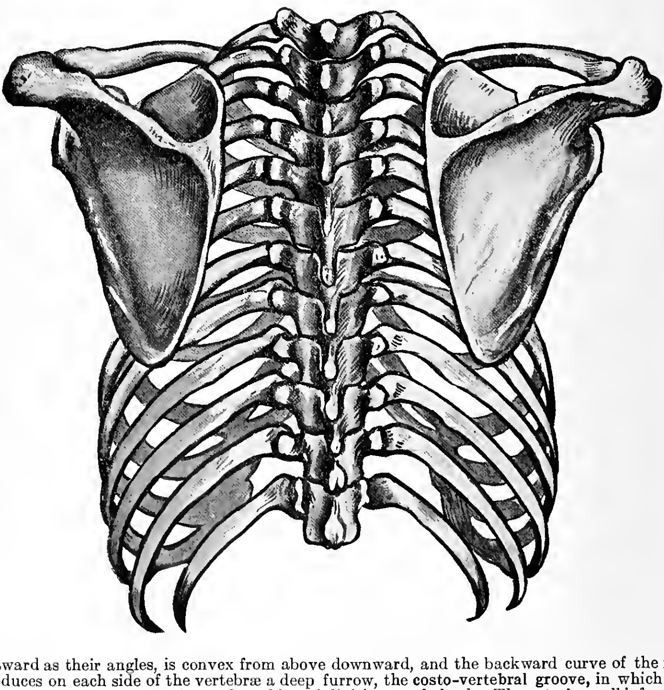
Abnormalities of the Sternum.—The mode of development of the sternum as described above is of importance in connection with some deviations to which it is occasionally subject. In rare instances the two lateral halves fail to unite, giving rise to the anomaly of a completely cleft sternum. The union of the two halves may occur in the region of the manubrium and fail below, whilst in other cases the upper and lower parts have fused but remain separate in the middle. The clefts are in many instances so small as not to be of any moment, and are not even recognised until the skeleton is prepared. In a few individuals, however, they have been so extensive as to allow the pulsation of the heart to be perceptible to the hand, and even to the eye, through the skin covering the defect in the bone.

A common variation in the sternum is asymmetry of the costal cartilages. Instead of corresponding, the cartilages may articulate with the sternum in an alternating manner. The cause of this asymmetry is not known.

THE THORAX AS A WHOLE

The bony thorax (fig. 166) is somewhat conical in shape, deeper behind than in front and compressed antero-posteriorly, so that in the adult it measures less in the sagittal than in the transverse axis. The posterior wall, formed by the thoracic vertebræ and the ribs as far

Fig. 167.—The Thorax. (Posterior view.) The scapulæ are drawn from an *X*-ray photograph of a man 33 years old.



outward as their angles, is convex from above downward, and the backward curve of the ribs produces on each side of the vertebræ a deep furrow, the **costo-vertebral groove,** in which the *sacro-spinalis* (*erector spinæ*) muscle and its subdivisions are lodged. The anterior wall is formed by the sternum and costal cartilages. It is slightly convex and inclined forward in its lower part, forming an angle of about 20° with the vertical plane. The lateral walls are formed by the ribs from the angles to the costal cartilages. The top of the thorax presents an elliptical aperture, the **superior thoracic aperture,** which measures on an average 12.5 centimetres (5 inches) transversely and 6.2 centimetres ($2\frac{1}{2}$ inches) in its sagittal axis. It is bounded by the first thoracic vertebra behind, the upper margin of the manubrium sterni in front, and the first rib on each side. As the upper margin of the manubrium sterni is oftenest on a level with the disc between the second and third thoracic vertebræ, it follows that the plane of the opening is directed obliquely upward and forward. The angle of the sternum (*angulus Ludovici*) is usually opposite the body of the fifth thoracic vertebra and the xiphi-sternal junction corresponds to the disc between the ninth and tenth thoracic vertebræ. The lower aperture of the thorax is very irregular, and is formed by the twelfth thoracic vertebra behind, the twelfth ribs laterally, and in front by two curved lines, ascending one on either side from the last rib, along the costal margin to the lower border of the gladiolus. The two borders form the **costal arch**, which in the median line below the sternum forms the **infrasternal angle.** From this angle the xiphoid process projects downward. The intervals between the ribs are the **intercostal spaces**, and are eleven in number on each side.

The ratio of the sagittal and the transverse diameter of the thorax forms the **thoracic index**, which is higher in the female and in children, in whom the thorax is more rounded. In the embryo, the index is very much higher, the sagittal diameter being greater than the transverse. In the early embryo, the index is nearly 200; at birth it is about 90. In the adults it varies from 70 to 75, averaging 2 or 3 per cent. lower in the male than in the female. It is also lower in the negro than in the white race. (Rodes, Zeitschr. f. Morph. u. Anthrop., Bd. 9.)

II. THE APPENDICULAR SKELETON

A. BONES OF THE UPPER EXTREMITY

The bones of the upper extremity may be arranged in four groups corresponding to the division of the limb into four segments. In the *shoulder* are the clavicle and the scapula, which together constitute the pectoral or shoulder girdle; in the *arm* is the humerus; in the *forearm* are the radius and ulna; and in the *hand* the carpus, the metacarpus, and the phalanges.

THE CLAVICLE

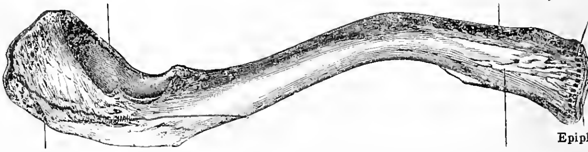
The **clavicle** [clavicula] or collar bone (figs. 168, 169) is situated immediately above the first rib and extends from the upper border of the manubrium sterni, laterally and backward to the acromion process of the scapula. It connects the upper limb with the trunk, and is so arranged that whilst the medial end rests on the sternum and first costal cartilage, the lateral end is associated with the scapula in all its movements, supporting it firmly in its various positions and preventing it from falling inward on the thorax.

The clavicle is a long bone, and when viewed from the front presents a double curvature, so that it somewhat resembles in shape the italic letter *f*. The medial curve, convex forward, extends over two-thirds of the length of the bone; the lateral, concave forward, is smaller and confined to the lateral part. For descriptive purposes the clavicle may be divided into a medial prismatic portion, a lateral flattened portion, and two extremities.

Prismatic portion.—The medial two-thirds of the bone, extending from the sternal extremity to a point opposite the coracoid process of the scapula, has the form of a triangular prism. This portion, however, is subject to considerable variations of form, being more cylindrical in ill-developed specimens and becoming almost quadrangular when associated with great muscular development. In a typical specimen it is marked by three borders separating three surfaces. Of these, the **anterior surface** is convex and divided near the sternal end by a prominent ridge into two parts, a lower, giving origin to the clavicular portion of the *pectoralis major;* an upper, for the clavicular portion of the *sterno-cleido-mastoid.* Near the middle of the shaft the ridge disappears, the surface is smooth, and is covered by the *platysma myoides.* Occasionally this surface is pierced by a small canal, transmitting a cutaneous nerve from the cervical plexus. The **posterior surface** is concave, forming an arch over the brachial plexus and the subclavian artery, broadest medially and smooth in its whole extent. It gives origin near the sternal extremity to a part of the *sterno-hyoid* and occasionally to a few fibres of the *sterno-thyreoid.* Somewhere near the middle of this surface is a small foramen, directed laterally, for the chief nutrient artery of the bone, derived from the transverse scapular (suprascapular) artery. Sometimes the foramen is situated on the inferior surface of the bone, in the subclavian groove. On the **inferior surface** near the sternal end is a rough area, the **costal tuberosity,** about three-quarters of an inch in length, for the attachment of the costo-clavicular ligament, by which the clavicle is fixed to the first rib. More laterally is a longitudinal groove for the *subclavius*, bordered by two lips, to which the sheath of the muscle is attached. To the posterior of the two lips the layer of deep cervical fascia which binds down the posterior belly of the omo-hyoid to the clavicle is also attached.

Of the three **borders,** the **superior** separates the anterior and posterior surfaces. Beginning at the sternal end, it is well-marked, becomes rounded and indistinct in the middle, whilst laterally it is continuous with the posterior border of the outer third. The **posterior border** separates the inferior and posterior surfaces and forms the posterior lip of the subclavian

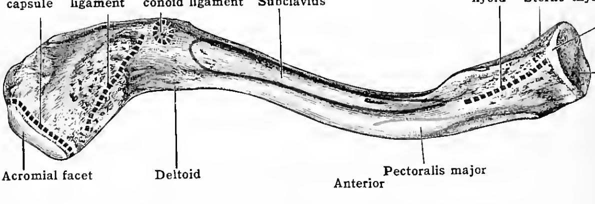
Fig. 168.—The Left Clavicle. (Superior surface.)



groove. It begins at the costal tuberosity and can be traced laterally as far as the coracoid tubercle, an eminence on the under aspect of the bone near the junction of prismatic and flattened portions. The **anterior border** is continuous with the anterior border of the flattened portion and separates the anterior and inferior surfaces. Medially, it forms the lower boundary of the elliptical area for the origin of the *pectoralis major*, and approaches the posterior border. Near the middle of the bone it coincides with the anterior lip of the subclavian groove.

Flattened portion.—The lateral third of the bone, extending from a point opposite the coracoid process of the scapula to the acromial extremity, is flattened from above downward and presents two surfaces and two borders. The **superior surface** is rough and looks directly upward and gives attachment to the *trapezius* behind and the *deltoid* in front; between the two areas the surface is subcutaneous. On the **inferior surface,** near the posterior border, is a rough elevation, the **coracoid** (conoid) **tubercle;** it overhangs the coracoid process and gives attachment to the conoid ligament. From the coracoid tubercle, a prominent ridge, the **trapezoid** or **oblique line,** runs laterally and forward to near the lateral end of the bone. To it the trapezoid ligament is attached. The conoid and trapezoid ligaments are the two parts of the coraco-clavicular ligament which binds the clavicle down to the coracoid process.

Fig. 169.—The Left Clavicle. (Inferior surface.)



The **anterior border** is sharp, gives origin to the *deltoid* muscle, and frequently presents near the junction of the flattened and prismatic portions a projection known as the **deltoid tubercle.** The **posterior border** is thick and rounded, and receives the insertion of the upper fibres of the *trapezius.*

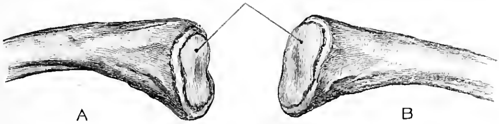
Extremities.—The **sternal extremity** of the clavicle presents a triangular articular surface, directed medially, downward, and a little forward, slightly concave from before backward and convex from above downward, which articulates with a facet on the upper border of the manubrium sterni through an interposed interarticular fibro-cartilage.

Of the three angles, one is above and two below. The *postero-inferior angle* is prolonged backward, and so renders this surface considerably larger than that with which it articulates; the *superior angle* receives the attachment of the upper part of the fibro-cartilage. The lower part of the surface is continuous with a facet on the under aspect of the bone, medial to the costal tuberosity, for the first costal cartilage. The circumference of the extremity is rough, and gives attachment to the interclavicular ligament above and the anterior and posterior sterno-clavicular ligaments in front and behind.

The **acromial extremity** presents a smooth, oval, articular facet, flattened or convex, directed slightly downward for the acromion; its border is rough, for the attachment of the capsule of the acromio-clavicular joint.

Structure.—The clavicle consists externally of a compact layer of bone, much thicker in the middle and thinning out gradually toward the two extremities. There is no true medullary

FIG. 170.—THE STERNAL ENDS OF TWO CLAVICLES WITH EPIPHYSES.
A, right clavicle from below and behind. B, left clavicle from below and behind.
(From Royal College of Surgeons Museum.)



cavity, for the interior is occupied from end to end by cancellous tissue, the amount in the various parts of the bone being in inverse proportion to the thickness of the outer compact shell

Ossification.—From observations made by F. P. Mall, D. C. L. Fitzwilliams, and E. Fawcett it seems almost certain that there are two centres of ossification of the shaft of the clavicle, at the juncture of the middle and lateral thirds. They appear very early, about the fifth week of embryonic life, and rapidly fuse. The ossific process extends medially and laterally along the shaft toward the medial and lateral extremities, respectively. About the eighteenth year a secondary centre appears at the sternal end and forms a small epiphysis which joins the shaft about the twenty-fifth year.

THE SCAPULA

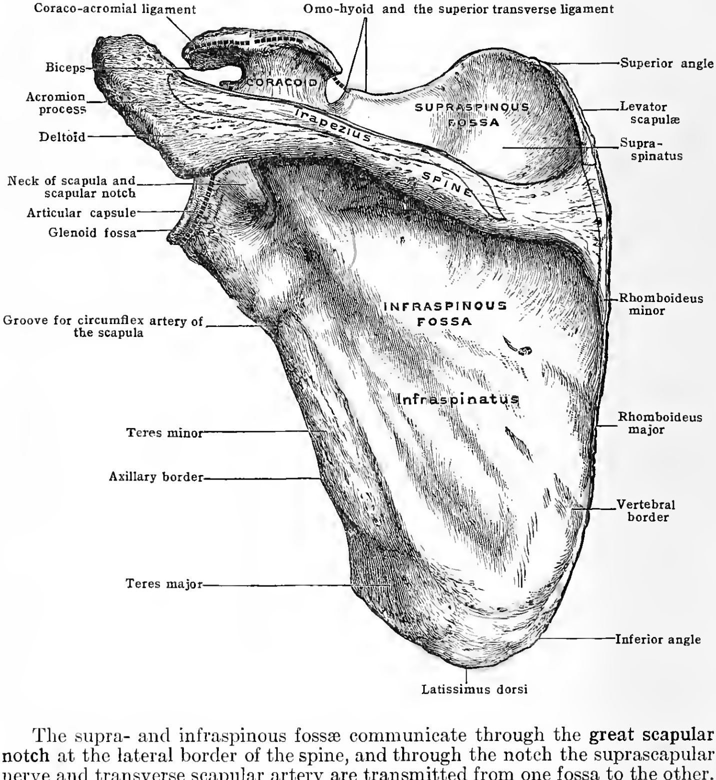
The **scapula** (figs. 171, 172) is a large flat bone, triangular in shape, situated on the dorsal aspect of the thorax, between the levels of the second and seventh ribs. Attached to the trunk by means of the clavicle and various muscles it articulates with the lateral end of the clavicle at the acromio-clavicular joint, and with the humerus at the shoulder-joint. The greater part of the bone consists of a triangular plate known as the *body*, from which two processes are prolonged: one anterior in position, is the *coracoid;* the other, posterior in position, is the *spine*, which is continued laterally into the a*cromion*.

The body presents for examination two surfaces, three borders, and three angles. The **costal** (anterior) **surface,** or venter, looks considerably medialward, is deeply concave, forming the **subscapular fossa,** and marked by several oblique lines which commence at the posterior border and pass obliquely upward and laterally; these lines or ridges divide the surface into several shallow grooves, from which the *subscapularis* takes origin, whilst the ridges give attachment to the tendinous intersections of that muscle. The lateral third of the surface is smooth and overlapped by the subscapularis, whilst medially are two small flat areas in front of the upper and lower angles respectively, but excluded from the subscapular fossa by fairly definite lines and joined by a ridge which runs close to the vertebral border. The ridge and its terminal areas serve for the insertion of the *serratus anterior (magnus)*.

The **dorsal** (posterior) **surface** is generally convex and divided by a prominent plate of bone—the **spine**—into two unequal parts. The hollow above the spine is the **supraspinous fossa** and lodges the *supraspinatus* muscle. The part below the spine is the **infraspinous fossa**; it is three times as large as the supraspinous fossa, is alternately concave and convex, and gives origin to the *infraspinatus.* The muscle is attached to its medial three-fourths and covers the lateral fourth, without taking origin from it.

The infraspinous fossa does not extend as far as the axillary border, but is limited laterally by a ridge—**the oblique line**—Which runs from the glenoid cavity—the large articular surface for the head of the humerus—downward and backward to join the posterior border a short distance above the inferior angle. This line, which gives attachment to a stout aponeurosis, cuts off an elongated surface, narrow above for the origin of the *teres minor,* and crossed near its middle by a groove for the circumflex (dorsal) artery of the scapula; below, the surface is broader for the origin of the *teres major* and occasionally a few fibres of the *latissimus dorsi.* The two areas are separated by a line which gives attachment to an aponeurotic septum situated between the two teres muscles.

Fig. 171.—The Left Scapula. (Dorsal surface.)



The supra- and infraspinous fossæ communicate through the **great scapular notch** at the lateral border of the spine, and through the notch the suprascapular nerve and transverse scapular artery are transmitted from one fossa to the other.

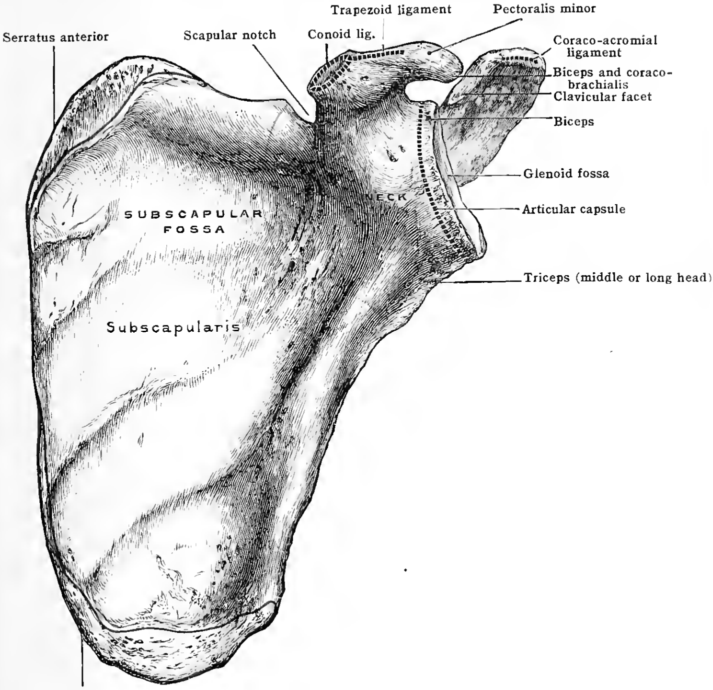
Borders.—The three borders of the scapula are named superior, vertebral, and axillary. The **superior** is short and thin and extends from the upper angle to the coracoid process. Laterally it presents a deep depression, the **scapular notch,** to the extremities of which the superior transverse ligament is attached.

Not infrequently the notch is replaced by a scapular foramen, and it is interesting to note that a bony foramen occurs normally in some animals, notably the great ant-eater (*Myrmecophaga jubata*). The notch or foramen transmits the suprascapular nerve, whilst the transverse scapular artery usually passes over the ligament. From the adjacent margins of the notch and from the ligament the posterior belly of the *omo-hyoid* takes origin.

The **vertebral border** (sometimes called the base) is the longest, and extends from the upper or medial to the lower angle of the bone. It is divisible into three parts, to each of which a muscle is attached: an upper portion, extending from the medial (superior) angle to the spine, for the insertion of the *levator scapulæ;* a middle portion, opposite the smooth triangular area at the commencement of the spine, for the *rhomboideus minor;* and the lowest and longest portion, extending below this as far as the inferior angle, for the *rhomboideus major*, the attachment of which takes place through the medium of a fibrous arch.

The **axillary border** is the thickest, and extends from the lower margin of the glenoid cavity to the inferior angle of the bone. Near its junction with the glenoid cavity there is a rough surface, about 2.5 cm. (1 in.) in length the **infraglenoid tubercle,** from which the long head of the *triceps* arises, and below

Fig. 172.—The Left Scapula. (Ventral surface.)



the tubercle is the groove for the circumflex (dorsal) artery of the scapula. The upper two-thirds of the border is deeply grooved on the ventral aspect and gives origin to a considerable part of the *subscapularis.*

Angles.—The three angles are named medial, inferior, and lateral.

The **medial** (or superior) **angle,** forming the highest part of the body, is thin, smooth, and either rounded or approximating a right angle. It is formed by the junction of the superior and vertebral borders and gives insertion to a few fibres of the *levatar scapulæ.* The **inferior angle,** constituting the lowest part of the body, is thick, rounded, and rough. It is formed by the junction of axillary and vertebral borders, gives origin to the *teres major,* and is crossed horizontally by the upper part of the *latissimus dorsi,* the latter occasionally receiving from it a small slip of fleshy fibres.

The **lateral angle** forms the expanded portion of the bone known as the **head,** bearing the **glenoid cavity,** and supported by a somewhat constricted **neck.** The glenoid cavity is a wide, shallow, pyriform, articular surface for the head of the humerus, directed forward and laterally, with the apex above and the broad end below. Its margin is raised, and affords attachment to the glenoid ligament, which deepens its concavity. The margin is not, however, of equal prominence throughout, being somewhat defective where it is overarched by the acromion, notched anteriorly, and emphasised above to form a small eminence, the **supraglenoid tubercle,** for the attachment of the long head of the *biceps.*

The circumference and adjoining part of the neck give attachment to the articular capsule of the shoulder-joint, and the anterior border to the three accessory ligaments of the capsule, known as the superior, middle, and inferior gleno-humeral folds. The superior fold (Flood's ligament) is attached above the notch near the upper end; of the two remaining folds, which together constitute Schlemm's ligament, the middle is attached immediately above the notch and the inferior below the notch. In the recent state the glenoid fossa is covered with hyaline cartilage. The **neck** is more prominent behind than before and below than above, where it supports the coracoid process. It is not separated by any definite boundary from the body.

Processes.—The **spine** is a strong, triangular plate of bone attached obliquely to the dorsum of the scapula and directed backward and upward. Its apex is situated at the vertebral border; the base, corresponding to the middle of the neck, is free, concave, and gives attachment to the inferior transverse ligament, which arches over the transverse scapular (suprascapular) vessels and suprascapular nerve. Of the two borders, one is joined to the body, whilst the other is free, forming a prominent subcutaneous **crest.** The latter commences at the vertebral border, in a smooth triangular area, over which the tendon of the *trapezius* glides, usually without the intervention of a bursa, as it passes to its insertion into a small tubercle on the crest beyond. Further laterally, this border is rough, and presents two lips—a superior for the insertion of the *trapezius* and an inferior for the origin of the *deltoid.* Laterally the crest is continued into the **acromion.**

The **spine** has two surfaces, the superior, which also looks medialward and forward, is concave, contributes to the formation of the supraspinous fossa, and gives origin to the *supraspinatus* muscle; the inferior surface, also slightly concave, is directed lateralward and backward, forms part of the infraspinous fossa, and affords origin to the *infraspinatus* muscle. On both surfaces are one or more prominent vascular foramina.

The **acromion,** a process overhanging the glenoid cavity, springs from the angle formed by the junction of the crest with the base of the spine. Somewhat crescentic in shape, it forms the summit of the shoulder and is compressed from above downward so as to present for examination two surfaces, two borders, and two extremities.

The posterior part sometimes terminates laterally in a prominent **acromial angle** (metacromion) and the process then assumes a more or less triangular form. Of the two extremities, the posterior is continuous with the spine, whilst the anterior forms the free tip. The upper surface, directed upward, backward, and slightly lateralward, is rough and convex, and affords origin at its lateral part to a portion of the *deltoid;* the remaining part of this surface is subcutaneous. The lower surface, directed downward, forward, and slightly medialward, is concave and smooth. The medial border, continuous with the upper lip of the crest, presents, from behind forward, an area for the insertion of the *trapezius;* a small, oval, concave articular facet for the lateral end of the clavicle, the edges of which are rough for the acromio-clavicular ligaments; and, beyond this, the anterior extremity or tip, to which is attached the apex of the coraco-acromial ligament. The lateral border, continuous with the inferior lip of the crest, is thick, convex, and presents three or four tubercles with intervening depressions; from the tubercles the tendinous septa in the acromial part of the *deltoid* arise, and from the depressions, some fleshy fibres of the same muscle.

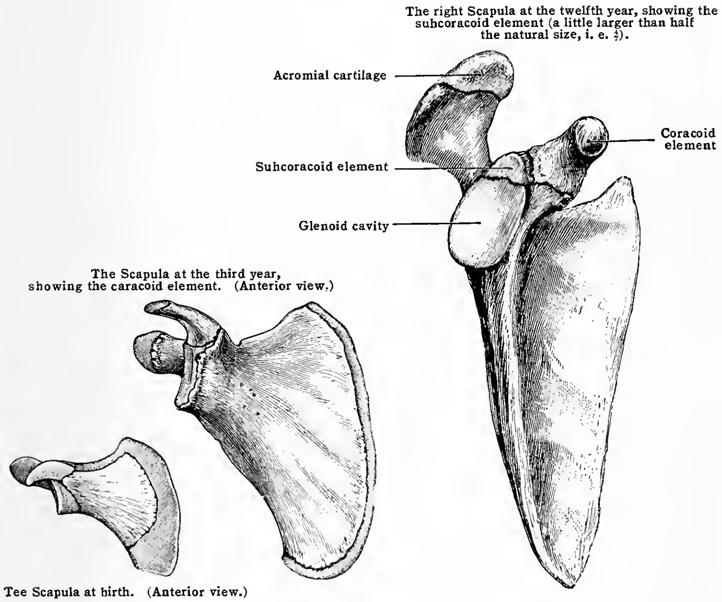
Projecting upward from the neck of the scapula is the **coracoid process,** bent finger-like, pointing forward and laterally. It consists of two parts, ascending and horizontal, arranged at almost a right angle to each other.

The *ascending part* arises by a wide root, extends upward and medially for a short distance, and is compressed from before backward; it is continuous above with the horizontal part and below with the neck of the scapula; the lateral border lies above the glenoid cavity and gives attachment to the coraco-humeral ligament; the medial border, which forms the lateral boundary of the scapular notch, gives attachment to the conoid ligament above and the transverse ligament below. Its anterior and posterior surfaces are in relation with the *subscapularis* and *supraspinatus* respectively. The *horizontal part* of the process runs forward and lateralward; it is compressed from above downward so as to present two borders, two surfaces, and a free extremity. The medial border gives insertion along its anterior half to the *pectoralis minor* and nearer the base to the costo-coracoid membrane; the lateral border is rough for the coraco-acromial and coraco-humeral ligaments; the upper surface is irregular and gives insertion in front to the *pectoralis minor*, and behind to the trapezoid ligament; the inferior surface is smooth and directed toward the glenoid cavity, which it overhangs; the free extremity or apex gives origin to the conjoined *coraco-brachialis* and short head of the *biceps*.

The greater part of the body of the scapula and the central parts of the spinous process are thin and transparent. The coracoid and acromion processes, the crest of the spine and inferior angle, the head, neck, and axillary border, are thick and opaque. The young bone consists of two layers of compact tissue with an intervening cancellous layer, but in the transparent parts of the adult bone the middle layer has disappeared. The vascular foramina on the costal surface transmit twigs from the subscapular and transverse scapular (suprascapular) arteries; those in the infraspinous fossa, twigs from the circumflex (dorsal) and transverse scapular (suprascapular) arteries, the latter also giving off vessels which enter the foramina in the supraspinous fossa. The acromion is supplied by branches from the thoraco-acromial (acromiothoracic) artery.

The line of attachment of the spinous process to the dorsum of the scapula is known as the **morphological axis**, and the obtuse angle in the subscapular fossa opposite the spine as the

FIG. 173.—OSSIFICATION OF THE SCAPULA.



subscapular angle. From the axis three plates of bone radiate as from a centre, the **prescapula** forward, the **mesoscapula** laterally, and the **postscapula** backward, being named in accordance with the long axis of the body in the horizontal position. In the human subject the postscapula is greatly developed, and this is associated with the freedom and versatility of movement possessed by the upper limb.

Ossification.—The scapula is ossified from nine centres. Of these, two (for the body of the scapula and the coracoid) may be considered as **primary**, and the remainder as secondary. The centre for the body appears in a plate of cartilage near the neck of the scapula about the eighth week of intra-uterine life, and quickly forms a triangular plate of bone, from which the spine appears as a slight ridge about the middle of the third month. At birth the glenoid fossa and part of the scapular neck, the acromion and coracoid processes, the vertebral border and inferior angle, are cartilaginous. During the first year a nucleus appears for the coracoid, and at the tenth year a second centre appears for the base of the coracoid and the upper part of the glenoid cavity (subcoracoid, fig. 173).

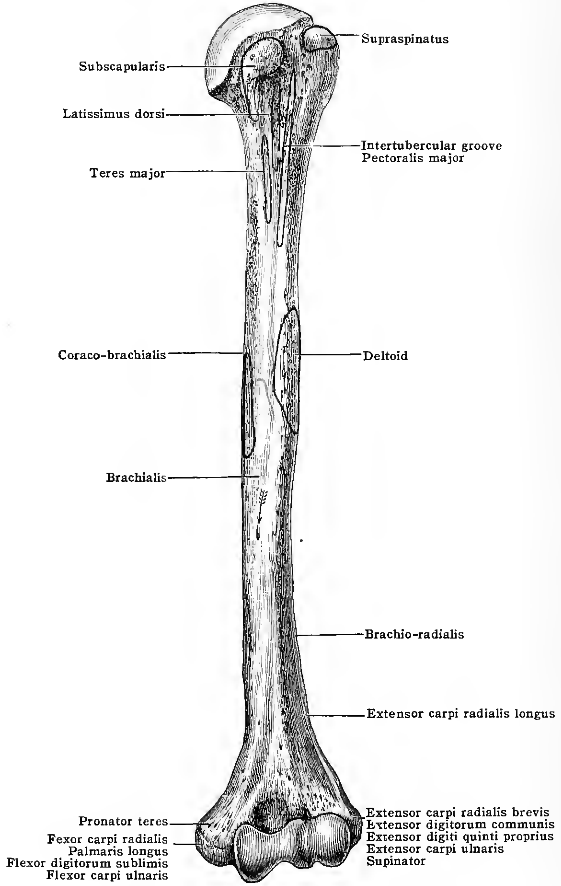
During the fifteenth year the coracoid unites with the scapula, and about this time the other secondary centres appear. Two nuclei are deposited in the acromial cartilage, and fuse to form the acromion, which joins the spine at the twentieth year. The union of spine and acromion may be fibrous, hence the latter is sometimes found separate in macerated specimens. The cartilage along the vertebral border ossifies from two centres, one in the middle, and another at the inferior angle. A thin lamina is added along the upper surface of the coracoid process and occasionally another at the margin of the glenoid cavity. These epiphyses join by the twenty-fifth year.

The occurrence of a special primary centre for the coracoid process is of morphological importance in that the process is the representative of what in the lower vertebrates is a distinct *coracoid bone*. This primarily takes part in the formation of the glenoid cavity and extends medially to articulate with the sternum. In man and all the higher mammals only the lateral portion of the bone persists.

THE HUMERUS

The **humerus** (figs. 174, 175, 176) is the longest and largest bone of the upper limb, and extends from the shoulder above, where it articulates with the scapula,

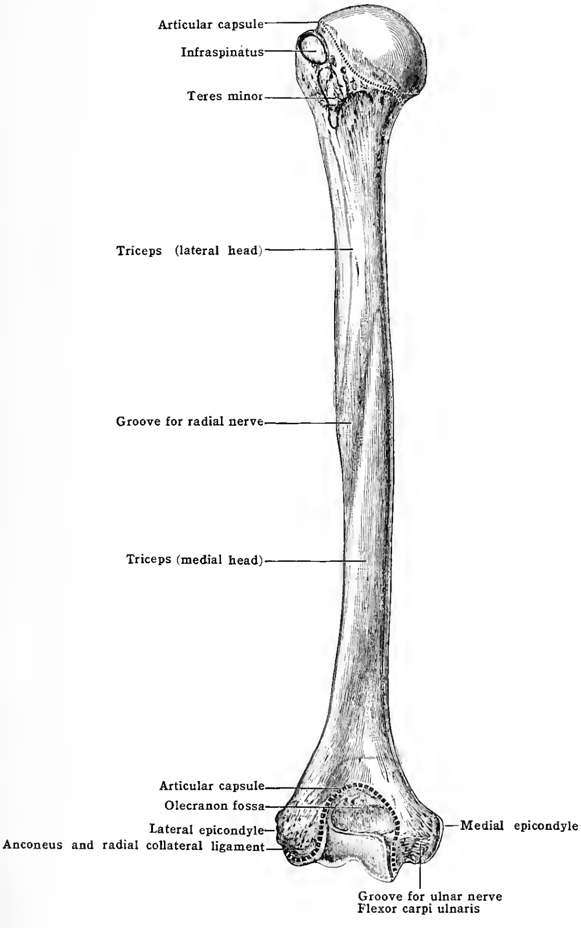
Fig. 174.—The Left Humerus. (Anterior view.)



to the elbow [cubitus] below, where it articulates with the two bones of the forearm [anti-brachium]. It is divisible into a shaft and two extremities; the *upper* extremity includes the head [caput], neck [collum], and two tuberosities—great and small; the *lower* extremity includes the articular surface with the surmounting fossæ in front and behind, and the two epicondyles.

Upper extremity.—The **head** forms a nearly hemispherical articular surface, cartilage-clad in the recent state and directed upward, medially, and backward toward the glenoid cavity. Below the head the bone is rough and somewhat constricted, constituting the **anatomical neck,** best marked superiorly, where it forms a groove separating the articular surface from the two tuberosities. The circumference of the neck gives attachment to the capsule of the shoulder-joint and the gleno-humeral folds, the upper of which is received into a depression near the top of the intertubercular (bicipital) groove. The lowest part of the capsule

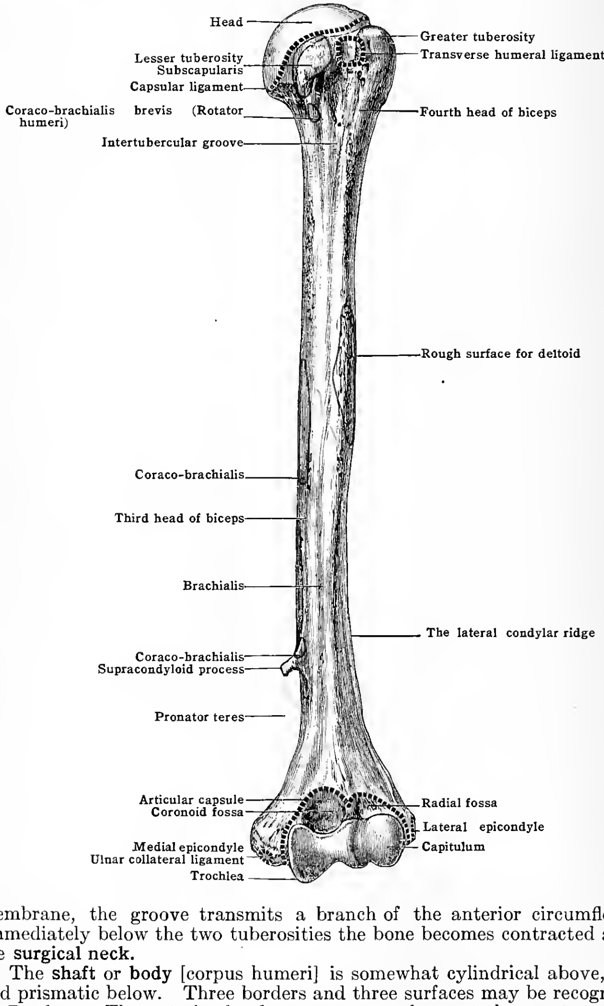
Fig. 175.—The Left Humerus. (Posterior view.)



descends upon the humerus some distance from the articular margin. Laterally and in front of the head are the two tuberosities, separated by a deep furrow. The **greater tuberosity** [tuberculum majus], lateral in position and reaching higher than the **lesser tuberosity** [tuberculum minus], is marked by three facets for the insertion of muscles: an upper one for the *supraspinatus,* a middle for the *in-*

fraspinatus, and a lower for the *teres minor*. The **lesser tuberosity** is situated in front of the head and is the more prominent of the two; it receives the insertion of the *subscapularis*. The furrow between the tuberosities lodges the long tendon of the biceps and forms the commencement of the **intertubercular** (bicipital) **groove,** which extends downward along the shaft of the humerus. Between the tuberosities the transverse humeral ligament converts the upper end of the groove into a canal. In addition to the long tendon of the biceps and its tube of synovial

FIG. 176.—THE LEFT HUMERUS WITH A SUPRACONDYLOID PROCESS AND SOME IRREGULAR MUSCLE ATTACHMENTS. (Anterior view.)

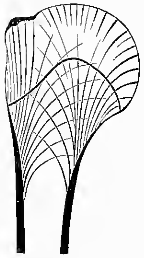


membrane, the groove transmits a branch of the anterior circumflex artery. Immediately below the two tuberosities the bone becomes contracted and forms the **surgical neck.**

The **shaft** or **body** [corpus humeri] is somewhat cylindrical above, flattened and prismatic below. Three borders and three surfaces may be recognised.

Borders.—The **anterior border** commences above at the greater tuberosity, and its upper part, forming the **crest** of this tuberosity [crista tuberculi majoris], receives the *pectoralis major*. In the middle of the shaft it is rough and prominent and gives insertion to fibres of the *deltoid;* below it is smooth and rounded, giving origin to fibres of the *brachialis*, and finally it passes along lateral to the coronoid fossa to become continuous with the ridge separating the capitulum and trochlea. It separates the antero-medial from the antero-lateral surface. The **lateral margin** extends from the lower and posterior part of the greater tuberosity to the lateral epicondyle. Smooth and indistinct above, it gives attachment to the *teres minor* and the lateral head of the *triceps;* it is interrupted in the middle by the **groove for the radial nerve** (musculo-spiral groove), but the lower third becomes prominent and curved laterally to form the **lateral supracondylar ridge,** which affords origin in front to the *brachio-radialis* and the *extensor carpi radialis longus;* behind to the medial head of the *triceps*, and between these muscles in front and behind to the lateral intermuscular septum. It separates the antero-lateral from the posterior surface. The **medial border** commences at the lesser tuberosity, forming its **crest** which receives the insertion of the *teres major*, and continuing downward to the medial epicondyle. Near the middle of the shaft it forms a ridge for the insertion of the *coraco-brachialis* and presents a foramen for the nutrient artery, directed downward toward the elbow-joint. Below it forms a distinct **medial supracondylar ridge,** curved medially, which gives origin to the *brachialis* in front, the medial head of the *triceps* behind, and the medial intermuscular septum in the interval between the muscles. This border separates the antero-medial from the posterior surface.

Fig. 177.—A Diagram showing Pressure and Tension Curves in the Head of the Humerus. (After Wagstaffe.)



Surfaces.—The **antero-lateral surface** is smooth above, rough in the middle, forming a large impression for the insertion of the *deltoid*, below which is the termination of the groove for the radial nerve. The lower part of the surface gives origin to the lateral part of the *brachialis*. The **antero-medial surface** is narrow above, where it forms the floor of the intertubercular (bicipital) groove, and receives the insertion of the *latissimus dorsi*. Near the junction of the upper and middle thirds of the bone the groove, gradually becoming shallower, widens out and, with the exception of a rough impression near the middle of the shaft for the *coraco-brachialis*, the remaining part of the antero-medial surface is flat and smooth, and gives origin to the *brachialis*.

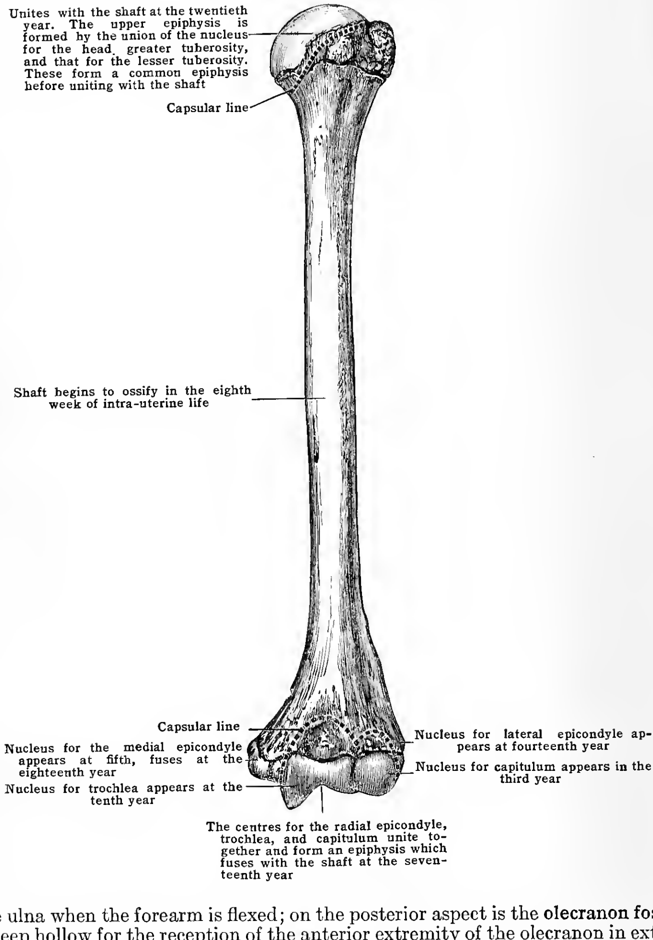
Occasionally, a prominent spine of bone, the **supracondylar process,** projects downward from the medial border about 5 cm. (2 in.) above the medial epicondyle, to which it is joined by a band of fibrous tissue. Through the ring thus formed, which corresponds to the supracondylar foraman in many of the lower animals, the median nerve and brachial artery are transmitted, though in some cases it is occupied by the nerve alone. The process gives origin to the *pronator teres*, and may afford insertion to a persistent lower part of the *coraco-brachialis*.

The **posterior surface** is obliquely divided by a broad shallow groove, which runs in a spiral direction from behind downward and forward and transmits the radial (musculo-spiral) nerve and the profunda artery. The lateral part of the surface above the groove gives attachment to the lateral head, and the part below the groove, to the medial head of the *triceps*.

The **lower extremity** of the humerus is flattened from before backward, and terminates below in a sloping articular surface, subdivided by a low ridge into the

trochlea and the **capitulum.** The **trochlea** is the pulley-like surface which extends over the end of the bone for articulation with the semilunar notch (great sigmoid cavity) of the ulna. It is constricted in the centre and expanded laterally to form two prominent edges, the medial of which is thicker, descends lower, and forms a marked projection; the lateral edge is narrow and corresponds to the interval between the ulna and radius. Above the trochlea are two fossæ: on the anterior surface is the **coronoid fossa,** an oval pit which receives the coronoid process of

FIG. 178.—OSSIFICATION OF THE HUMERUS; THE FIGURE ALSO SHOWS THE RELATIONS OF THE EPIPHYSIAL AND CAPSULAR LINES



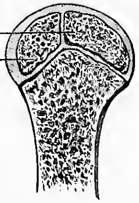
the ulna when the forearm is flexed; on the posterior aspect is the **olecranon fossa,** a deep hollow for the reception of the anterior extremity of the olecranon in extension of the forearm. These fossæ are usually separated by a thin, translucent plate of bone, sometimes merely by fibrous tissue, so that in macerated specimens a perforation, the **supratrochlear foramen,** exists. The **capitulum,** or radial head, is much smaller than the trochlea, somewhat globular in shape, and limited to the anterior and inferior surfaces of the extremity. It articulates with the concavity on the summit of the radius. The **radial fossa** is a slight depression on the front of the bone, immediately above the capitulum, which receives the anterior edge of the head of the radius in complete flexion of the forearm, whilst between the capitulum and the trochlea is a shallow groove occupied by the medial margin of the head of the radius.

In the recent state the inferior articular surface is covered with cartilage, the fossæ are lined by synovial membrane, and their margins give attachment to the capsule of the elbow-joint. Projecting on either side from the lower end of the humerus are the two **epicondyles.** The medial one is large and by far the more prominent of the two, rough in front and below, smooth behind, where there is a shallow groove for the ulnar nerve. The rough area serves for origin of the *pronator teres* above, the common tendon of origin of the *flexor carpi radialis, palmaris longus, flexor digitorum sublimis* and *flexor carpi ulnaris* in the middle, and the ulnar collateral ligament below. The lateral epicondyle is flat and irregular. Above, it gives attachment to a common tendon of origin of the *extensor carpi radialis brevis, extensor digitorum communis, extensor quinti digiti proprius, extensor carpi ulnaris,* and *supinator;* to a depression near the outer margin of the capitulum, the radial collateral ligament is attached, and from an area below and behind, the *anconeus* takes origin.

Architecture.—The interior of the shaft of the humerus is hollowed out by a large medullary canal, whereas the extremities are composed of cancellated tissue invested by a thin compact layer. The arrangement of the cancellous tissue at the upper end of the humerus is shown in fig. 177. The lamellæ converge to the axis of the bone and form a series of superimposed arches which reach upward as far as the epiphysial line. In the epiphyses the spongy tissue forms a fine network, the lamellæ resulting from "pressure" being directed at right angles to the articular surface of the head and to the great tuberosity.

Blood-supply.—The foramina which cluster round the circumference of the head and tuberosities transmit branches from the transverse scapular (suprascapular) and anterior and posterior circumflex arteries. At the top of the intertubercular groove is a large nutrient foramen

Fig. 179.—The Head of the Humerus at the Sixth Year. (In section.)



for a branch of the anterior circumflex artery which supplies the head. The nutrient artery of the shaft is derived from the brachial, and in many cases, an additional branch, derived from the profunda artery, enters the foramen in the groove for the radial nerve (musculo-spiral groove). The lower extremity is nourished by branches derived from the profunda (superior profunda), the superior and inferior ulnar collateral (inferior profunda and anastomotic), and the recurrent branches of the radial, ulnar, and interosseous arteries.

Ossification.—The humerus is ossified from one primary centre (diaphysial) and six secondary centres (epiphysial). The centre for the shaft appears about the eighth week of intra-uterine life and grows very rapidly. At birth only the two extremities are cartilaginous, and these ossify in the following manner: Single centres appear for the head in the first year, for the greater tuberosity in the third year, and for the lesser tuberosity in the fifth year, though sometimes the latter ossifies by an extension from the greater tuberosity. These three nuclei coalesce at six years to form a single epiphysis, which joins the shaft about the twentieth year.

The inferior extremity ossifies from four centres: one for the capitulum appears in the third year, a second for the medial epicondyle in the fifth year, a third for the trochlea in the tenth year, and a fourth for the lateral epicondyle in the fourteenth year. The nuclei for the capitulum, trochlea, and lateral epicondyle coalesce to form a single epiphysis which joins the shaft in the seventeenth year. The nucleus of the medial epicondyle joins the shaft independently at the age of eighteen years.

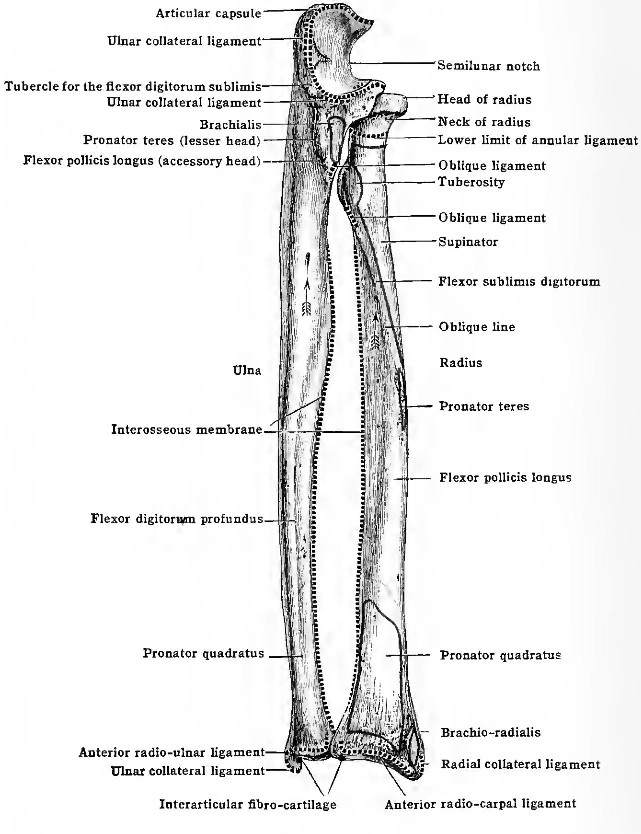
A study of the upper end of the humeral shaft before its union with the epiphysis is of interest in relation to what is known as the neck of the humerus. The term neck is applied to three parts of this bone. The *anatomical* neck is the constriction to which the articular capsule is mainly attached, and its position is accurately indicated by the groove which lies internal to the tuberosities. The upper extremity of the humeral shaft, before its union with the epiphysis, terminates in a low three-sided pyramid, the surfaces of which are separated from one another by ridges. The medial of these three surfaces underlies the head of the bone, and the two lateral surfaces underlie the tuberosities. The part supporting the head constitutes the *morphological* neck of the humerus, whilst the *surgical* neck is the indefinite area below the tuberosities where the bone is liable to fracture.

THE RADIUS

The **radius** (figs. 180–185) is the lateral and shorter of the two bones of the forearm. Above, it articulates with the humerus; below, with the carpus; and on the medial side with the ulna. It presents for examination a shaft and two extremities.

The **upper extremity,** smaller than the lower, includes the head, neck, and tuberosity. The **head** [capitulum], covered with cartilage in the recent state, is a circular disc forming the expanded, articular end of the bone. Superiorly it presents the capitular depression [fovea capituli] for the reception of the capitulum

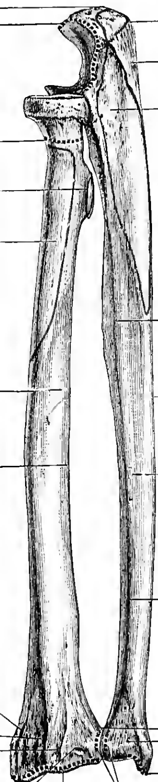
Fig. 180.—The Left Ulna and Radius. (Antero-medial view.)



of the humerus; its circumference [circumferentia articularis], deeper on the medial aspect, articulates with the radial notch (lesser sigmoid cavity) of the ulna, and is narrow elsewhere for the annular ligament by which it is embraced. Below the head is a short cylindrical portion of bone, somewhat constricted, and known as the **neck.** The upper part is surrounded by the ligament which embraces the head, and below this it gives insertion antero-laterally to the *supinator*. Below the neck, at the antero-medial aspect of the bone, is an oval eminence, the radial **tuberosity,** divisible into two parts: a rough posterior portion for the insertion of the tendon of the *biceps*, and a smooth anterior surface in relation with a bursa which is situated between the tendon and the tuberosity.

The **body** [corpus radii] or **shaft** is somewhat prismatic in form, gradually increasing in size from the upper to the lower end, and slightly curved so as to be concave toward the ulna. Three borders and three surfaces may be recognised. Of the borders, the medial or **interosseous crest** [crista interossea] is best marked. Commencing at the posterior edge of the tuberosity, its first part is round and indistinct, and receives the attachment of the oblique cord of the radius; it is con-

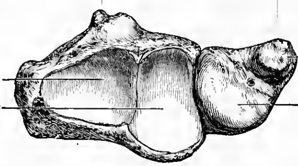
Fig. 181.—The Left Ulna and Radius. (Postero-lateral view.)



tinued as a sharp ridge which divides near the lower extremity to become continuous with the anterior and posterior margins of the ulnar notch (sigmoid cavity). The prominent ridge and the posterior of the two lower lines give attachment to the interosseous membrane, whilst the triangular surface above the ulnar notch receives a part of the *pronator quadratus*. The interosseous crest separates the volar from the dorsal surface. The **volar border** [margo volaris] runs from the tuberosity obliquely downward to the lateral side of the bone and then descends vertically to the anterior border of the styloid process. The upper third, constituting the **oblique line** of the radius, gives origin to the radial head of the *flexor digitorum sublimis*, limits the insertion of the *supinator* above, and the origin of the *flexor pollicis longus* below. The volar border separates the volar from the lateral surface. The **dorsal border** extends from the back of the tuberosity to the prominent middle tubercle on the posterior aspect of the lower extremity. Separating the lateral from the dorsal surface, it is well marked in the middle third, but becomes indistinct above and below.

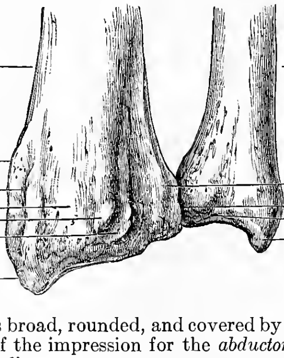
Surfaces.—The **volar** (or anterior) **surface** is narrow and concave above; broad, flat, and smooth below. The upper two-thirds is occupied chiefly by the *flexor pollicis longus* and a little less than the lower third by the *pronator quadratus*. Near

FIG. 182.—ARTICULAR FACETS ON THE LOWER END OF LEFT RADIUS AND ULNA.



the junction of the upper and middle thirds of the volar surface is the nutrient foramen, directed upward toward the proximal end of the bone. It transmits a branch of the volar interosseous artery. The **lateral surface** is rounded above and affords insertion to the *supinator;* marked near the middle by a rough, low, vertical ridge for the *pronator teres;* smooth below, where the tendons of the *extensor carpi radialis longus* and *brevis* lie upon it, and where it is crossed by the *abductor pollicis longus* and *extensor pollicis brevis*. The **dorsal** (or posterior) **surface,** smooth and rounded above, is covered by the *supinator;* grooved longitudinally in the middle third for the *abductor pollicis longus* and the *extensor pollicis*

FIG. 183.—DORSAL VIEW OF THE LOWER END OF THE RADIUS AND ULNA.



brevis; the lower third is broad, rounded, and covered by tendons. The line which forms the upper limit of the impression for the *abductor pollicis longus* is known as the **posterior oblique line.**

The **lower extremity** of the radius is quadrilateral; its **carpal surface** [facies articularis carpea] is articular and divided by a ridge into a medial quadrilateral portion, concave for articulation with the lunate bone; and a lateral triangular portion, extending onto the styloid process for articulation with the navicular (scaphoid) bone. The medial surface, also articular, presents the **ulnar notch** (sigmoid cavity) for the reception of the rounded margin of the head of the ulna. To the border separating the ulnar and carpal articular surfaces the base of the articular disc is attached, and to the anterior and posterior borders, the anterior and posterior radio-ulnar ligaments respectively. The **anterior surface** is raised into a prominent area for the anterior ligament of the wrist-joint. The **lateral surface** is represented by the **styloid process,** a blunt pyramidal eminence, to the base of which the *brachio-radialis* is inserted, whilst the tip serves for the attachment of the radial (external) collateral ligament of the wrist. Its lateral surface is marked by two shallow furrows for the tendons of the *abductor pollicis longus* and *extensor pollicis brevis.* The **posterior surface** is convex, and marked by three prominent ridges separating three furrows. The posterior annular ligament is attached to these ridges, thus forming with the bone a series of tunnels for the passage of tendons.

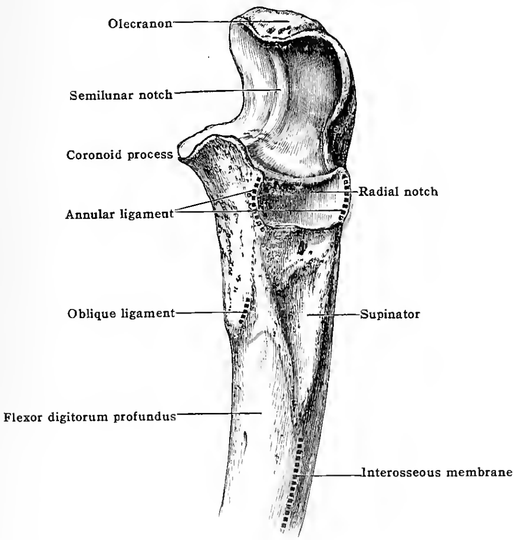
The most lateral is broad, shallow, and frequently subdivided by a low ridge. The lateral subdivision is for the *extensor carpi radialis longus*, the medial for the *extensor carpi radialis brevis* The middle groove is narrow and deep for the tendon of the *extensor pollicis longus.* The most medial is shallow and transmits the *extensor indicis proprius*, the *extensor digitorum communis*, the dorsal branch of the interosseous artery, and the dorsal interosseous nerve. When the radius and ulna are articulated, an additional groove is formed for the tendon of the *extensor quinti digiti proprius.*

Ossification.—The radius is ossified from a centre which appears in the middle of the shaft in the eighth week of intra-uterine life and from two epiphysial centres which appear after birth. The nucleus for the lower end appears in the second year, and that for the upper end, which forms simply the disc-shaped head, in the fifth year. The head unites with the shaft at the seventeenth year, whilst the inferior epiphysis and the shaft join about the twentieth year.

THE ULNA

The **ulna** (figs. 180, 181, 189) is a long, prismatic bone, thicker above than below, on the medial side of the forearm and parallel with the radius, which it

Fig. 184.—Upper End of Left Ulna. (Lateral view.)



exceeds in length by the extent of the olecranon process. It articulates at the upper end with the humerus, at the lower end indirectly with the carpus, and on the lateral side with the radius. It is divisible into a shaft and two extremities.

The **upper extremity** is of irregular shape and forms the thickest and strongest part of the bone. The superior articular surface is concave from above downward, convex from side to side, and transversely constricted near the middle. It belongs partly to the **olecranon,** the thick upward projection from the shaft, and partly to the **coronoid process,** which projects horizontally forward from the front of the ulna. This semilunar excavation forms the **semilunar notch** (greater sigmoid cavity) and articulates with the trochlear surface of the humerus. The **olecranon** is the large curved eminence forming the highest part of the bone.

The superior surface of the olecranon, uneven and somewhat quadrilateral in shape, receives behind, where there is a rough impression, the insertion of the *triceps*, and along the anterior margin the articular capsule of the elbow-joint. The posterior surface, smooth and triangular in outline, is separated from the skin by a bursa. The anterior surface, covered with cartilage in the recent state, is directed downward and forward, and its margins give attachment to the articular capsule of the elbow-joint. This surface, as already noticed, forms the upper and back part of the semilunar notch. On the medial surface of the olecranon is a tubercle for the origin of the ulnar head of the *flexor carpi ulnaris*, and in front of this a fasciculus of the ulnar collateral ligament of the elbow-joint is attached to the bone; the lateral surface is rough, concave, and gives insertion to a part of the *anconeus*. The extremity of the olecranon lies during extension of the elbow in the olecranon fossa of the humerus.

FIG. 185.—OSSIFICATION OF THE RADIUS AND ULNA; THE FIGURE ALSO SHOWS THE RELATIONS OF THE EPIPHYSIAL AND CAPSULAR LINES.

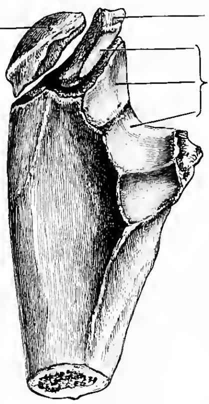
The **coronoid process,** forming the lower and anterior part of the semilunar notch, has a superior articular surface continuous with the anterior surface of the olecranon, and, like it, covered with cartilage. The inferior aspect is rough and concave, and gives insertion to the *brachialis*.

It is continuous with the volar surface of the shaft, and near the junction of the two is a rough eminence, named the **tuberosity of the ulna,** which receives the attachment of the oblique cord of the radius and the insertion of the *brachialis*. The medial side presents above a smooth tubercle for the origin of the ulnar portion of the *flexor digitorum sublimis*, and a ridge below for the lesser head of the *pronator teres* and the rounded accessory bundle of the *flexor pollicis longus*, whilst immediately behind the sublimis tubercle there is a triangular depressed surface for the upper fibres of the *flexor digitorum profundus*.

On the lateral surface is the **radial notch** (lesser sigmoid cavity), an oblong articular surface which articulates with the circumference of the head of the radius, the anterior and posterior margins of which afford attachment to the annular ligament and the radial collateral ligament of the elbow-joint. In flexion of the elbow the tip of the process is received into the coronoid fossa of the humerus.

The **body** [corpus ulnæ] or **shaft** throughout the greater part of its extent is three-sided, but tapers toward the lower extremity, where it becomes smooth and rounded. It has three borders and three surfaces. Of the three borders, the **lateral,** the **interosseous crest,** is best marked. In the middle three-fifths of the shaft it is sharp and prominent, but becomes indistinct below; above it is continued by two lines which pass to the anterior and posterior extremities of the radial notch and enclose a depressed triangular area (bicipital hollow), the fore part of which lodges the tuberosity of the radius and the insertion of the biceps tendon during pronation of the hand, while from the posterior part the *supinator* takes origin. The **interosseous crest** separates the volar from the dorsal surface and gives attachment by the lower four-fifths of its extent to the interosseous membrane. The **volar border** is directly continuous with the medial edge of the rough surface for the brachialis and terminates inferiorly in front of the styloid process.

Fig. 186.—Upper End of Ulna Showing Two Epiphyses. (E. Fawcett.)



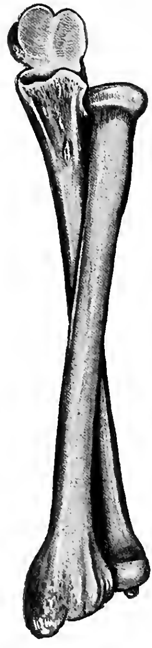
Throughout the greater part of its extent it is smooth and rounded, and affords origin to the *flexor digitorum profundus* and the *pronator quadratus.* It separates the volar from the medial surface. The **dorsal border** commences above at the apex of the triangular subcutaneous area on the back of the olecranon, and takes a sinuous course to the back part of the styloid process. The upper three-fourths gives attachment to an aponeurosis common to three muscles, viz., the *flexor* and *extensor carpi ulnaris* and the *flexor digitorum profundus.* This border separates the medial from the dorsal surface.

Surfaces.—The **volar** (or anterior) **surface** is grooved in the upper three-fourths of its extent for the origin of the *flexor digitorum profundus,* narrow and convex below, for the origin of the *pronator quadratus.* The upper limit of the area for the latter muscle is sometimes indicated by an oblique line—the **pronator ridge.** Near the junction of the upper and middle thirds of the anterior surface is the nutrient foramen, directed upward toward the proximal end of the bone. It transmits a branch of the volar interosseous artery. The **medial surface,** smooth and rounded, gives attachment, on the upper two-thirds, to the *flexor digitorum profundus,* whereas the lower third is subcutaneous. The **dorsal** (or posterior) **surface,** directed laterally as well as backward, presents at its upper part the **oblique line** of the ulna running from the posterior extremity of the radial notch to the dorsal border.

The oblique line gives attachment to a few fibres of the *supinator* and marks off the posterior surface into two unequal parts. That above the line, much the smaller of the two, receives the insertion of the *anconeus.* The more extensive part below is subdivided by a vertical ridge into a medial portion, smooth, and covered by the *extensor carpi ulnaris,* and a lateral portion which gives origin to three muscles, viz., the *abductor pollicis longus,* the *extensor pollicis longus* and the *extensor indicis proprius,* from above downward.

The **lower extremity** of the ulna is of small size and consists of two parts, the **head** and the **styloid process,** separated from each other on the inferior surface by a groove into which the apex of the articular disc is inserted. That part of the head adjacent to the groove is semilunar in shape and plays upon the articular disc which thus excludes the ulna from the radio-carpal or wrist-joint. The margin of the head is also semilunar, and is received into the ulnar notch of the radius. The **styloid process** projects from the medial and back part of the bone, and appears as a continuation of the dorsal border. To its rounded summit the ulnar collateral ligament of the wrist-joint is attached, and its dorsal surface is grooved for the passage of the tendon of the *extensor carpi ulnaris.* Immediately above the articular margin of the head the anterior and posterior radio-ulnar ligaments are attached in front and behind.

Fig. 187.—The Left Radius and Ulna in Pronation. (Anterior view.)



Ossification.—The ulna is ossified from three centres. The primary nucleus appears near the middle of the shaft in the eighth week of intra-uterine life. At birth the inferior extremity and the greater portion of the olecranon are cartilaginous. The nucleus for the lower end appears during the fourth year and the epiphysis joins with the shaft from the eighteenth to the twentieth year. The greater part of the olecranon is ossified from the shaft, but an epiphysis is subsequently formed from a nucleus which appears in the tenth year.

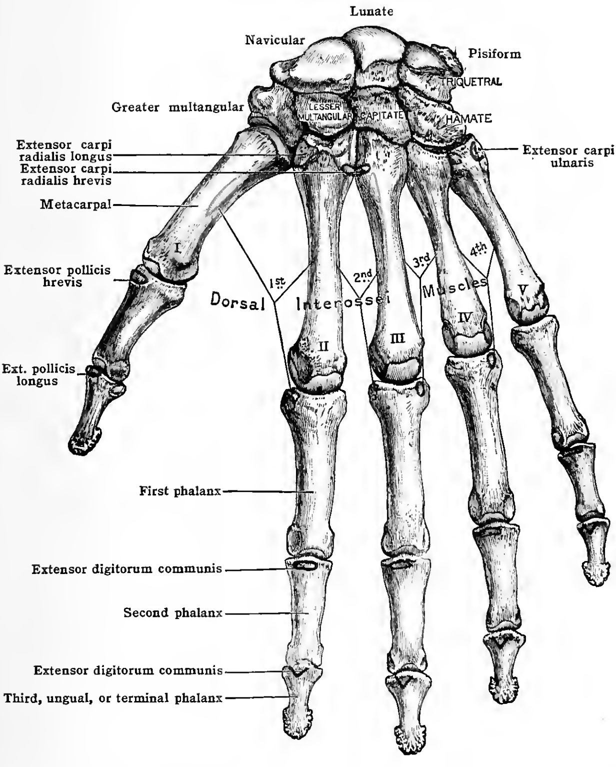
The epiphysis varies in size, and may be either scale-like and form a thin plate on the summit, or involve the upper fourth of the olecranon and the corresponding articular surface. In the latter case the epiphysis is probably composed of two parts fused together: (1) The scale on the summit of the olecranon process, and (2) the beak centre which enters into the formation of the upper end of the semilunar notch (see fig. 186). The epiphysis unites to the shaft in the sixteenth or seventeenth year.

THE CARPUS

The **carpus** (figs. 188, 189) consists of eight bones, arranged in two rows, four bones in each row. Enumerated from the radial to the ulnar side, the bones of the proximal row are named **navicular** (scaphoid), **lunate** (semilunar), **triquetral** (cuneiform), and **pisiform**; those of the distal row, **greater multangular** (trapezium), **lesser multangular** (trapezoid), **capitate** (os magnum), and **hamate** (unciform).

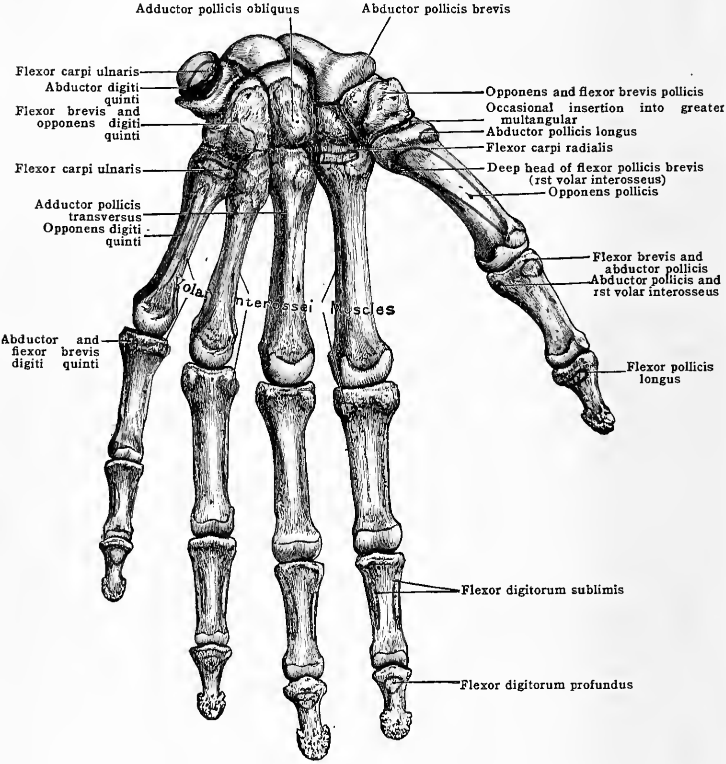
When the bones of the carpus are articulated, they form a mass somewhat quadrangular in outline, wider below than above, and with the long diameter transverse. The dorsal surface is convex and the volar surface concave from side to side. The concavity is increased by four prominences, which project forward, one

FIG. 188.—BONES OF THE LEFT HAND. (Dorsal surface.)



from each extremity of each row. On the radial side are the tuberosity of the navicular and the ridge of the greater multangular; on the ulnar side, the pisiform and the hook of the hamate. Stretched transversely between these prominences, in the recent state, is the transverse carpal ligament forming a canal for the passage of the flexor tendons and the median nerve into the palm of the hand. The proximal border of the carpus is convex and articulates with the distal end of the radius and the articular disc. The pisiform, however, takes no share in this articulation, being attached to the volar surface of the triquetral. The distal border forms an undulating articular surface for the bases of the metacarpal bones. The line of articulation between the two rows of the carpus is concavo-convex from side to side, the lateral part of the navicular being received into the concavity formed by the greater multangular, lesser multangular, and capitate, and the capitate and hamate into that formed by the navicular, lunate, and triquetral bones.

Fig. 189.—Bones of the Left Hand. (Volar surface.)



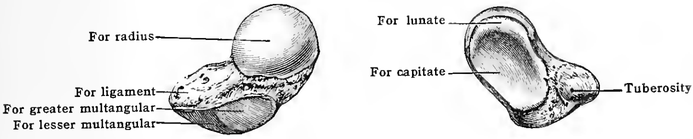
The individual carpal bones have several points of resemblance. Each bone (excepting the pisiform) has six surfaces, of which the anterior or volar and posterior or dorsal are rough for the attachment of ligaments, the volar surface being the broader in the proximal row, the dorsal surface in the distal row. The superior and inferior surfaces are articular, the former being generally convex and the latter concave. The lateral surfaces, when in contact with adjacent bones, are also articular, but otherwise rough for the attachment of ligaments. Further, the whole of the carpus is cartilaginous at birth and each bone is ossified from a single centre.

The Navicular

The **navicular** [os naviculare] or scaphoid (fig. 190) is the largest bone of the proximal row, and so disposed that its long axis runs obliquely downward and lateralward.

The superior surface is convex and somewhat triangular in shape for articulation with the lateral facet on the distal end of the radius. The **inferior surface,** smooth and convex, is divided into two parts by a ridge running from before backward. The lateral part articulates with the greater multangular, the medial with the lesser multangular. The **volar surface**, rough and concave above, is elevated below into a prominent **tubercle** for the attachment of the transverse carpal ligament and the *abductor pollicis brevis*. The **dorsal surface** is narrow, being reduced

Fig. 190.—The Left Navicular.



to a groove running the whole length of the bone; it is rough and serves for the attachment of the dorsal radio-carpal ligament. The **medial surface** is occupied by two articular facets, of which the upper is crescentic in shape for the lunate bone, whilst the lower is deeply concave for the reception of the head of the capitate. The **lateral surface** is narrow and rough for the attachment of the radial collateral ligament of the wrist-joint.

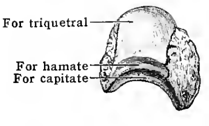
Articulations.—With the radius above, greater and lesser multangular below, lunate and capitate medially.

The Lunate

The **lunate** [os lunatum] or semilunar (fig. 191), placed in the middle of the proximal row of the carpus, is markedly crescentic in outline.

The **superior surface** is smooth and convex and articulates with the medial of the two facets on the distal end of the radius. The **inferior surface** presents a deep concavity divided into two parts by a line running from before backward. Of these, the lateral and larger articulates with the capitate; the medial and smaller with the hamate. The **volar surface** is large and convex,

Fig. 191.—The Left Lunate.



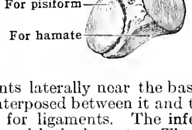
the **dorsal surface** narrow and flat, and both are rough for the attachment of ligaments. The **medial surface** is marked by a smooth quadrilateral facet for the base of the triquetral. The **lateral surface** forms a narrow crescentic articular surface for the lunate.

Articulations.—With the radius above, capitate and hamate below, navicular laterally and triquetral medially.

The Triquetral

The **triquetral** [os triquetrum] or cuneiform (fig. 192) is pyramidal in shape and placed obliquely, so that its base looks upward and laterally and the apex downward and medially.

Fig. 192.—The Left Triquetral.



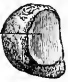
The **superior surface** presents laterally near the base a small, convex articular facet which plays upon the articular disc interposed between it and the distal end of the ulna, and medially a rough non-articular portion for ligaments. The **inferior surface** forms a large, triangular undulating facet for articulation with the hamate. The **volar surface** can be readily recognised by the conspicuous oval facet near the apex for the pisiform bone. The **dorsal surface** is rough for the attachment of ligaments. The **medial** and **lateral surfaces** are represented by the base and the apex of the pyramid. The base is marked by a flat quadrilateral facet for the lunate. The apex forms the lowest part of the bone and is roughened for the attachment of the ulnar collateral ligament of the wrist.

Articulations.—With the pisiform in front, lunate laterally, hamate below, articular disc above.

The Pisiform

The **pisiform** [os pisiforme] (fig. 193), the smallest of the carpal bones, is in many of its characters a complete contrast to the rest of the series. It deviates from the general type in its shape, size, position, use, and development. Forming a rounded bony nodule with the long axis directed vertically, it is situated on a plane in front of the other bones of the carpus.

Fig. 193.—The Left Pisiform.

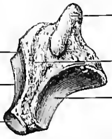


On the **dorsal surface** is a single articular facet for the triquetral which reaches to the upper end of the bone, but leaves a free non-articular portion below. The **volar surface**, rough and rounded, gives attachment to the transverse carpal ligament, the *flexor carpi ulnaris*, the *abductor quinti digiti*, the piso-metacarpal and the piso-hamate ligaments. The median and lateral surfaces are also rough and the lateral presents a shallow groove for the ulnar artery. It is usually considered that the pisiform is a sesamoid bone developed in the tendon of the *flexor carpi ulnaris*, though by some writers it is regarded as part of a rudimentary digit.

The Greater Multangular

The **greater multangular** [os multangulum majus] or trapezium (fig. 194), situated between the navicular and first metacarpal, is oblong in form with the lower angle prolonged downward and medially.

Fig. 194.—The Left Greater Multangular.



The **superior surface** is concave and directed upward and medially for articulation with the lateral of the two facets on the distal surface of the navicular, and on the **inferior surface** is a saddle-shaped facet for the base of the first metacarpal. The **volar surface** presents a prominent ridge with a deep groove on its medial side which transmits the tendon of the *flexor carpi radialis*. The **ridge** gives attachment to the transverse carpal ligament, the *abductor pollicis brevis*, the *opponens pollicis*, and occasionally a tendinous slip of insertion of the *abductor pollicis longus*. The **dorsal** and **lateral surfaces** are rough for ligaments. The **medial surface** is divided into two parts by a horizontal ridge. The upper and larger portion is concave and articulates with the lesser multangular; the lower—a small flat facet on the projecting lower angle—articulates with the base of the second metarcarpal.

Articulations.—With the navicular above, first metacarpal below, the lesser multangular and second metacarpal on the medial side.

The Lesser Multangular

The **lesser multangular** [os multangulum minus] or trapezoid (fig. 195), the smallest of the bones in the distal row, is somewhat wedge-shaped, with the broader end dorsally and the narrow end ventrally.

Fig. 195.—The Left Lesser Multangular.

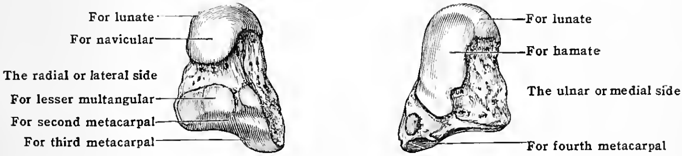
The **superior** surface is marked by a small, quadrilateral, concave facet, for the media of the two facets on the lower surface of the navicular. The **inferior surface** is convex from side to side and concave from before backward, forming a saddle-shaped articular surface for the base of the second metacarpal. Of the **volar** and **dorsal surfaces**, the former is narrow and rough, the latter broad and rounded, constituting the widest surface of the bone, and both are rough for the attachment of ligaments. The **lateral surface** slopes downward and medially and is convex for articulation with the corresponding surface of the greater multangular. On the **medial surface** in front is a smooth flat facet for the capitate; elsewhere it is rough for ligaments.

Articulations.—With the navicular above, second metacarpal below, greater multangular laterally, and the capitate medially.

THE CAPITATE

The **capitate** [os capitatum] or os magnum (fig. 196) is the largest bone of the carpus. Situated in the centre of the wrist, the upper expanded portion, globular in shape and known as the **head,** is received into the concavity formed above by the navicular and lunate. The cubical portion below forms the **body,** whilst the intermediate constricted part is distinguished as the **neck.**

FIG. 196.—THE LEFT CAPITATE.



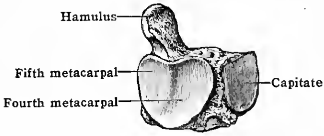
Of the six surfaces, the **superior** is smooth and convex, elongated from before backward for articulation with the concavity of the lunate bone. The **inferior surface** is divided into three unequal parts by two ridges. The middle portion, much the larger, articulates with the base of the third metacarpal; the lateral, narrow and concave, looks lateral as well as downward to articulate with the second metacarpal, whilst the medial portion is a small facet, placed on the projecting angle of the bone dorsally, for the fourth metacarpal bone. The **volar surface** is convex and rough, giving origin to fibres of the oblique *adductor pollicis;* the **dorsal surface** is broad and deeply concave. The **lateral surface** presents, from above downward:—(1) a smooth convex surface, forming the outer aspect of the head, with the superior surface of which it is continuous, for articulation with the navicular; (2) a groove representing the neck, indented for ligaments; (3) a small facet, flat and smooth, for articulation with the lesser multangular. Behind this facet is a rough area for attachment of an interosseous ligament. The **medial surface** has extending along its whole hinder margin an oblong articular surface for the hamate; the lower part of this smooth area sometimes forms a detached facet. The volar part of the surface is rough for an interosseous ligament.

Articulations.—With the lunate and navicular above, second, third, and fourth metacarpals below, lesser multangular laterally, and hamate medially.

THE HAMATE

The **hamate** [os hamatum] or unciform (fig. 197) is a large wedge-shaped bone, bearing a hook-like process, situated between the capitate and triquetral, with the base directed downward and resting on the two medial metacarpals.

FIG. 197.—THE LEFT HAMATE.



The apex of the wedge forms the narrow **superior surface,** directed upward and laterally for articulation with the lunate. The **inferior surface** or base is divided by a ridge into two quadrilateral facets for the fourth and fifth metacarpal bones. The **volar surface** is triangular in outline and presents at its lower part a prominent **hamulus** (unciform process), a hook-like eminence, projecting forward and curved toward the carpal canal. It is flattened from side to side so as to present two surfaces, two borders, and a free extremity. To the latter the transverse carpal ligament and the *flexor carpi ulnaris* (by means of the piso-hamate ligament) are attached, whilst the medial surface affords origin to the *flexor brevis* and the *opponens digiti quinti.* The lateral surface is concave and in relation to the flexor tendons. The **dorsal surface** is triangular and rough for ligaments. The **lateral surface** has extending along its upper and hinder edges a long flat surface, wider above than below, for articulation with the capitate. In front of this articular facet the surface is rough for the attachment of an interosseous ligament. The **medial surface** is oblong and undulating, i. e., concavo-convex from base to apex, for articulation with the triquetral.

Articulations.—With the triquetral, lunate, capitate, and the fourth and fifth metacarpal bones.

Ossification of the Carpal Bones

Capitate	first year	Greater multangular	fifth year
Hamate	second year	Navicular	sixth year
Triquetral	third year	Lesser multangular	eighth year
Lunate	fourth year	Pisiform	twelfth year

Additional carpal elements are occasionally met with. The **os centrale** occurs normally in the carpus of many mammals, and in the human fœtus of two months it is present as a small cartilaginous nodule which soon becomes fused with the cartilage of the navicular. Failure of fusion, with subsequent ossification of the nodule, leads to the formation of an os centrale in the human carpus which is then found on the dorsal aspect, between the navicular, capitate, and lesser multangular. In most individuals, however, it coalesces with the navicular or undergoes suppression.

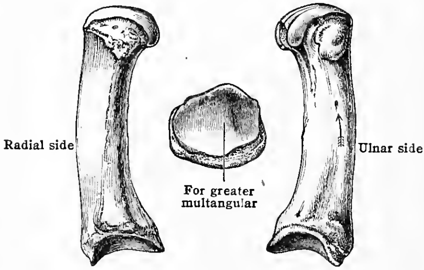
An additional centre of ossification, leading to the formation of an accessory carpal element, occasionally appears in connection with the greater multangular and the hamate. An accessory element (*os Vesalianum*) also occurs occasionally in the angle between the hamate and the fifth metacarpal, and others occur between the second and third metacarpals and the lesser multangular and capitate.

THE METACARPALS

The **metacarpus** (figs. 188, 189) consists of a series of five cylindrical bones [ossa metacarpalia], well described as 'long bones in miniature.' Articulated with the carpus above, they descend, slightly diverging from each other, to support the fingers, and are numbered from the lateral to the medial side. With the exception of the first, which in some respects resembles a phalanx, they conform to a general type.

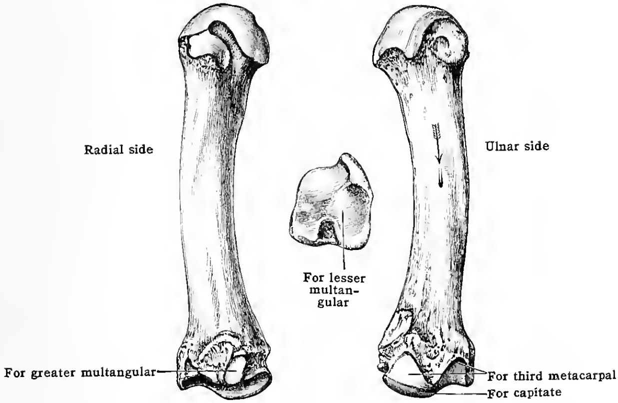
A typical metacarpal bone presents for examination a shaft and two extremities. The **body** or **shaft** is prismatic and curved so as to be slightly convex toward the back of the hand. Of the three surfaces, two are **lateral** in position,

Fig. 198.—The First (Left) Metacarpal.



separated in the middle part of the shaft by a prominent palmar ridge, and concave for the attachment of *interosseous* muscles. The third or **dorsal surface** presents for examination a large, smooth, triangular area with the base below and apex above, covered in the recent state by the extensor tendons of the fingers, and two sloping areas, near the carpal extremity, also for *interosseous* muscles. The triangular area is bounded by two lines, which commence below in two dorsal tubercles, and, passing upward, converge to form a median ridge situated between the sloping areas on either side. A little above or below the middle of the shaft, and near the volar border, is the medullary foramen, entering the bone obliquely upward. The **base** or carpal extremity, broader behind than in front, is quadrilateral, and both palmar and dorsal surfaces are rough for ligaments; it articulates above with the carpus and on each side with the adjacent metacarpal bones. The **head** [capitulum] or digital extremity presents a large rounded articular surface, extending further on the palmar than on the dorsal aspect, for articulation with the base of the first phalanx. The volar surface is grooved for the flexor tendons and raised on each side into an articular eminence. On each side of the head is a prominent tubercle, and immediately in front of this a well-marked fossa, to both of which the collateral ligament of the metacarpo-phalangeal joint is attached.

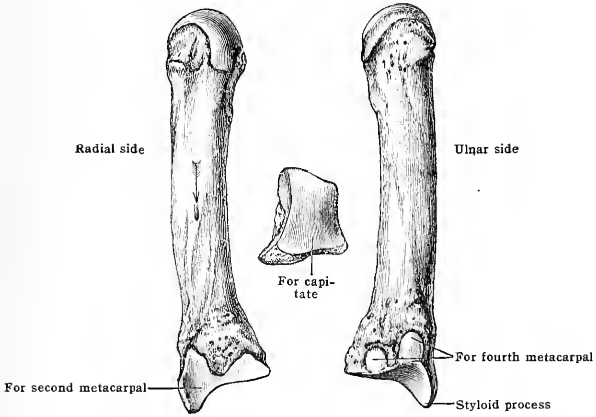
FIG. 199.—THE SECOND (LEFT) METACARPAL.



The second is the longest of all the metacarpal bones, and the third, fourth, and fifth successively decrease in length. The several metacarpals possess distinctive characters by which they are readily identified.

The **first metacarpal** (fig. 198) is the shortest and widest of the series. Diverging from the carpus more widely than any of the others the **palmar surface** is directed medially and marked

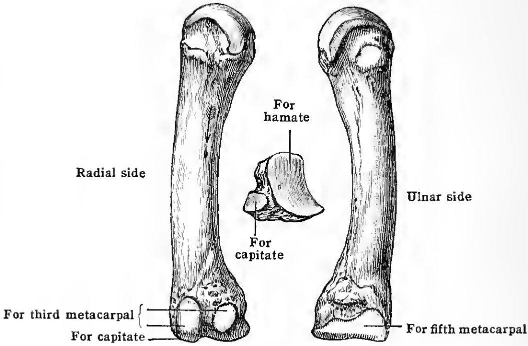
FIG. 200.—THE THIRD (LEFT) METACARPAL.



by a ridge placed nearer to the medial border. The lateral portion of the surface slopes gently to the lateral border and gives attachment to the *opponens pollicis;* the medial portion, the smaller of the two, slopes more abruptly to the medial border, is in relation to the deep head of the *flexor pollicis brevis,* and presents the nutrient foramen, directed downward toward the head of the bone and transmitting a branch of the arteria princeps pollicis. The **dorsal surface,** wide and flattened, is in relation to the tendons of the *extensor pollicis longus* and *brevis.*

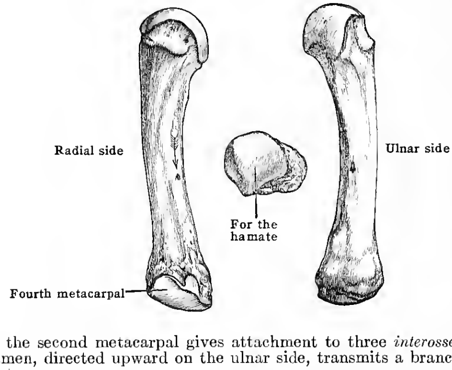
The **base** presents a saddle-shaped articular surface for the greater multangular, prolonged in front into a thin process. There are no lateral facets, but laterally a small tubercle receives the insertion of the *abductor pollicis longus*. Medially is a rough area from which fibres of the inner head of the *flexor pollicis brevis* take origin. The margin of the articular surface gives attachment to the articular capsule of the carpo-metacarpal joint. The inferior extremity or **head** is rounded and articular, for the base of the first phalanx; the greatest diameter is from side to side and the surface is less convex than the corresponding surface of the other metacarpal bones. On the volar surface it presents two articular eminences corresponding to the two sesamoid bones of the thumb. Of the two margins, the medial gives origin to the lateral head of the *first dorsal interosseous*, the lateral receives fibres of insertion of the *opponens pollicis*.

Fig. 201.—The Fourth (Left) Metacarpal.



The second metacarpal (fig. 199).—The distinctive features of the four remaining metacarpals are almost exclusively confined to the carpal extremities. The second is easily recognised by its deeply cleft base. The terminal surface presents three articular facets, arranged as follows, from lateral to medial border:—(1) a small oval facet for the greater multangular; (2) a hollow for the lesser multangular; and (3) an elongated ridge for the capitate. The dorsal surface is rough for the insertions of the *extensor carpi radialis longus* and a part of the *extensor carpi radialis brevis;* the palmar surface receives the insertion of the *flexor carpi radialis* and gives origin to a few fibres of the *oblique adductor pollicis*. The lateral aspect of the extremity is rough and non-articular; the medial surface bears a bilobed facet for the third metacarpal.

Fig. 202.—The Fifth (Left) Metacarpal.



The shaft of the second metacarpal gives attachment to three *interosseous* muscles, and the nutrient foramen, directed upward on the ulnar side, transmits a branch of the second volar metacarpal artery.

The third metacarpal (fig. 200) is distinguished by the prominent **styloid process** projecting upward from the lateral and posterior angle of the base. Immediately below it, on the dorsal surface, is a rough impression for the *extensor carpi radialis brevis*. The carpal surface is concave behind and convex in front, and articulates with the middle of the three facets on the inferior surface of the capitate. On the lateral side is a bilobed articular facet for the second metacarpal, and on the medial side two small oval facets for the fourth metacarpal. The volar aspect of the base is rough and gives attachment to fibres of the *oblique adductor pollicis* and sometimes a slip of insertion of the *flexor carpi radialis*. The shaft of the third metacarpal serves for the origin of the transverse *adductor pollicis* and two *interosseous* muscles. The nutrient foramen is directed upward on the radial side and transmits a branch of the second volar metacarpal artery.

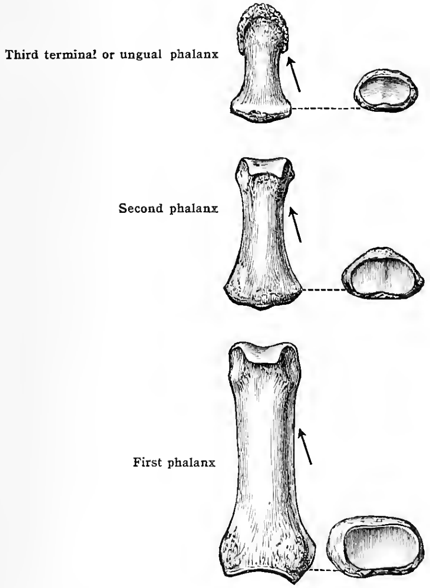
The **fourth metacarpal** (fig. 201) has a small base. The carpal surface presents two facets: a medial, large and flat, for articulation with the hamate, and a small facet, at the lateral and posterior angle, for the capitate. On the lateral side are two small oval facets for the corresponding surfaces on the third metacarpal and a single concave facet on the medial side for the fifth metacarpal. The shaft of the fourth metacarpal gives attachment to three *interosseous* muscles, and the nutrient foramen, directed upward on the radial side, transmits a branch of the third volar metacarpal artery.

The **fifth metacarpal** (fig. 202) is distinguished by a semilunar facet on the lateral side of the base for the fourth metacarpal, and a rounded tubercle on the medial side for the *extensor carpi ulnaris*, in place of the usual medial facet. The carpal surface is saddle-shaped for the hamate; the palmar surface is rough for ligaments including the piso-metacarpal prolongation from the *flexor carpi ulnaris*. The dorsal surface of the shaft presents an *oblique line* separating a lateral concave portion for the fourth dorsal *interosseous* muscle from a smooth medial portion covered by the extensor tendons of the little finger. The palmar surface gives attachment laterally to the third palmar *interosseous* muscle and medially to the *opponens digiti quinti*. The nutrient foramen is directed upward on the radial side and transmits a branch of the fourth volar metacarpal artery.

THE PHALANGES

The **phalanges** (fig. 203) are the bones of the fingers, and number in all fourteen. Each finger consists of three phalanges distinguished as first or proximal, second

FIG. 203.—THE PHALANGES OF THE THIRD DIGIT OF THE HAND. (Dorsal view.)
[The arrows indicate the direction of the nutrient canals.]



or middle, and third or distal. In the thumb, the second phalanx is wanting. Arranged in horizontal rows, the phalanges of each row resemble one another and differ from those of the other two rows. In all the phalanges the nutrient canal is directed downward, toward the distal extremity.

First phalanx.—The shaft of a phalanx from the first row is flat on the palmar surface, smooth and rounded on the dorsal surface, i. e., semi-cylindrical in shape. The borders of the palmar surface are rough for the attachment of the sheaths of the flexor tendons. The base or metacarpal extremity presents a single concave articular surface, oval in shape, for the convex head of the metacarpal bone. The distal extremity forms a pulley-like surface, grooved in the centre and elevated at each side to form two miniature condyles, for articulation with the base of a second phalanx.

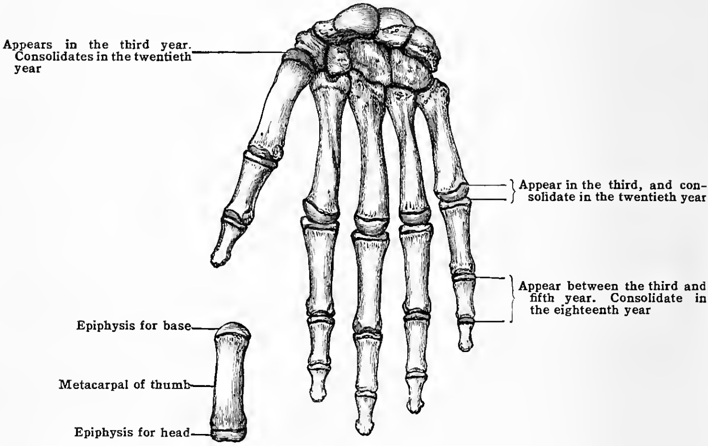
Second phalanx.—The second phalanges are four in number and are shorter than those of the first row, which they closely resemble in form. They are distinguished, however, by the articular surface on the proximal extremity, which presents two shallow depressions, separated by a ridge and corresponding to the two condyles of the first phalanx. The distal end for the base of the third phalanx is trochlear or pulley-like, but smaller than that of the first phalanx. The palmar surface of the shaft presents on each side an impression for the tendon of the *flexor digitorum sublimis*, and the dorsal aspect of the base is marked by a projection for the insertion of the *extensor digitorum communis*.

Third phalanx.—A third phalanx is readily recognised by its small size. The proximal end is identical in shape with that of a second phalanx, and bears a depression in front for the tendon of the *flexor digitorum profundus*. The free, flattened and expanded distal extremity presents on its palmar surface a rough semilunar elevation for the support of the pulp of the finger. The somewhat horseshoe-shaped free extremity is known as the **ungual tuberosity** [tuberositas unguicularis], and the bone is accordingly referred to as the **ungual phalanx.**

Ossification of the Metacarpus and Phalanges

Each of the metacarpal bones and phalanges is ossified from a primary centre for the greater part of the bone, and from one epiphysial centre. The primary nucleus appears from the eighth to the tenth week of intra-uterine life. In four metacarpal bones the epiphysis is distal, whilst

Fig. 204.—Ossification of the Metacarpals and Phalanges.



in the first metacarpal bone, and in all the phalanges, it is proximal. The epiphysial nuclei appear from the third to the fifth year and are united to their respective shafts about the twentieth year. In many cases the first metacarpal has two epiphyses, one for the base in the third year and an additional one for the head in the seventh year, but the latter is never so large as in the other metacarpal bones. The third metacarpal occasionally has an additional nucleus for the prominent styloid process which may remain distinct and form a *styloid bone,* and traces of a proximal epiphysis have been observed in the second metacarpal bone. In many of the Cetacea (whales, dolphins, and porpoises) and in the seal, epiphyses are found at both ends of the metacarpal bones and phalanges (Flower).

The ossification of a terminal phalanx is peculiar. Like the other phalanges, it has a primary nucleus and a secondary nucleus for an epiphysis. But whereas in other phalanges the primary centre appears in the middle of the shaft, in the case of the distal phalanges the earthy matter is deposited in the free extremity.

Sesamoid Bones

The sesamoid bones are small and rounded and occur imbedded in certain tendons where they exert a considerable amount of pressure on subjacent bony structures. In the hand five sesamoid bones are of almost constant occurrence, namely, two over the metacarpo-phalangeal joint of the thumb in the tendons of the flexor pollicis brevis, one over the interphalangeal joint of the thumb, and one over the metacarpo-phalangeal joints of the second and fifth fingers.

Occasionally sesamoids occur over the metacarpo-phalangeal joint of the third and fourth digits, and an additional one may occur over that of the fifth.

Very rarely a sesamoid is developed in the tendon of the biceps over the tuberosity of the radius.

B. THE BONES OF THE LOWER EXTREMITY

The bones of the lower extremity may be arranged in four groups corresponding to the division of the limb into the *hip, thigh, leg,* and *foot.* In the *hip* is the coxal or hip-bone, which constitutes the pelvic girdle [cingulum extremitatis inferioris], and contributes to the formation of the pelvis; in the *thigh* is the femur; in the *leg,* the tibia and fibula, and in the *foot* the tarsus, metatarsus, and phalanges. Associated with the lower end of the femur is a large sesamoid bone, the patella or knee-cap.

THE COXAL BONE

The **coxal** (innominate) **bone** or hip-bone [os coxæ] (figs. 205, 206) is a large, irregularly shaped bone articulated behind with the sacrum, and in front with its fellow of the opposite side, the two bones forming the anterior and side walls of the pelvis. The coxal bone consists of three parts, named **ilium, ischium,** and **pubis,** which, though separate in early life, are firmly united in the adult. The three parts meet together and form the **acetabulum** (or cotyloid fossa), a large, cup-like socket situated near the middle of the lateral surface of the bone for articulation with the head of the femur.

The **ilium** [os ilium] is the upper expanded portion of the bone, and by its inferior extremity forms the upper two-fifths of the acetabulum. It presents for examination three borders and two surfaces.

Borders.—When viewed from above, the thick **crest** [crista iliaca] or superior border is curved somewhat like the letter *f,* being concave medially in front and concave laterally behind. Its anterior extremity forms the **anterior superior iliac spine,** which gives attachment to the inguinal (Poupart's) ligament and the *sartorius;* the posterior extremity forms the **posterior superior iliac spine** and affords attachment to the sacro-tuberous (great sacro-sciatic) ligament, the posterior sacro-iliac ligament, and the *multifidus.* The crest is narrow in the middle, thick at its extremities, and may be divided into an inner lip, an outer lip, and an intermediate line. About two and a half inches from the anterior superior spine is a prominent tubercle on its external lip.

The external lip of the crest gives attachment in front to the *tensor fasciæ latæ;* along its whole length, to the *fascia lata;* along its anterior half to the *external oblique;* and behind this, for about an inch, to the *latissimus dorsi.* The anterior two-thirds of the intermediate line gives origin to the *internal oblique.* The internal lip gives origin, by its anterior two-thirds, to the *transversus;* behind this is a small area for the *quadratus lumborum,* and the remainder is occupied by the *sacro-spinalis* (*erector spinæ*). The internal lip, in the anterior two-thirds, also serves for the attachment of the iliac fascia.

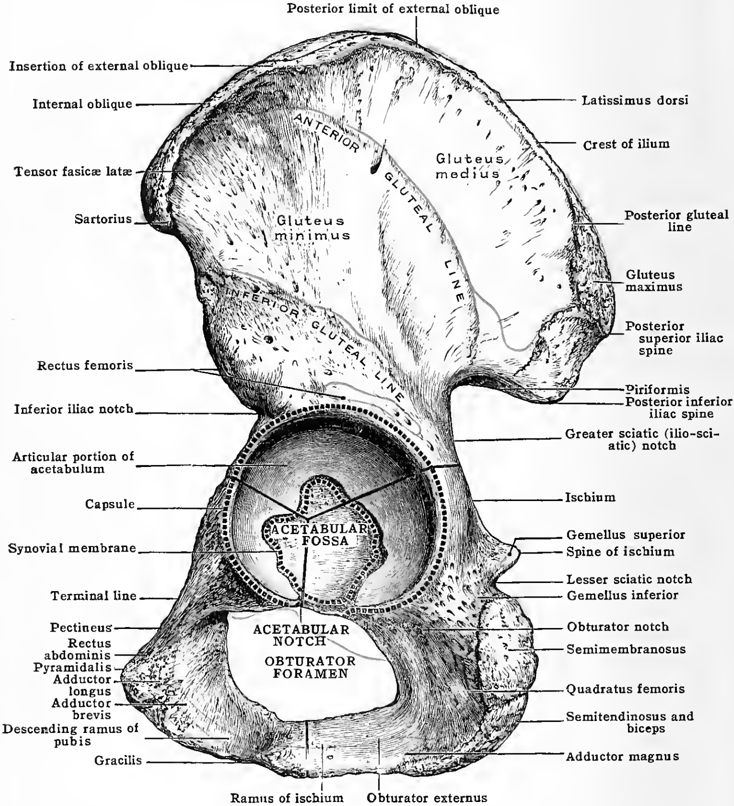
The **anterior border** of the ilium extends from the **anterior superior iliac spine** to the margin of the acetabulum. Below the spine is a prominent notch from which fibres of the *sartorius* arise, and this is succeeded by the **anterior inferior iliac spine,** smaller and less prominent than the superior, to which the straight head of the *rectus* and the ilio-femoral ligament are attached. On the medial side of the anterior inferior spine is a broad, shallow groove for the *ilio-psoas* as it passes from the abdomen into the thigh, limited below by the **ilio-pectineal** eminence, which indicates the point of union of the ilium and pubis.

The **posterior border** of the ilium presents the **posterior superior iliac spine,** and below this, a shallow notch terminating in the **posterior inferior iliac spine** which corresponds to the posterior extremity of the auricular surface and gives attachment to a portion of the sacro-tuberous (great sacro-sciatic) ligament. Below the spine the posterior border of the ilium forms the upper limit of the greater sciatic notch.

Surfaces.—The **external surface** or **dorsum** is concave behind, convex in front, limited above by the thick superior border or **crest,** and traversed by three gluteal lines.

The posterior gluteal line commences at the crest about two inches from the posterior superior iliac spine and curves downward to the upper margin of the greater sciatic notch. The space included between this ridge and the crest affords origin at its upper part to the *gluteus maximus*, and at its lower part, to a few fibres of the *piriformis*, while the intermediate portion is smooth and free from muscular attachment. The **anterior gluteal line** begins at the crest, one inch behind its anterior superior iliac spine, and curves across the dorsum to terminate near the lower end of the superior line, at the upper margin of the greater sciatic notch. The surface of bone between this line and the crest is for the origin of the *gluteus medius*. The **inferior gluteal line** commences at the notch immediately below the anterior

FIG. 205.—THE LEFT COXAL OR HIP-BONE. (Lateral view.)



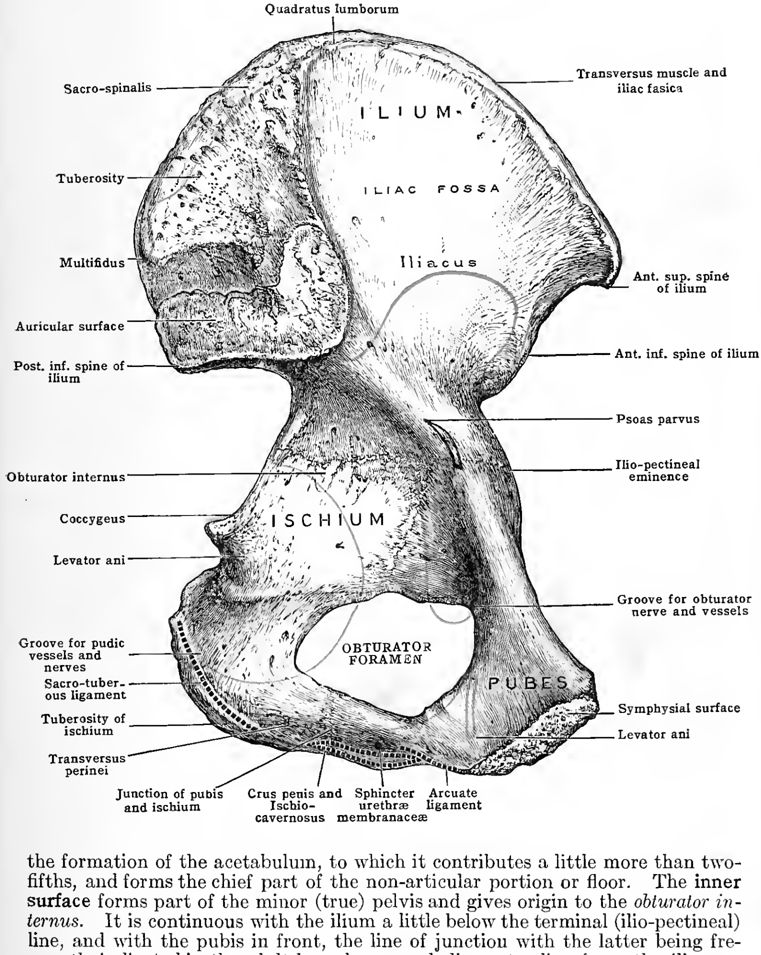
superior iliac spine and terminates posteriorly at the front part of the greater sciatic notch. The space between the anterior and inferior gluteal lines, with the exception of a small area adjacent to the anterior end of the spine for the *tensor fasciæ latæ*, gives origin to the *gluteus minimus*. Between the inferior gluteal line and the margin of the acetabulum the surface affords attachment to the capsule of the hip-joint, and on a rough area (sometimes a depression) toward its anterior part, to the *reflected tendon of the rectus femoris*.

The **internal surface** presents in front a smooth concave portion termed the **iliac fossa**, which lodges the *iliacus* muscle. The fossa is limited below by linea arcuata, the iliac portion of the terminal (ilio-pectineal) line. This is a rounded border separating the fossa from a portion of the internal surface below the line, which gives attachment to the *obturator internus* and enters into the formation of the minor (true) pelvis. Behind the iliac fossa the bone is uneven and presents

an auricular surface, covered with cartilage in the recent state, for articulation with the lateral aspect of the upper portion of the sacrum; above the auricular surface are some depressions for the posterior sacro-iliac ligaments and a rough area reaching as high as the crest, from which parts of the *sacro-spinalis* (*erector spinæ*) and *multifidus* take origin. The rough surface above the auricular facet is known as the **tuberosity of the ilium.**

The **ischium** [os ischii] consists of a body, a tuberosity, and a ramus. The **body,** which has somewhat the form of a triangular pyramid, enters superiorly into

Fig. 206.—The Left Coxal or Hip-bone. (Medial aspect.)



the formation of the acetabulum, to which it contributes a little more than two-fifths, and forms the chief part of the non-articular portion or floor. The **inner surface** forms part of the minor (true) pelvis and gives origin to the *obturator internus.* It is continuous with the ilium a little below the terminal (ilio-pectineal) line, and with the pubis in front, the line of junction with the latter being frequently indicated in the adult bone by a rough line extending from the ilio-pectineal eminence to the margin of the obturator foramen. The **outer surface** includes the portion of the acetabulum formed by the ischium. The **posterior surface** is broad and bounded laterally by the margin of the acetabulum and behind by the posterior border. The capsule of the hip-joint is attached to the lateral part and the *piriformis*, the great sciatic and posterior cutaneous nerves, the inferior gluteal (sciatic) artery, and the nerve to the *quadratus femoris* lie on the surface as they leave the pelvis. Inferiorly this surface is limited by the **obturator groove**, which receives the posterior fleshy border of the *obturator externus* when the thigh is flexed. Of the three borders, the **external**, forming the prominent rim of the acetabulum, separates the posterior from the external surface and gives attachment to the glenoid lip. The **inner border** is sharp and forms the lateral boundary of the obturator foramen. The **posterior border** is continuous with the posterior border of the ilium, with which it joins to complete the margin of the **great sciatic notch** [incisura ischiadica major]. The notch is converted into a foramen by the sacro-spinous (small sacro-sciatic) ligament, and transmits the *piriformis* muscle, the gluteal vessels, the superior and inferior gluteal nerves, the sciatic and posterior cutaneous nerves, the internal pudic vessels and nerve, and the nerves to the *obturator internus* and *quadratus femoris*. Below the notch is the prominent **ischial spine**, which gives attachment internally to the *coccygeus* and *levator ani*, externally to the *gemellus superior*, and at the tip to the sacro-spinous ligament. Below the spine is the **small sciatic notch** [incisura ischiadica minor], covered in the recent state with cartilage, and converted into a foramen by the sacro-tuberous (great sacro-sciatic) ligament. It transmits the tendon of the *obturator internus*, its nerve of supply, and the internal pudic vessels and nerve.

The **rami** form the flattened part of the ischium which runs first downward, then upward, forward and medially from the tuberosity toward the inferior ramus of the pubis, with which it is continuous. The **rami** together form an **L**-shaped structure with an upper vertical ramus [ramus superior] and a lower horizontal ramus [ramus inferior]. The outer surface of the rami gives origin to the *adductor magnus* and *obturator externus;* the inner surface, forming part of the anterior wall of the pelvis, receives the crus penis (or clitoridis) and the *ischio-cavernosus*, and gives origin to a part of the *obturator internus*. Of the two borders, the upper is thin and sharp, and forms part of the boundary of the obturator foramen; the lower is rough and corresponds to the inferior ramus. It is somewhat everted and gives attachment to the fascia of Colles, and the *transversus perinei*. To a ridge immediately above the impression for the crus penis (or clitoridis) and the *ischio-cavernosus*, the urogenital trigone (triangular ligament) is attached. The posterior and inferior aspect of the superior ramus is an expanded area forming the **tuberosity** [tuber ischiadicum].

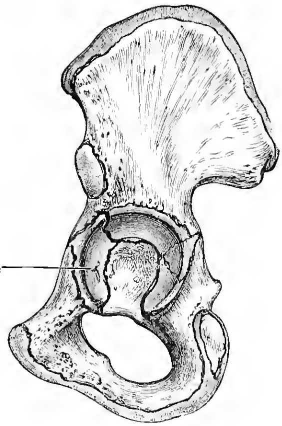
The **tuberosity** is that portion of the ischium which supports the body in the sitting posture. It forms a rough, thick eminence continuous with the inferior border of the inferior ramus, and is marked by an oblique line separating two impressions, an upper and lateral for the *semimembranosus*, and a lower and medial for the common tendon of the *biceps* and *semitendinosus*, while the lower part is markedly uneven and gives origin to the *adductor magnus*. The upper border gives origin to the *inferior gemellus;* the inner border, sharp and prominent, receives the sacro-tuberous (great sacro-sciatic) ligament, while the surface of the tuberosity immediately in front is in relation with the internal pudic vessels and nerve. The outer border gives origin to the *quadratus femoris*.

The **pubis** [os pubis] consists of a **body** and two **rami**—superior and inferior. The **body** is somewhat quadrilateral in shape and presents for examination two surfaces and three borders. The **anterior surface** looks downward, forward and slightly outward, and gives origin to the *adductor longus*, the *adductor brevis*, the *obturator externus*, and the *gracilis*. The **posterior surface** is smooth, looks into the pelvis, and affords origin to the *levator ani*, the *obturator internus*, and the pubo-prostatic ligaments. The **upper border** or crest of the body is rough and presents laterally a prominent bony point, known as the **tubercle** [tuberculum pubicum] or spine, for the attachment of the inguinal (Poupart's) ligament. The upper border extends from the pubic tubercle medialward to the upper end of the symphysis, with which it forms the *angle* of the pubis. The upper border is a short horizontal ridge, which gives attachment to the *rectus abdominis* and *pyramidalis*. The **medial border** is oval in shape, rough, and articular, forming with the bone of the opposite side the *symphysis pubis* [facies symphyseos]. The **lateral border** is sharp and forms part of the boundary of the obturator foramen.

The **inferior ramus,** like the inferior ramus of the ischium, with which it is continuous, is thin and flattened. To its **anterior surface** are attached the *adductor brevis, adductor magnus,* and *obturator externus.* The **posterior surface** is smooth and gives attachment to the *crus penis* or *clitoridis*, the *sphincter urethræ* (urogenitalis), the *obturator internus,* and the urogenital trigone (triangular ligament). The **lateral border** forms part of the circumference of the obturator foramen, and the **medial border** forms part of the pubic arch and gives attachment to the *gracilis.*

The **superior ramus** extends from the body of the pubis to the ilium, forming by its lateral extremity the anterior one-fifth of the articular surface of the acetabulum. It is prismatic in shape and increases in size as it passes laterally. Above it presents a sharp ridge, the **pecten** or pubic portion of the terminal (ilio-pectineal) line continuous with the iliac portion at the ilio-pectineal eminence, and affording

FIG. 207.—AN IMMATURE COXAL (INNOMINATE) BONE, SHOWING A COTYLOID BONE.



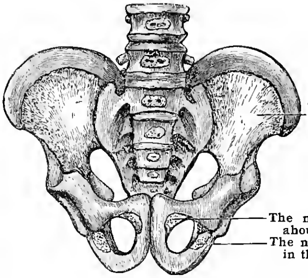
attachment to the conjoined tendon [falx aponeurotica inguinalis], the lacunar (Gimbernat's) ligament, the reflected inguinal ligament (fascia triangularis), and the pubic portion of the fascia lata; the iliac portion of the terminal (ilio-pectineal) line gives attachment to the *psoas minor,* the iliac fascia, and the pelvic fascia. Immediately in front of the pubic portion of the line is the **pectineal surface**; it gives origin at its posterior part to the *pectineus,* and is limited below by the **obturator crest,** which extends from the pubic tubercle to the acetabular notch. The **inferior surface** of the ascending ramus forms the upper boundary of the obturator foramen and presents a deep groove [sulcus obturatorius] for the passage of the obturator vessels and nerve. The **posterior surface** is smooth, forms part of the anterior wall of the pelvic cavity, and gives attachment to a few fibres of the *obturator internus.*

According to the BNA, the body [corpus ossis pubis] is the portion corresponding to the acetabulum. The remainder of the bone is described as consisting of the ramus superior and the ramus inferior, which meet at the symphysis. Thus the divisions according to the BNA are different from those in the description above given.

The **acetabulum** is a circular depression in which the head of the femur is lodged and consists of an articular and a non-articular portion. The articular portion is circumferential and semilunar in shape [facies lunata], with the deficiency in the lower segment. One-fifth of the acetabulum is formed by the pubis, two-fifths by the ischium, and the remaining two-fifths are formed by the ilium. In rare instances the pubis may be excluded by a fourth element, the **cotyloid bone.** The non-articular portion [fossa acetabuli] is formed mainly by the ischium, and is continuous below with the margin of the obturator foramen. The articular portion presents a lateral rim to which the glenoid lip is attached, and a medial margin to which the synovial membrane which excludes the ligamentum teres from the synovial cavity is connected. The opposite extremities of the articular lunate surface which limit the **acetabular notch** are united by the transverse ligament, and through the **acetabular foramen** thus formed a nerve and vessels enter the joint.

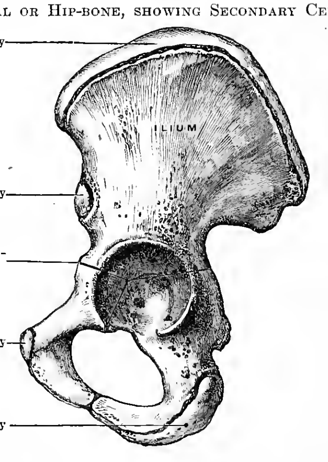
The **obturator** (thyreoid) **foramen** is situated between the ischium and pubis. Its margins are thin, and serve for the attachment of the obturator membrane. At the upper and posterior angle it is deeply grooved for the passage of the obturator vessels and nerve.

FIG. 208.—THE PELVIS OF A FŒTUS AT BIRTH, TO SHOW THE THREE PORTIONS OF THE COXAL BONES.



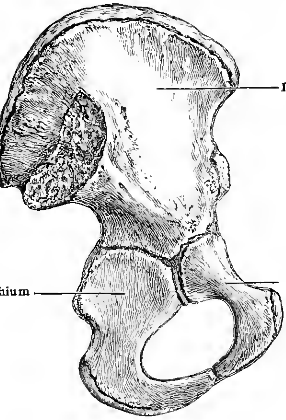
Blood-supply.—The chief vascular foramina of the coxal bone are found where the bone is thickest. On the inner surface, the ilium receives twigs from the ilio-lumbar, deep circumflex iliac, and obturator arteries, by foramina near the crest, in the iliac fossa, and below the terminal line near the greater sciatic notch. On the outer surface the chief foramina are found below the inferior gluteal line and the nutrient vessels are derived from the gluteal arteries. The ischium receives nutrient vessels from the obturator, internal and external circumflex arteries, and the largest foramina are situated between the acetabulum and the ischial tuberosity. The pubis is supplied by twigs from the obturator, internal and external circumflex arteries, and from the pubic branches of the common femoral artery.

FIG. 209.—COXAL OR HIP-BONE, SHOWING SECONDARY CENTRES.



Ossification.—The cartilaginous representative of the hip-bone consists of three distinct portions, an iliac, an **ischiatic**, and a **pubic** portion; the iliac and ischiatic portions first unite and later the pubic portion, so that eventually there is found a single cartilaginous mass. Early in the second month a centre of ossification appears above the acetabulum for the ilium. A little later a second nucleus appears below the cavity for the ischium, and this is followed in the fourth month by a deposit in the pubic portion of the cartilage. At birth, the three nuclei are of considerable size, but are surrounded by relatively wide tracts of cartilage; ossification has, however, extended into the margin of the acetabulum. In the eighth year the rami of the pubis and ischium become united by bone, and in the twelfth year the triradiate cartilage which separates the three segments of the bone in the acetabulum begins to ossify from several centres. Of these, one is more constant than the others and is known as the acetabular nucleus. The triangular piece of bone to which it gives rise is regarded as the representative of the *cotyloid* or acetabular bone, constantly present in a few mammals. It is situated at the medial part of the acetabulum and is of such a size as to exclude entirely the pubis from the cavity. With this bone, however, it eventually fuses, and afterward becomes joined with the ilium and

Fig. 210.—Coxal or Hip-bone (Inner Surface) at the Eighth Year.



ischium, so that by the eighteenth or twentieth year the several parts of the acetabulum have become united. In the fifteenth year other centres appear in the cartilage of the crest of the ilium, the anterior inferior iliac spine, the tuberosity of the ischium, and the pubic pecten. The epiphyses fuse with the main bone about the twentieth year. The fibrous tissue connected with the tubercle of the pubis represents the epipubic bones of marsupials.

THE PELVIS

The **pelvis** (figs. 211, 212, 213, 214) is composed of four bones: the two coxal or hip-bones, the sacrum, and the coccyx. The hip-bones form the lateral and anterior boundaries, meeting each other in front to form the pubic symphysis [symphysis ossium pubis]; posteriorly they are separated by the sacrum. The interior of the pelvis is divided into the **major** and **minor** pelvic cavity.

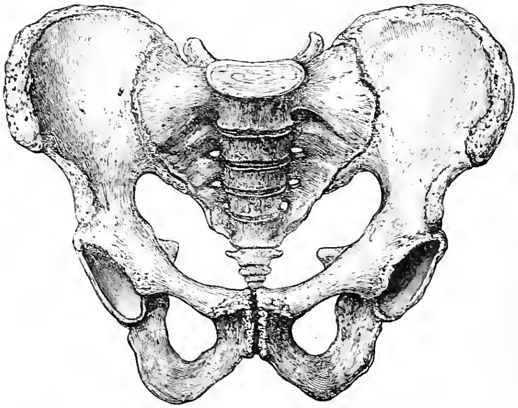
The **major** (or false) **pelvis** is that part of the cavity which lies above the terminal (iliopectineal) lines and between the iliac fossæ. This part belongs really to the abdomen, and is in relation with the hypogastric and iliac regions.

The **minor** (or true) **pelvis** is situated below the terminal (ilio-pectineal) lines. The upper circumference, known as the **superior aperture** (inlet or brim) of the pelvis, is bounded anteriorly by the tubercle and pecten of the pubis on each side, posteriorly by the anterior margin of the base of the sacrum, and laterally by the terminal lines. The inlet in normal pelves is heart-shaped, being obtusely pointed in front; posteriorly it is encroached upon by the promontory of the sacrum. It has three principal **diameters**; of these, the antero-posterior, called the **conjugate** diameter [conjugata], is measured from the **sacro-vertebral angle** to the symphysis. The **transverse** diameter represents the greatest width of the pelvic cavity. The **oblique** diameter is measured from the sacro-iliac synchondrosis of one side to the ilio-pectineal eminence of the other.

The **cavity** of the minor (true) pelvis is bounded in front by the pubes, behind by the sacrum and coccyx, and laterally by a smooth wall of bone formed in part by the ilium and in part by the ischium. The cavity is shallow in front, where it is formed by the pubes, and is deepest posteriorly.

The **inferior aperture,** or outlet, of the minor pelvis is very irregular, and encroached upon by three bony processes: the posterior process is the coccyx, and the two lateral processes are the ischial tuberosities. They separate three notches. The anterior notch is the **pubic arch,** and is bounded ou each side by the conjoined rami of the pubes and ischium. Each of the two remaining gaps, bounded by the

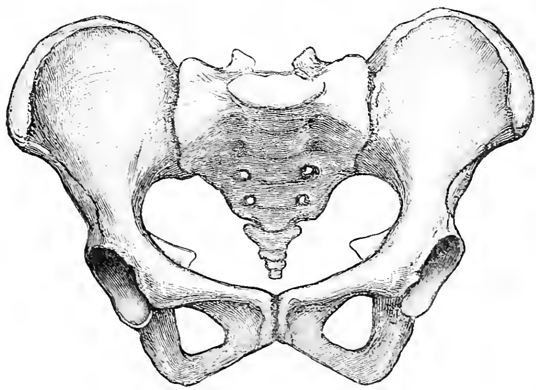
FIG. 211.—THE MALE PELVIS.



ischium anteriorly, the sacrum and coccyx posteriorly, and the ilium above, corresponds to the greater and lesser sciatic notches. These are converted into foramina by the sacro-tuberous (great sacro-sciatic) and sacro-spinous (small sacro-sciatic) ligaments.

The position of the pelvis.—In the erect position of the skeleton the plane of the pelvic inlet forms an angle with the horizontal plane, which varies in individnals from 50° to 60°.

FIG. 212.—THE FEMALE PELVIS.



The base of the sacrum in an average pelvis lies nearly ten centimetres (four inches) above the upper margin of the symphysis pubis.

The axis of the pelvis.—This is an imaginary curved line drawn through the minor pelvis at right angles to the planes of the inlet, cavity, and outlet through their central points.

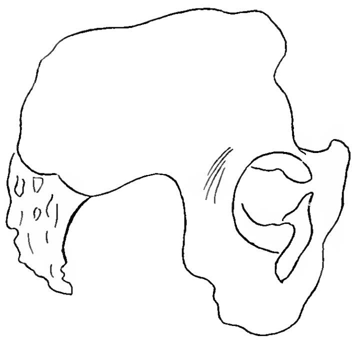
As the posterior wall, formed by sacrum and coccyx, is nearly five inches long and concave, and the anterior wall at the symphysis pubis one one and a half to two inches long, it follows that the axis mnst be curved.

The average measurements of the diameters of the minor pelvis in the three planes are given below:—

	Conjugate or Antero-posterior.	Oblique.	Transverse.
Inlet............	4¼ inches (10.6 cm.)	5 inches (12.5 cm.)	5¼ inches (13.0 cm.)
Cavity...........	4¾ " (11.8 cm.)	5¼ " (13.0 cm.)	4¾ " (11.8 cm.)
Outlet...........	3¾ " (9.0 cm.)	4½ " (11.2 cm.)	4¼ " (10.6 cm.)

Fig. 213.—Male Pelvis. (Lateral view.)

Fig. 214.—Female Pelvis. (Lateral view.)



There is, however, a difference between the sexes, the diameters of the male pelvis in general averaging slightly less, and those of the female slightly greater than the figures above given.

Differences according to sex.—There is a marked difference in the size and form of the male and female pelvis, the peculiarities of the latter being necessary to qualify it for its functions in parturition. The various points of divergence may be tabulated as follows:—

Male.	Female.
Bones heavier and rougher.	Bones more slender.
Ilia less vertical.	Ilia more vertical.
Iliac fossæ deeper.	Iliac fossæ shallower.
Major pelvis relatively wider.	Major pelvis relatively narrower.
Minor pelvis deeper.	Minor pelvis shallower.
" " narrower.	" " wider.
Superior aperture more heart-shaped.	Superior aperture more oval.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia inflexed.	Tuberosities of ischia everted.
Pubic angle narrow and pointed.	Pubic arch wider and more rounded.
Margins of ischio-pubic rami more everted.	Margins of ischio-pubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of minor pelvis less.	Capacity of minor pelvis greater.

The sexual characters of the pelvis as shown by A. Thomson are manifest as early as the fourth month of fœtal life.

Quite recently attention has been drawn by D. Derry to some special points in which the os coxæ differ in the two sexes, and two figures are shown here in which one of these points is clearly brought out. It will be seen that the great sciatic notch is larger in the female, and that the sacrum projects less forward at its apex. Moreover the facies auricularis is smaller whilst below and in front of this surface, the *sulcus preauricularis*, a depression for the attachment of the *ligamenta sacroiliaca anteriora*, is usually more pronounced.

In comparison with the pelves of lower animals, which, speaking generally, are elongated and narrow, the human pelvis is characterised by its breadth, shallowness, and great capacity. Differences are also to be recognised in the form of the pelvis in the various races of mankind, the most important being the relation of the antero-posterior to the transverse diameter, measured at the inlet. This is expressed by the *pelvic index* $= \frac{100 \times \text{conjugate diameter}}{\text{transverse diameter}}$.

In the average European male the index is about 80; in the lower races of mankind, 90 to 95. Pelves with an index below 90 are *platypellic*, from 90 to 95 are *mesatipellic*, and above 95 *dolichopellic*. (Sir William Turner.)

12

THE FEMUR

The **femur** or thigh bone (figs. 215, 216) is the largest and longest bone in the skeleton, and transmits the entire weight of the trunk from the hip to the tibia. In the erect posture it inclines from above downward and medially, approaching at the lower extremity its fellow of the opposite side, but separated from it above by the width of the true pelvis. It presents for examination a superior extremity, including the head, neck, and two trochanters, an inferior extremity, expanded laterally into two condyles, and a shaft.

The **upper extremity** is surmounted by a smooth, globular portion called the **head,** forming more than half a sphere, directed upward and medially for articulation with the acetabulum. With the exception of a small rough depression, the **fovea,** for the ligamentum teres, a little below and behind the centre of the head, its surface is covered with cartilage in the recent state. The head is connected with the shaft by the **neck,** a stout rectangular column of bone which forms with the shaft, in the adult, an angle of about 125°. Its anterior surface is in the same plane with the front aspect of the shaft, but is marked off from it by a ridge to which the capsule of the hip-joint is attached. The ridge, which commences at the great trochanter in a small prominence, or **tubercle,** extends obliquely downward, and winding to the back of the femur, passes by the lesser trochanter and becomes continuous with the medial lip of the linea aspera, on the posterior aspect of the shaft. This ridge forms the **intertrochanteric line** or **spiral line** of the femur. The intertrochanteric line receives the bands of the ilio-femoral thickening of the capsule of the hip-joint. The posterior surface of the neck is smooth and concave and its medial two-thirds is enclosed in the capsule of the hip-joint. The superior border of the neck, perforated by large nutrient foramina, is short and thick, and runs downward to the great trochanter. The inferior border, longer and narrower than the superior, curves downward to terminate at the lesser trochanter.

The **trochanters** are the prominences which afford attachment to the rotator muscles of the thigh; they are two in number—great and lesser.

The **great trochanter** is a thick, quadrilateral process surmounting the junction of the neck with the shaft, and presents for examination two surfaces and four borders. The lateral surface is broad, rough, and continuous with the lateral surface of the shaft. It is marked by a diagonal ridge running from the postero-superior to the antero-inferior angle, which receives the insertion of the *gluteus medius.* The ridge divides the surface into two triangular areas: an upper, covered by the *gluteus medius,* and occasionally separated from it by a bursa, and a lower, covered by a bursa to permit the free gliding of the tendon of the *gluteus maximus.* Of the **medial** surface the lower and anterior portion is joined with the rest of the bone; the upper and posterior portion is free, concave, and presents a deep depression, the **trochanteric** or **digital fossa,** which receives the tendon of the *obturator externus.* The fore part of the surface is marked by an impression for the insertion of the *obturator internus* and two *gemelli.*

Of the four borders, the superior, thick and free, presents near the centre an oval mark for the insertion of the *piriformis;* the anterior border, broad and irregular, receives the *gluteus minimus;* the posterior border, thick and rounded, is continuous with the **intertrochanteric crest,** the prominent ridge uniting the two trochanters behind. Above the middle of this line is an elevation, termed the **tubercle of the quadratus,** for the attachment of the upper part of the *quadratus femoris.* The inferior border corresponds with the line of junction of the base of the trochanter with the shaft; it is marked by a prominent ridge for the origin of the upper part of the *vastus lateralis.*

The lesser **trochanter** is a conical eminence projecting medially from the posterior and medial aspect of the bone, where the neck is continuous with the shaft. Its summit is rough and gives attachment to the tendon of the *ilio-psoas.* The fibres of the *iliacus* extend beyond the trochanter and are inserted into the surface of the shaft immediately below.

The **body** or **shaft** of the femur is almost cylindrical, but is slightly flattened in front and strengthened behind by a projecting longitudinal ridge, the **linea aspera,** for the origin and insertion of muscles. The linea aspera extends along the middle third of the shaft and presents a medial lip and a lateral lip separated by a narrow interval. When followed into the upper third of the shaft, the three parts diverge. The lateral lip becomes continuous with the **gluteal tuberosity** and ends at the base of the great trochanter. The ridge affords insertion to the *gluteus maximus,*

Fig. 215.—The Left Femur. (Anterior view.)

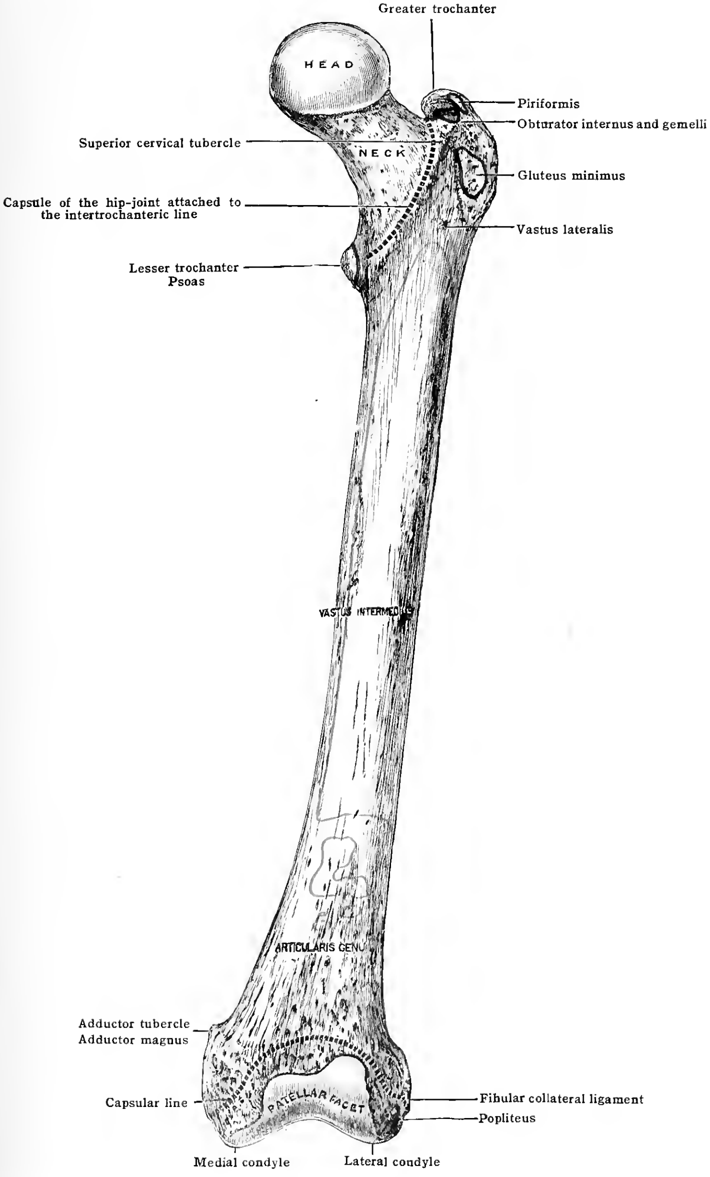


Fig. 216.—The Left Femur. (Posterior view.)

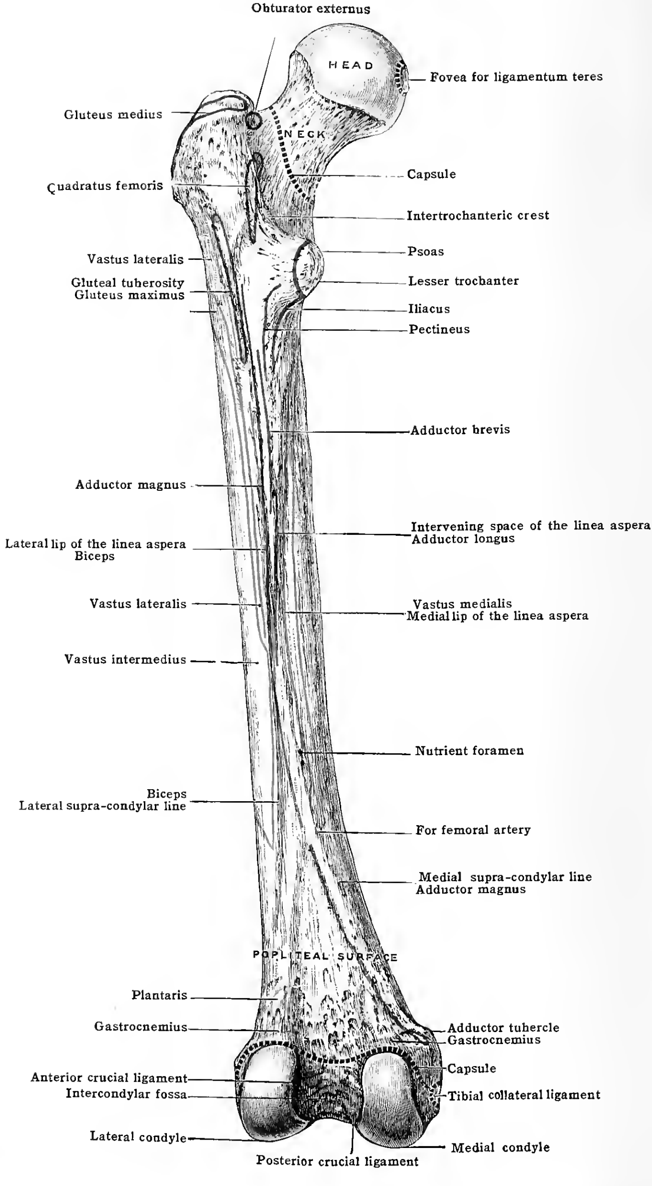
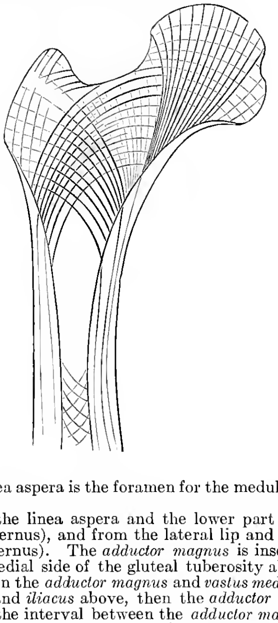


and when very prominent is termed the **third trochanter.** The medial lip curves medialward below the lesser trochanter, where it becomes continuous with the intertrochanteric line; the intervening portion bifurcates and is continued upward as two lines, one of which ends at the small trochanter, and receives some fibres of the *iliacus*, whilst the other is the **linea pectinea** and marks the insertion of the pectineus muscle.

Toward the lower third of the shaft the medial and lateral lips of the linea aspera again diverge, and are prolonged to the condyles by the **medial** and **lateral supra-condylar lines,** enclosing between them a triangular surface of bone, the popliteal surface [**planum popliteum**] of the femur, which forms the upper part of the floor of the popliteal space. The lateral line is the more prominent and terminates below in the lateral epicondyle. The medial one is interrupted above, where the femoral vessels are in relation with the bone, better marked below, where it terminates in the **adductor tubercle,** a small sharp projection at the summit of the medial epicondyle, which affords attachment to the tendon of the *adductor magnus*.

Fig. 217.—A Diagram to show the Pressure and Tension Curves of the Femur. (After Wagstaffe.)



Near the centre of the linea aspera is the foramen for the medullary artery, directed upward toward the head of the bone.

From the medial lip of the linea aspera and the lower part of the intertrochanteric line arises the *vastus medialis* (internus), and from the lateral lip and the side of the gluteal ridge arises the *vastus lateralis* (externus). The *adductor magnus* is inserted into the medial lip of the linea aspera, from the medial side of the gluteal tuberosity above, and the medial supra-condylar line below. Between the *adductor magnus* and *vastus medialis* (internus) four muscles are attached: the *pectineus* and *iliacus* above, then the *adductor brevis*, and lowest of all, the *adductor longus*. Above, in the interval between the *adductor magnus* and the *vastus lateralis* (externus), the *gluteus maximus* is inserted; in the interval lower down is the short head of the *biceps*, taking origin from the lower two-thirds of the lateral lip of the linea aspera and the upper two-thirds of the lateral supra-condylar line. On the popliteal surface of the bone, just above the condyles, are two rough areas from which fibres of the two heads of the *gastrocnemius* take origin. Above the area for the lateral head of the gastrocnemius is a slight roughness for the *plantaris*.

For purposes of description it is convenient to regard the shaft of the femur as presenting anterior, medial, and lateral surfaces, although definite borders separating the surfaces from one another do not exist. All three surfaces are smooth and the anterior is not separated from the lateral by ridges of any kind. In the middle third of the shaft the medial and lateral surfaces approach one another behind, being separated by the linea aspera.

The shaft is overlapped on its medial side by the *vastus medialis* (internus), and on its lateral side by the *vastus lateralis* (externus). The upper three-fourths of the anterior and lateral surfaces afford origin to the *vastus intermedius* (crureus), and the lower fourth of the anterior surface, to the *articularis genu* (sub-crureus). The medial surface is free from muscular attachment.

Fig. 218.—Transverse Section of Shaft of Femur to show the Medullary Cavity.

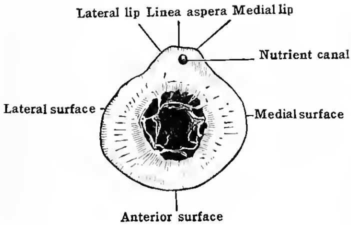


Fig. 219.—Section of Upper End of Femur to show the Calcar Femorale.

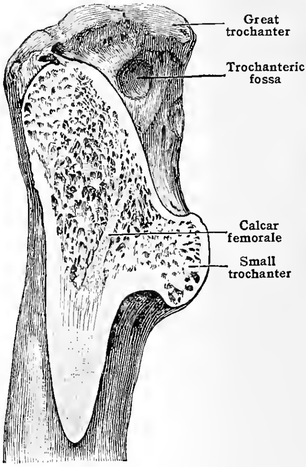

Fig. 220.—The Femur at Birth.

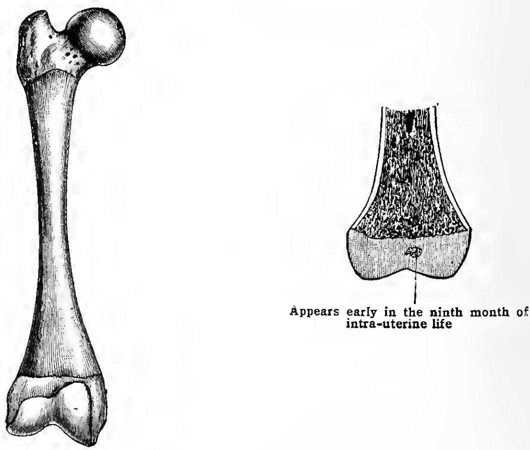
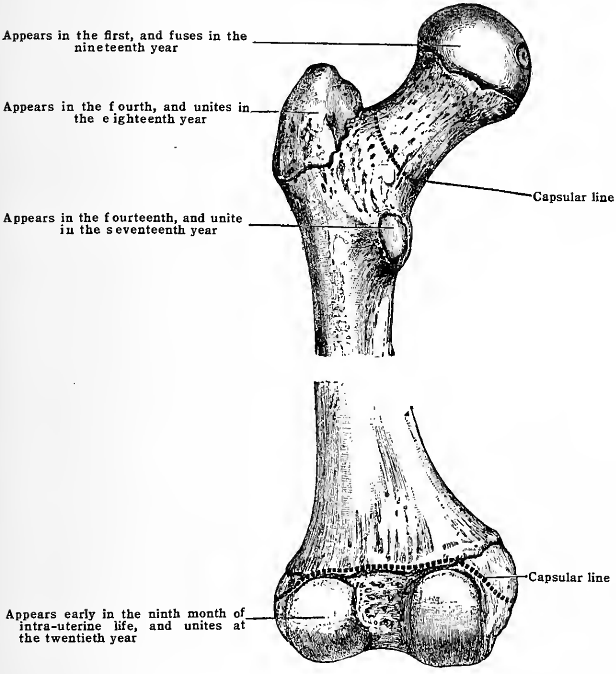


The **lower extremity** presents two cartilage-covered eminences or **condyles,** separated behind by the **intercondyloid fossa.** The lateral condyle is wider than its fellow and more prominent anteriorly; the medial condyle is narrower, more prominent, and longer, to compensate for the obliquity of the shaft. When the femur is in the natural position, the inferior surfaces of the condyles are on the same plane, and almost parallel, for articulation with the upper surfaces on the head of the tibia. The two condyles are continuous in front, forming a smooth trochlear surface [facies patellaris] for articulation with the patella. This surface presents a median vertical groove and two convexities, the lateral of which is wider, more prominent, and prolonged farther upward. The patellar surface is faintly marked off from the tibial articular surfaces by two irregular grooves, best seen while the lower end is still coated with cartilage. The lateral groove commences on the medial margin of the lateral condyle near the front of the intercondylar fossa, and extends obliquely forward to the lateral margin of the bone. The general direction of the medial groove is from front to back, turning medially in front and extending backward as a faint ridge which marks off from the

Fig. 221.—The Left Femur at the Twentieth Year. (Posterior view.) The figure shows the relations of the epiphysial and capsular lines.



rest of the medial condyle a narrow semilunar facet for articulation with the medial perpendicular facet of the patella in extreme flexion. The grooves receive the semilunar menisci in the extended position of the joint. The tibial surfaces are almost parallel except in front, where the medial turns laterally to become continuous with the patellar surface.

The opposed surfaces of the two condyles form the boundaries of the intercondylar fossa and give attachment to the crucial ligaments which are lodged within it. The posterior crucial ligament is attached to the fore part of the lateral surface of the medial condyle and the anterior crucial ligament to the back part of the medial surface of the lateral condyle. The two remaining surfaces of the condyles are broad and convex, and each presents an **epicondyle** (tuberosity) for the attachment of lateral ligaments. The medial epicondyle, the larger of the two, is surmounted by the adductor tubercle, behind which is an impression for the medial head of the *gastrocnemius* on the upper aspect of the condyle; below and behind the lateral epicondyle is a deep groove which receives the tendon of the *popliteus* muscle when the knee is flexed, and its anterior end terminates in a pit from which the tendon takes origin. Above the lateral epicondyle is a rough impression for the lateral head of the *gastrocnemius*.

The interior of the shaft of the femur is hollowed out by a large medullary canal, and the extremities are composed of cancellated tissue invested by a thin compact layer. The arrangement of the cancelli in the upper end of the bone forms a good illustration of the effect produced by the mechanical conditions to which bones are subject. In the upper end of the bone the cancellous tissue is arranged in divergent curves. One system springs from the lower part of the neck and upper end of the shaft medially and spreads into the great trochanter ('pressure lamellæ'). A second system springs from the lateral part of the shaft and arches upward into the neck and head ('tension lamellæ'), crossing the former almost at right angles. A second set of pressure lamellæ springs from the lower thick wall of the neck, and extends into the upper part of the head to end perpendicularly in the articular surface mainly along the lines of greatest pressure. A nearly vertical plate of compact tissue (calcar femorale) projects into the neck of the bone from the inferior cervical tubercle toward the great trochanter. This is placed in the line through which the weight of the body falls, and adds to the stability of the neck of the bone; it is said to be liable to absorption in old age. In the lower end of the bone the vertical and horizontal fibres are so disposed as to form a rectangular meshwork.

Blood-supply.—The head and neck of the femur receive branches from the inferior gluteal, obturator, and circumflex arteries, and the trochanters from the circumflex arteries. The nutrient vessel of the shaft is derived from either the second or third perforating artery, or there may be two nutrient vessels arising usually from the first and third perforating. The vessels of the inferior extremity arise from the articular branches of the popliteal and the anastomotic branch of the femoral (supremagenu).

Ossification.—The femur is ossified from one primary centre for the shaft and from four epiphysial centres. The shaft begins to ossify in the seventh week of intra-uterine life. Early in the ninth month a nucleus appears for the lower extremity. During the first year the nucleus for the head of the bone is visible, and in the fourth year that for the trochanter major. The centre for the lesser trochanter appears about the thirteenth or fourteenth year. The lesser trochanter joins the shaft at the seventeenth, the great trochanter at the eighteenth, the head about the nineteenth, and the lower extremity at the twentieth year.

The neck of the femur is an *apophysis*, or outgrowth from the shaft. The line of fusion of the condylar epiphysis with the shaft passes through the adductor tubercle.

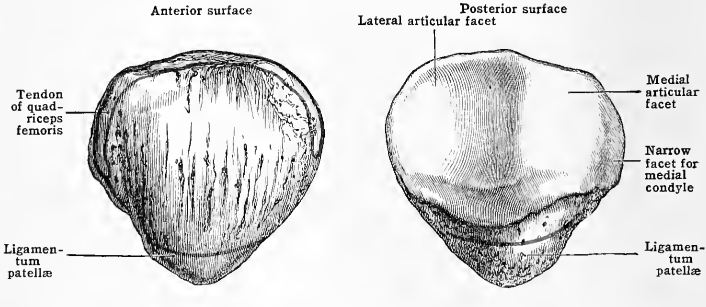
The morphological relation of the patellar facet to the tibial portions of the condyles is worthy of notice. In a few mammals, such as the ox, this facet remains separated from the condyles by a furrow of rough bone.

The angle which the neck of the femur forms with the shaft at birth measures, on an average, 160°. In the adult it varies from 110° to 140°; hence the angle decreases greatly during the period of growth. When once growth is completed, the angle, as a rule, remains fixed. (Humphry.)

THE PATELLA

The **patella** (fig. 222) or knee-pan, situated in front of the knee-joint, is a sesamoid bone, triangular in shape, developed in the tendon of the *quadriceps femoris*. Its **anterior surface**, marked by numerous longitudinal striæ, is slightly convex, and

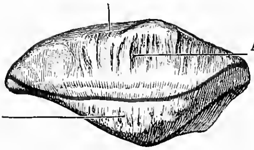
Fig. 222.—The Left Patella.



perforated by small openings which transmit nutrient vessels to the interior of the bone. It is covered in the recent state by a few fibres prolonged from the common tendon of insertion (supra-patellar tendon) of the *quadriceps femoris*, into the ligamentum patellæ (infra-patellar tendon), and is separated from the skin by one or more bursæ. The **posterior surface** is largely articular, covered with cartilage in the recent state, and divided by a slightly marked vertical ridge, corresponding to the groove on the trochlear surface of the femur, into a lateral larger portion for the lateral condyle, and a medial smaller portion for the medial condyle. Close to the medial edge a faint vertical ridge sometimes marks off a narrow articular facet, for the lateral margin of the medial condyle of the femur in extreme flexion of the leg. Below the articular surface is a rough, non-articular depression, giving attachment to the ligamentum patellæ, and separated by a mass of fat from the head of the tibia.

The **base** or superior border is broad, sloped from behind downward and forward, and affords attachment, except near the posterior margin, to the common

FIG. 223.—THE SUPERIOR BORDER OR BASE OF THE LEFT PATELLA.



tendon of the *quadriceps*. The **borders,** thinner than the base, converge to the apex below, and receive parts of the two *vasti* muscles. The **apex** forms a blunt point directed downward, and gives attachment to the ligamentum patellæ, by which the patella is attached to the tibia.

Structurally the patella consists of dense cancellous tissue covered by a thin compact layer, and it receives nutrient vessels from the articular branch of the suprema genu (anastomotic), the anterior tibial recurrent, and the inferior articular branches of the popliteal.

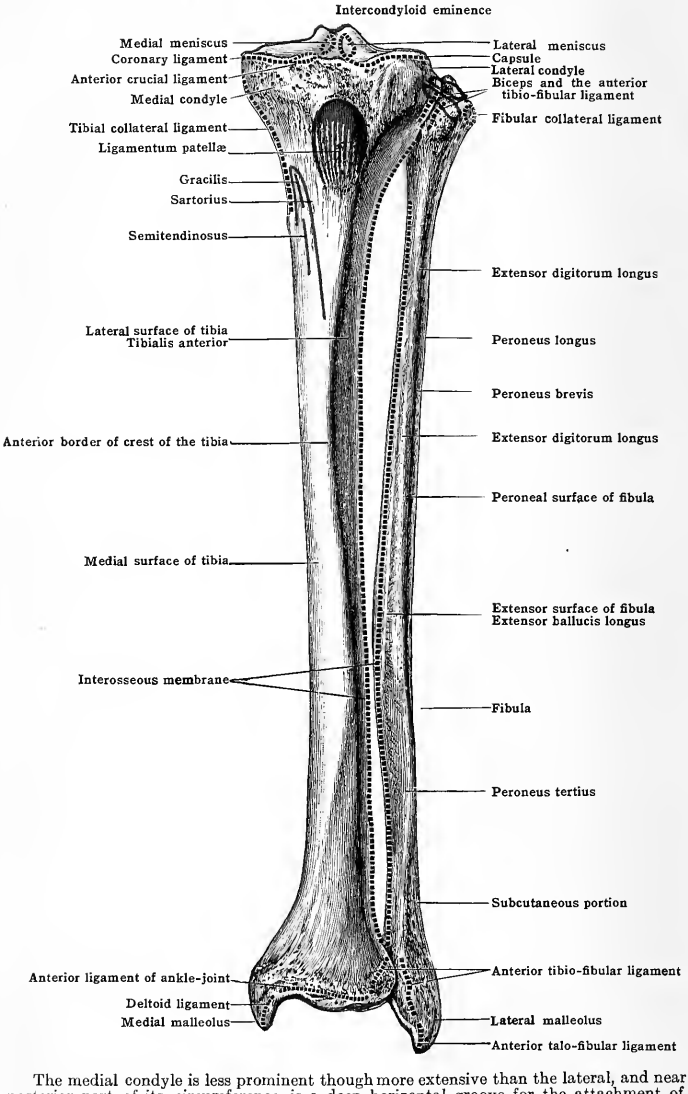
Ossification.—The cartilaginous deposit in the tendon of the *quadriceps* muscle takes place in the fourth month of intra-uterine life. Ossification begins from a single centre during the third year, and is completed about the age of puberty.

THE TIBIA

The **tibia** (figs. 224, 225) or shin-bone is situated at the front and medial side of the leg and nearly parallel with the fibula. Excepting the femur, it is the largest bone in the skeleton, and alone transmits the weight of the trunk to the foot. It articulates above with the femur, below with the tarsus, and laterally with the fibula. It is divisible into two extremities and a shaft.

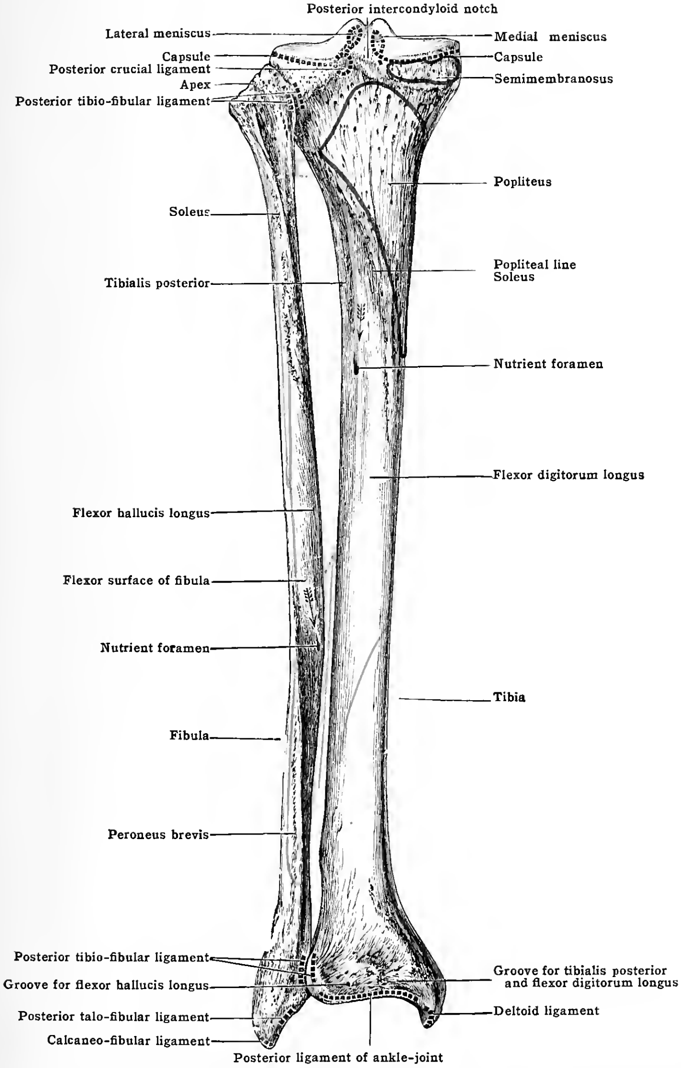
The **upper extremity** (or head) consists of two lateral eminences, or **condyles.** Their superior articular surfaces receive the condyles of the femur, the articular parts being separated by a non-articular interval, to which ligaments are attached. The medial articular surface is oval in shape and concave for the medial condyle of the femur. The lateral articular surface is smaller, somewhat circular in shape, and presents an almost plane surface for the lateral condyle. The peripheral portion of each articular surface is overlaid by a fibro-cartilaginous meniscus of semilunar shape, connected with the margins of the condyles by bands of fibrous tissue termed coronary ligaments. Each semilunar meniscus is attached firmly to the rough interval separating the articular surfaces. This interval is broad and depressed in front, **the anterior intercondyloid fossa,** where it affords attachment to the anterior extremities of the medial and lateral menisci and the anterior crucial ligament; elevated in the middle to form the **intercondyloid eminence** or spine of the tibia, a prominent eminence, presenting at its summit two compressed **intercondyloid tubercles,** on to which the condylar articular surfaces are prolonged; the posterior aspect of the base of the eminence affords attachment to the posterior extremities of the lateral and medial semilunar menisci, and limits a deep notch, inclined toward the medial condyle, known as the **posterior intercondyloid fossa** or popliteal notch. It separates the condyles on the posterior aspect of the head and gives attachment to the posterior crucial ligament, and part of the posterior ligament of the knee-joint. Anteriorly, the two condyles are confluent, and form a somewhat flattened surface of triangular outline, the apex of which forms the **tuberosity** of the tibia. The tuberosity is divisible into two parts. The upper part, rounded and smooth, receives the attachment of the ligamentum patellæ. The lower part is rough, and into its lateral edges prolongations of the ligamentum patellæ are inserted. A prominent bursa intervenes between the ligament and the anterior aspect of the upper extremity of the bone.

Fig. 224.—The Left Tibia and Fibula. (Anterior view.)



The medial condyle is less prominent though more extensive than the lateral, and near the posterior part of its circumference is a deep horizontal groove for the attachment of the central portion of the *semimembranosus* tendon. The margins of this groove, and the surface of bone below, give attachment to the tibial (internal) lateral ligament of the knee. On the under aspect of the lateral condyle is a rounded articular facet for the head of the fibula, flat and nearly circular in outline, directed downward, backward, and laterally. The circumference of the facet is rough and gives attachment to the ligaments of the superior tibio-fibular joint, while above and in front of the facet, at the junction of the anterior and lateral surfaces

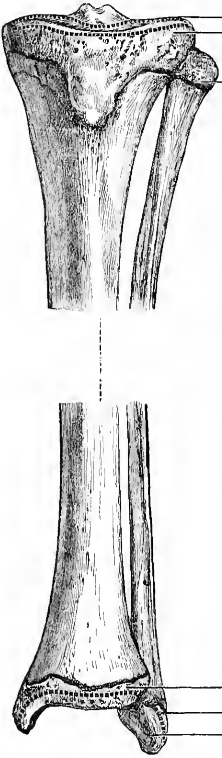
Fig. 225.—The Left Tibia and Fibula. (Posterior view.)



of the condyle, is a ridge for the ilio-tibial band. A slip from the tendon of the *biceps* and parts of the *extensor longus digitorum* and *peroneus longus* muscles are attached to the head below the ilio-tibial band.

The **shaft** or body [corpus] of the tibia, thick and prismatic above, becomes thinner as it descends for about two-thirds of its length, and then gradually expands toward its lower extremity. It presents for examination three borders and three surfaces. The **anterior border** is very prominent and known as the **anterior crest** of the tibia. It commences above on the lateral edge of the tuberosity and terminates below at the anterior margin of the medial malleolus. It runs a somewhat sinuous course, and gives attachment to the deep fascia of the leg. The **medial border** extends from the back of the medial condyle to the posterior margin of the medial malleolus, and affords attachment above, for about three inches, to

FIG. 226.—THE TIBIA AND FIBULA AT THE SIXTEENTH YEAR.
The figure shows the relations of the epiphysial and capsular lines.



the tibial (internal) lateral ligament of the knee-joint and in the middle third, to the *soleus*. The **interosseous crest** or lateral border, thin and prominent, gives attachment to the interosseous membrane. It commences in front of the fibular facet, on the upper extremity, and toward its termination bifurcates to enclose a triangular area for the attachment of the interosseous ligament uniting the lower ends of the tibia and fibula.

The **medial surface** is bounded by the medial margin and the anterior crest; it is broad above, where it receives the insertions of the *sartorius*, *gracilis*, and *semitendinosus;* convex and subcutaneous in the remainder of its extent. The **lateral surface** lies between the crest of the tibia and the interosseous crest. The upper two-thirds presents a hollow for the origin of the *tibialis anterior;* the rest of the surface is convex and covered by the extensor tendons and the anterior tibial vessels. The **posterior surface** is limited by the interosseous crest and the medial border. The upper part is crossed obliquely by a rough **popliteal line,** extending from the fibular facet on the lateral condyle to the medial border, a little above the middle of the bone.

The popliteal line gives origin to the *soleus* and attachment to the popliteal fascia, while the triangular surface above is occupied by the *popliteus* muscle. Descending along the posterior surface from near the middle of the popliteal line is a vertical ridge, well marked at its commencement, but gradually becoming indistinct below. The portion of the surface between the ridge and the medial border gives origin to the *flexor digitorum longus;* the lateral and narrower part, between the ridge and the interosseous border, to fibres of the *tibialis posterior*. The lower third of the posterior surface is covered by flexor tendons and the posterior tibial vessels. Immediately below the popliteal line and near the interosseous border is the large medullary foramen directed obliquely downward.

The **lower extremity,** much smaller than the upper, is quadrilateral in shape and presents a strong process called the **medial malleolus,** projecting downward from its medial side. The anterior surface of the lower extremity is smooth and rounded above, where it is covered by the extensor tendons, rough and depressed below for the attachment of the anterior ligament of the ankle-joint. It sometimes bears a facet for articulation with the neck of the talus (astragalus). (A. Thomson.) The posterior surface is rough and is marked by two grooves. The medial and deeper of the two encroaches on the malleolus, and receives the tendons of the *tibialis posterior* and *flexor digitorum longus;* the lateral, very shallow and sometimes indistinct, is for the tendon of the *flexor hallucis longus*. The lateral surface is triangular and hollowed for the reception of the lower end of the fibula and rough for the interosseous ligament which unites the two bones, except near the lower border, where there is usually a narrow surface, elongated from before backward, covered with cartilage in the recent state for articulation with the fibula. The lines in front of and behind the triangular surface afford attachment to the anterior and posterior ligaments of the inferior tibio-fibular articulation. The medial surface, prolonged downward on the medial malleolus, is rough, convex, and subcutaneous. The lateral surface of this process is smooth and articulates with the facet on the medial side of the talus (astragalus). Its lower border is notched, and from the notch, as well as from the tip and anterior border, the fibres of the deltoid ligament of the ankle-joint descend. The inferior or terminal surface, by which the tibia articulates with the talus, is of quadrilateral form, concave from before backward, wider in front than behind, and laterally than medially where it is continuous with the lateral surface of the malleolus.

The occasional facet on the anterior surface of the lower extremity of the tibia is a pressure facet, produced by extreme flexion of the ankle joint. It is therefore sometimes designated as the "squatting facet." (See fig. 333.)

Blood-supply.—The tibia is a very vascular bone. The nutrient artery of the shaft is furnished by the posterior tibial, and is the largest of its kind in the body. The head of the bone receives numerous branches from the inferior articular arteries of the popliteal and the recurrent branches of the anterior and posterior tibial. The lower extremity receives twigs from the posterior and anterior tibial, the peroneal, and the medial malleolar arteries.

Ossification.—The tibia is ossified from one principal centre for the shaft, which appears in the eighth week of intra-uterine life, and two epiphyses, the centres for which appear in the cartilaginous head of the bone toward the end of the ninth month, and in the lower extremity during the second year. The latter unites with the shaft at eighteen, but the union of the head with the shaft does not take place until the twenty-first year, and it may even be delayed until twenty-five. The upper part of the tubercle of the tibia is ossified from the upper epiphysis, and the lower part from the diaphysis.

THE FIBULA

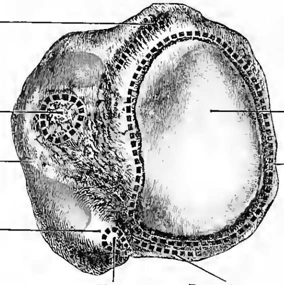
The **fibula** (figs. 224, 225) is situated on the lateral side of the leg and, in proportion to its length is the most slender of all the long bones. It is placed nearly parallel to the tibia with which it is connected above and below. In man it is a rudimentary bone and bears none of the weight of the trunk, but is retained on account of the muscles to which it gives origin and its participation in the formation of the ankle-joint. Like other long bones, it is divisible into a shaft and two extremities.

The **head** [capitulum fibulæ], or upper extremity, is a rounded prominence. Its upper surface presents laterally a rough eminence for the attachment of the *biceps* tendon and the fibular (long external) collateral ligament of the knee-joint, medially it presents a round or oval facet [facies articularis capituli], directed upward, forward, and medially, for articulation with the lateral condyle (tuberosity) of the tibia. The margin of the facet gives attachment to the articular capsule of the superior tibio-fibular articulation. Posteriorly, the head rises into a pointed **apex** (styloid process), which affords attachment to the short lateral ligament of the knee-joint, and on the lateral side, to part of the *biceps* tendon.

The posterior aspect of the head gives attachment to the *soleus*, the lateral aspect, extending also in front of the eminence for the *biceps*, to the *peroneus longus;* from the anterior aspect fibres of the *extensor digitorum longus* arise, whilst the medial side lies adjacent to the tibia.

The **shaft** [corpus fibulæ], in its upper three-fourths, is quadrangular, possessing four borders and four surfaces, whereas its lower fourth is flattened from side to side, so as to be somewhat triangular. The borders and surfaces vary exceedingly so that their description is difficult. The **anterior crest** (or antero-lateral border) commences in front of the head and terminates below by dividing to enclose a subcutaneous surface, triangular in shape, immediately above the

FIG. 227.—THE UPPER END OF THE LEFT FIBULA TO SHOW MUSCULAR AND LIGAMENTOUS ATTACHMENTS × 2. (G. J. Jenkins.)



lateral malleolus. It gives attachment to a septum separating the extensor muscles in front from the peronei muscles on the lateral aspect. The **interosseous crest** (or antero-medial border), so named from giving attachment to the interosseous membrane, also commences in front of the head, close to the anterior crest, and terminates below by dividing to enclose a rough triangular area immediately above the facet for the *talus* (*astragalus*); this area gives attachment to the inferior interosseous ligament, and may present at its lower end a narrow facet for articulation with the tibia. The **medial crest** (or postero-medial border), sometimes described as the **oblique line** of the fibula, commences at the medial side of the head and terminates below by joining the interosseous crest, in the lower fourth of the shaft. It gives attachment to an aponeurosis separating the *tibialis posterior* from the *soleus* and *flexor hallucis longus*. The **lateral crest** (or postero-lateral border) runs from the back of the head to the medial border of the peroneal groove on the back of the lower extremity; it gives attachment to the fascia separating the peronei from the flexor muscles.

The **anterior** or **extensor surface** is the interval between the interosseous and anterior crests. In the upper third it is extremely narrow, but broadens out below, where it is slightly grooved longitudinally. It affords origin to three muscles: laterally, in the upper two-thirds, to the *extensor digitorum longus*, and, in the lower third, to the *peroneus tertius;* medially, in the middle third, also to the *extensor hallucis longus*. The **medial surface,** situated between the interosseous and medial crests, is narrow above and below, and broadest in the middle. It is grooved and sometimes crossed obliquely by a prominent ridge, the **secondary oblique line** of the fibula; the surface gives origin to the *tibialis posterior*, and the ridge to a tendinous septum in the substance of the muscle. The **posterior surface** is the interval between the medial and lateral crests, and is somewhat twisted so as to look backward above and medially below. It serves, in its upper third, for the origin of the *soleus,* and in its lower two-thirds for the *flexor hallucis longus.* Near the middle of the surface is the medullary foramen, directed downward toward the ankle. The **lateral surface,** situated between the anterior and lateral crests, is also somewhat twisted, looking laterally above and backward below, where it is continuous with the groove on the back of the lateral malleolus. The surface is often deeply grooved and is occupied by the *peroneus longus* in the upper two-thirds and by the *peroneus brevis* in the lower two-thirds.

The **lateral malleolus** or lower extremity is pyramidal in form, somewhat flattened from side to side, and joined by its base to the shaft. It is longer, more prominent, and descends lower than the medial malleolus. Its lateral surface is convex, subcutaneous, and continuous with the triangular subcutaneous surface on the shaft, immediately above. The medial surface is divided into an anterior and upper area [facies articularis malleoli], triangular in outline and convex from above downward for articulation with the lateral side of the talus (astragalus), and a lower and posterior excavated area, the **digital fossa,** in which are attached the transverse inferior tibio-fibular ligament and the posterior talo-fibular (posterior fasciculus of the external lateral) ligament of the ankle. The anterior border is rough and gives attachment to the anterior talo-fibular (anterior fasciculus of the external lateral) ligament of the ankle, and the anterior inferior tibio-fibular ligament. The posterior border is grooved for the peronei tendons, and near its upper part gives attachment to the posterior inferior tibio-fibular ligament. The apex or summit of the process affords attachment to the calcaneo-fibular (middle fasciculus of the external lateral) ligament of the ankle.

Blood-supply.—The shaft of the fibula receives its nutrient artery from the peroneal branch of the posterior tibial. The head is nourished by branches from the inferior lateral articular branch of the popliteal artery, and the lateral malleolus is supplied mainly by the peroneal, and its perforating and malleolar branches.

Ossification.—The shaft of the fibula commences to ossify in the eighth week of intra-uterine life. A nucleus appears for the lower extremity in the second year, and one in the upper extremity during the fourth or fifth year. The lower extremity fuses with the shaft about twenty, but the upper extremity remains separate until the twenty-second year or even later.

It is interesting, in connection with the times of appearance of the two epiphyses of the fibula, to note that the ossification of the lower epiphysis is contrary to the general rule—viz., that the epiphysis toward which the nutrient artery is directed is the last to undergo ossification. This is perhaps explained by the rudimentary nature of the upper extremity. In birds the head of the bone is large and enters into the formation of the knee-joint; and in human embryos, during the second month, the fibula is quite close up to the femur.

The human fibula is characterised by the length of its malleolus, for in no other vertebrate does this process descend so far below the level of the tibial malleolus. On the other hand, in the majority of mammals the tibial descends to a lower level than the fibular malleolus. In the human embryo of the third month, the lateral is equal in length to the medial malleolus. At the fifth month the lateral malleolus exceeds the medial by 1.5 mm.; at birth, the lateral malleolus is still longer; and by the second year it assumes its adult proportion.

THE TARSUS

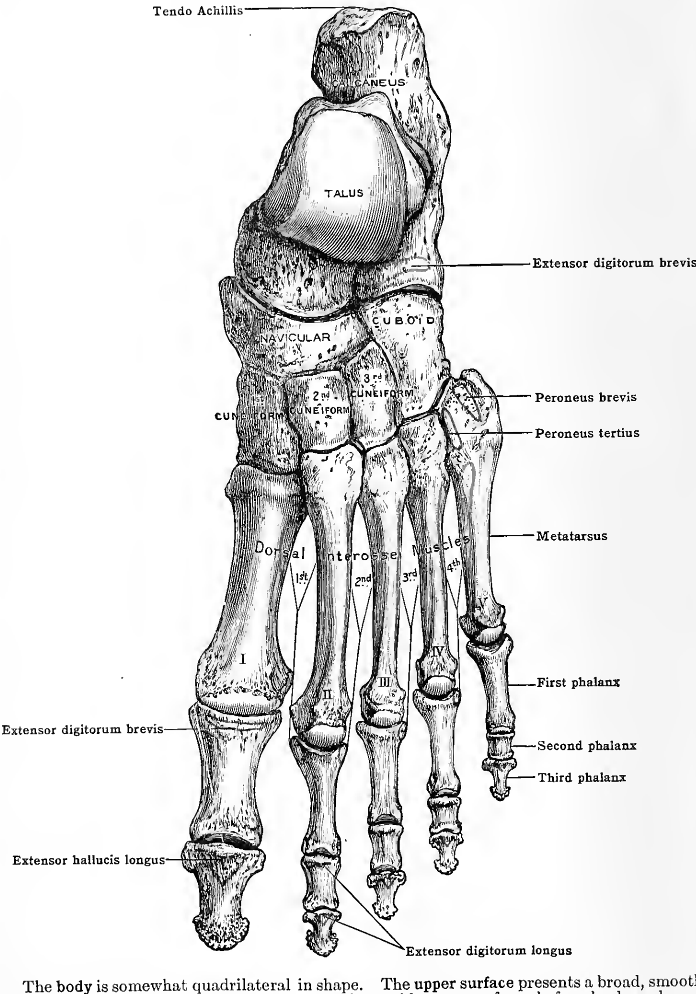
The **tarsal bones** [ossa tarsi] (figs. 228, 229) are grouped in two rows:—a proximal row, consisting of the **talus** and **calcaneus,** and a distal row, consisting of four bones which, enumerated from tibial side, are the **first, second,** and **third cuneiform** bones and the **cuboid.** Interposed between the two rows on the tibial side of the foot is a single bone, the **navicular;** on the fibular side the proximal and distal rows come into contact.

Compared with the carpus, the tarsal bones present fewer common characters, and greater diversity of size and form, in consequence of the modifications for supporting the weight of the trunk. On each, however, six surfaces can generally be recognised, articular when in contact with neighbouring bones, elsewhere subcutaneous or rough for the attachment of ligaments. As regards ossification, they correspond in the main with that of the bones of the carpus. Each tarsal bone is ossified from a single centre, but the calcaneus has, in addition, an epiphysis for a large part of its posterior extremity, and the talus, an occasional centre for the os trigonum.

The Talus

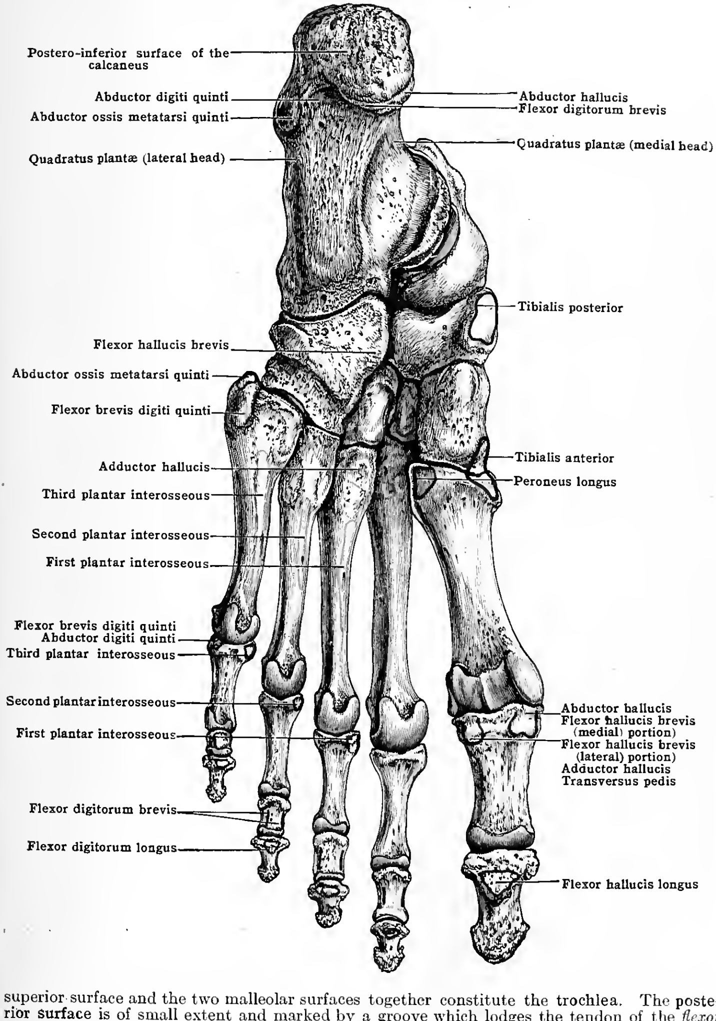
The **talus** (or astragalus) (figs. 230, 231) is, next to the calcaneus, the largest of the bones of the tarsus. Above it supports the tibia, below it rests on the calcaneus, at the sides it articulates with the two malleoli, and in front it is received into the navicular. For descriptive purposes, it may be divided into a **head, neck,** and **body.**

Fig. 228.—The Left Foot. (Superior surface.)



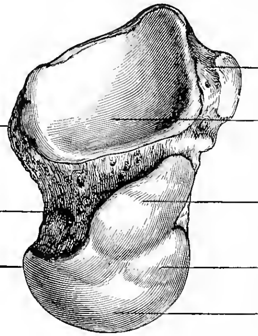
The **body** is somewhat quadrilateral in shape. The **upper surface** presents a broad, smooth surface for the tibia, slightly concave from side to side, convex from before backward, and wider in front than behind. The diminution in width posteriorly is associated with an obliquity of the lateral margin, which is directed medially as well as backward and downward. The **inferior surface is** occupied by a transversely disposed oblong facet [facies articularis calcanea posterior], deeply concave from side to side, which articulates with a corresponding surface on the calcaneus. Of the malleolar surfaces, the lateral is almost entirely occupied by a large triangular facet, broad above, where it is continuous with the superior surface, concave from above downward, for articulation with the lateral malleolus; on the **medial malleolar surface** is a pyriform facet continuous with the superior surface, broad in front and narrow behind, which articulates with the medial malleolus. Below this facet the medial surface is rough for the attachment of the deep fibres of the deltoid (internal lateral) ligament of the ankle. The

Fig. 229.—The Left Foot. (Plantar surface.)



superior surface and the two malleolar surfaces together constitute the **trochlea**. The **posterior surface** is of small extent and marked by a groove which lodges the tendon of the *flexor hallucis longus*. Bounding the groove on either side are two tubercles, of which the lateral [processus posterior tali] is usually the more prominent, for attachment of the posterior talo-fibular ligament of the ankle-joint; the medial tubercle gives attachment to the medial talo-calcaneal ligament.. Continuous with the anterior aspect of the body is the **neck**, a constricted part of the bone supporting the head. Above it is rough, and perforated by numerous vascular foramina. Below, it presents a deep groove [sulcus tali], directed from behind forward and lateralward. When the talus is articulated with the calcaneus, this furrow is converted into a canal [sinus tarsi] in which is lodged the interosseous talo-calcaneal ligament. The **head** is the rounded anterior end of the bone, and its large articular surface is divisible into three parts: in front, a smooth, oval convex area, directed downward and forward for the navicular bone; below, an elongated facet, convex from front to back, for articulation with the sustentaculum tali of the calcaneus; and between these, is a small facet which rests on the calcaneo-

Fig. 230.—The Left Talus. (Plantar view.)

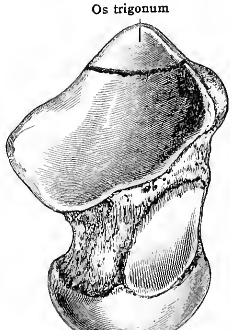


navicular ligament, separated from it by the synovial membrane of the talo-calcaneo-navicular joint.

Articulations.—The talus articulates with four bones and two ligaments. Above and medially with the tibia, below with the calcaneus, in front with the navicular, laterally with the fibula. The head articulates with the calcaneo-navicular ligament and the lateral border of the superior surface, at its posterior part, with the transverse ligament of the inferior tibiofibular joint.

The talus is a very vascular bone and is nourished by the dorsalis pedis artery and its tarsal branch. It gives attachment to no muscles.

Fig. 231.—A Talus with the Os Trigonum.



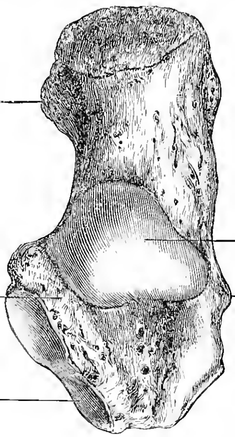
Ossification.—The talus is ossified from one, occasionally from two, nuclei. The principal centre for this bone appears in the middle of the cartilaginous talus at the seventh month of intra-uterine life. The additional centre is deposited in the posterior portion of the bone, and forms the lateral posterior tubercle which may remain separate from the rest of the bone and form the **os trigonum**. At birth, the talus presents some important peculiarities in the disposition of the articular facet on the tibial side of its body, and in the obliquity of its neck. If, in the adult talus, a line be drawn through the middle of the superior trochlear surface parallel with its medial border, and a second line be drawn along the lateral side of the neck of the bone so as to intersect the first, the angle formed by these two lines will express the obliquity of the neck of the bone. This in the adult varies greatly, but the average may be taken as 10°. In the fœtus at birth the angle averages 35°, whilst in a young orang it measures 45°. In the normal adult talus the articular surface on the tibial side is limited to the body of the bone. In the fœtal talus it extends for some distane on to the neck, and sometimes reaches almost as far forward as the navicular facet on the head of the bone. This disposition of the medial malleolar facet is a characteristic feature of the talus in the chimpanzee and the orang. It is related to the inverted position of the foot which is found in the human fœtus almost up to the period of birth, and is of interest to the surgeon in connection with some varieties of club-foot. (Shattock and Parker.)

The Calcaneus

The **calcaneus** (or os calcis) (figs. 232, 233) is the largest and strongest bone of the foot. It is of an elongated form, flattened from side to side, and expanded at its posterior extremity, which projects downward and backward to form the heel. It presents six surfaces, superior, inferior lateral, medial, anterior and posterior.

The **superior surface** presents in the middle a large, oval, convex, articular facet for the under aspect of the body of the talus. In front of the facet the bone is marked by a deep

Fig. 232.—The Left Calcaneus. (Dorsal view.)



depression, the floor of which is rough for the attachment of ligaments, especially the talo-calcaneal, and the origin of the *extensor digitorum brevis* muscle; when the calcaneus and talus are articulated, this portion of the bone forms the floor of a cavity called the **sinus tarsi**. Medially, the upper surface of the bone presents a well-marked process, the **sustentaculum tali**, furnished with an elongated concave facet, occasionally divided into two, for articulation with the under aspect of the head of the talus. The posterior part of the upper surface is non-articular, convex from side to side, and in relation with a mass of fat placed in front of the tendo Achillis.

The **inferior surface** is narrow, rough, uneven, and ends posteriorly in two processes: the **medial** is the larger and broader, the **lateral** is narrower but prominent. The medial process affords origin to the *abductor hallucis*, the *flexor digitorum brevis*, and the *abductor digiti quinti;* the last muscle also arises from the lateral process and from the ridge of bone between. The rough surface in front of the tubercles gives attachment to the long plantar ligament (calcaneo-cuboid) and the lateral head of the *quadratus plantæ*. Near its anterior end this surface forms a rounded eminence, the **anterior tubercle**, from which (as well as from the shallow groove in front) the plantar (short) calcaneo-cuboid ligament arises. (According to the BNA nomenclature, the medial and lateral processes belong to the *tuber calcanei* or the posterior extremity of the bone.)

The **lateral surface** is broad, flat, and slightly convex. It represents near the middle a small eminence for the calcaneo-fibular ligament of the ankle-joint. Below and in front of this is a well-marked tubercle—the **trochlear process** [processus trochlearis] (or peroneal tubercle), separating two grooves, the upper for the *peroneus brevis* and the lower for the *peroneus longus*.

The **medial surface** is deeply concave, the hollow being increased by the prominent medial process behind and the overhanging **sustentaculum tali** in front. The latter forms a prominence of bone projecting horizontally, concave and articular above, grooved below for the tendon of the *flexor hallucis longus*, and giving attachment to a slip of the tendon of the *tibialis posterior*, the inferior calcaneo-navicular ligament, and some fibres of the deltoid ligament of the ankle-joint. The hollow below the process receives the plantar vessels and nerves and its lower part gives attachment to the medial head of the *quadratus plantæ*.

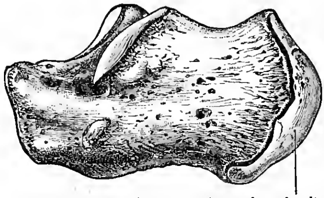
The **anterior surface** is somewhat quadrilateral in outline with rounded angles, and presents a saddle-shaped articular surface for the cuboid.

The **posterior surface** is oval in shape, rough, and convex. It is divided into three parts:—an upper, smooth and separated by a bursa from the tendo Achillis; a middle part giving attachment to the *tendo Achillis* and the *plantaris*, and a lower part in relation to the skin and fat of the heel. The expanded posterior extremity of the bone is known as the **tuber calcanei.**

Articulations.—The calcaneus articulates with two bones, the talus above and the cuboid in front.

Blood-supply.—The calcaneus is nourished by numerous branches from the posterior tibial and the medial and lateral malleolar arteries. They enter the bone chiefly on the inferior and medial surfaces.

FIG. 233.—THE CALCANEUS AT THE FIFTEENTH YEAR, SHOWING THE EPIPHYSIS.

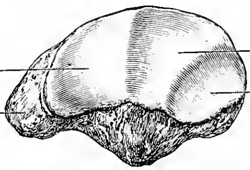


Ossification.—The primary nucleus appears in the sixth month of intra-uterine life. The epiphysis, for its posterior extremity, begins to be ossified in the tenth year and is united to the body of the bone by the sixteenth year. It may extend over the whole of the posterior surface, as shown in fig. 233, or over the lower two-thirds only, leaving a part above in relation to the bursa beneath the tendo Achillis, which is formed from the primary nucleus. The medial and lateral processes are formed by the epiphysis.

THE NAVICULAR

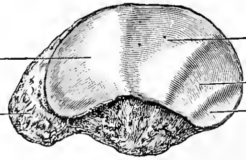
The **navicular** [os naviculare pedis] (figs. 234, 235) is oval in shape, flattened from before backward, and situated between the talus behind and the three cuneiform bones in front. It is characterised by a large oval, concave, articular

FIG. 234.—THE LEFT NAVICULAR. (Anterior view.)



facet on the **posterior surface,** which receives the head of the talus; a broad, rough, rounded eminence on the **medial surface,** named the **tuberosity** of the navicular, the lower part of which projects downward and gives insertion to the tendon of

FIG. 235.—THE LEFT NAVICULAR, SHOWING A FACET FOR THE CUBOID.



the *tibialis posterior;* and an oblong-shaped **anterior surface,** convex and divided by two vertical ridges into three facets which articulate with the three cuneiform bones. The **superior** (dorsal) **surface** is rough, convex, and slopes downward to the tuberosity; the **inferior** (plantar) **surface** is irregular and rough for the attachment of the inferior calcaneo-navicular ligament, and the **lateral surface** is rough and sometimes presents a small articular surface for the cuboid.

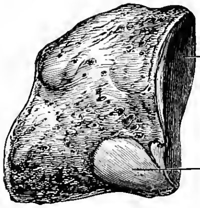
Articulations.—With the talus behind, with the three cuneiform bones in front, and occasionally with the cuboid on its lateral aspect.

Ossification.—The nucleus for the navicular appears in the course of the fourth year. The tuberosity of the navicular, into which the *tibialis posterior* acquires its main insertion, occasionally develops separately, and sometimes remains distinct from the rest of the bone.

The Cuneiform Bones

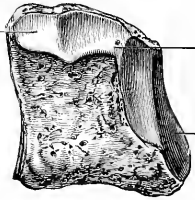
Of the three cuneiform bones, the first is the largest, the second is the smallest, and the third intermediate in size. They are wedge-shaped bones placed between the navicular and the first, second and third metatarsal bones. Posteriorly, the ends of the bones lie in the same transverse line, but in front, the first and third project farther forward than the second, and form the sides of a deep recess into which the base of the second metatarsal bone is received.

Fig. 236.—The Left First Cuneiform. (Medial surface.)



The **first cuneiform** [os cuneiforme primum] (figs. 236, 237) is distinguished by its large size and by the fact that when articulated, the base of the wedge is directed downward and the apex upward. The **posterior surface** is concave and pyriform for articulation with the medial facet on the anterior surface of the navicular. The **anterior surface** forms a reniform articular facet for the base of the first metatarsal. The **medial surface** is rough, and presents an oblique groove for the tendon of the *tibialis anterior;* this groove is limited inferiorly by an oval facet into which a portion of the tendon is inserted. The **lateral surface** is concave and presents along its superior and posterior borders a reversed **L**-shaped facet for articulation with the second cuneiform, and, at its anterior extremity, with the second metatarsal. Anteriorly it is rough for ligaments. The **inferior surface** is rough for the insertion of the *peroneus longus, tibialis anterior,* and (usually) the *tibialis posterior.* The **superior surface** is the narrow part of the wedge and is directed upward.

Fig 237.—The Left First Cuneiform. (Lateral aspect.)

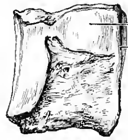


Articulations.—With the navicular behind, second cuneiform and second metatarsal on its lateral side, and first metatarsal in front.

Ossification.—From a single nucleus which appears in the course of the third year.

The **second cuneiform** [os cuneiforme secundum] (figs. 238, 239) is placed with the broad extremity upward and the narrow end downward, and is readily recognised by its nearly square base. The **posterior surface,** triangular and concave, articulates with the middle facet on the anterior surface of the navicular. The **anterior surface,** also triangular, but narrower than the posterior surface, articulates with the base of the second metatarsal. The **medial surface** has a reversed **L**-shaped facet running along its superior and posterior margins for articulation with the corresponding facet on the first cuneiform, and is rough elsewhere for the attachment of ligaments. On the **lateral surface** near its posterior border is a vertical facet, sometimes bilobed, for the third cuneiform, and occasionally a second facet at the anterior inferior angle. The **superior surface** forms the square-cut base of the wedge and is rough for the attachment of ligaments. The **inferior surface** is sharp and rough for ligaments and a slip of the tendon of the *tibialis posterior*.

Fig. 238.—The Left Second Cuneiform. (Medial surface.)

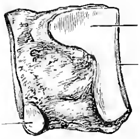


Articulations.—With the navicular behind, second metatarsal in front, third cuneiform on the lateral side, and first cuneiform on the medial side.

Ossification.—From a single nucleus which appears in the fourth year.

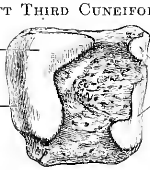
The **third cuneiform bone** (figs. 240, 241) also placed with the broad end directed upward and the narrow end downward, is distinguished by the oblong shape of its base. Like the

Fig. 239.—The Left Second Cuneiform. (Lateral surface.)



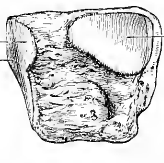
second cuneiform, the **posterior surface** presents a triangular facet for the navicular; and the **anterior surface** a triangular facet, longer and narrower, for the third metatarsal. The **medial surface** has a large facet extending along the posterior border for the second cuneiform, and along the anterior border a narrow irregular facet for the lateral side of the base of the second metatarsal. Occasionally, a small facet is present near the anterior inferior angle for the second

Fig. 240.—The Left Third Cuneiform. (Medial surface.)



cuneiform. The **lateral surface** has a large distinctive facet near its posterior superior angle for the cuboid, and at the anterior superior angle there is usually a small facet for the medial side of the base of the fourth metatarsal. The **superior surface**, oblong in shape, is rough for ligaments, and the **inferior**, forming a rounded margin, receives a slip of the *tibialis posterior* and gives origin to a few fibres of the *flexor hallucis brevis*.

Fig. 241.—The Left Third Cuneiform. (Lateral surface.)



Articulations.—With the navicular behind, third metartarsal in front, cuboid and fourth metatarsal on the lateral side, second cuneiform and second metatarsal on the medial side.

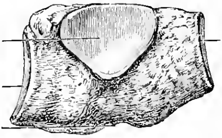
Ossification.—A single nucleus appears in the course of the first year.

The Cuboid

The **cuboid** (figs. 242, 243, 244), irregularly cubical in shape, is placed on the lateral aspect of the foot, forming a continuous line with the calcaneus and the fourth and fifth metatarsals.

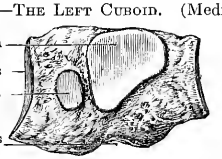
Its **posterior surface** is somewhat quadrangular with rounded angles and presents a saddle-shaped articular surface for the calcaneus. Its lower and medial angle is somewhat prolonged backward beneath the sustentaculum tali (calcaneal process of the cuboid), an arrangement to oppose the upward or outward movement of the bone. This process occasionally terminates

Fig. 242.—The Left Cuboid. (Medial view.)



in a rounded facet which plays on the head of the talus lateral to the facet for the calcaneo navicular ligament. The **anterior surface** is smaller and divided by a vertical ridge into two articular facets, a lateral for the base of the fifth, and a medial for the base of the fourth metatarsal. The **superior surface** is rough, non-articular, and directed obliquely upward. The **inferior surface** presents a prominent ridge for the attachment of the long plantar (calcaneo-cuboid) ligament, in front of which is a deep groove—the **peroneal groove**—running obliquely forward and medially and lodging the tendon of the *peroneus longus*. The ridge terminates laterally in an eminence, the **tuberosity** of the cuboid, on which there is usually a facet for a sesamoid bone of the tendon contained in the groove. The part of the surface behind the ridge is rough for the attachment of the plantar (short) calcaneo-cuboid ligament, a slip of the *tibialis posterior*, and a few fibres of the *flexor hallucis brevis*.

Fig. 243.—The Left Cuboid. (Medial view.)

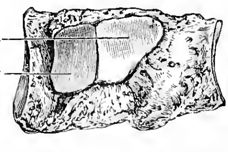


The **medial surface** presents, near its middle and upper part, an oval facet for articulation with the third cuneiform bone (fig. 242); behind this, a second facet for the navicular is frequently seen (fig. 243). Generally the two facets are confluent and then form an elliptical surface (fig. 244). The remainder of this surface is rough for the attachment of strong interosseous ligaments.

The **lateral surface**, the smallest and narrowest of all the surfaces, presents a deep notch which leads into the peroneal groove.

Articulations.—With the calcaneus behind, fourth and fifth metatarsals in front, third cuneiform and frequently the navicular on the medial side; occasionally also the talus.

Fig. 244.—The Left Cuboid. (Medial view.)



Ossification.—The cuboid is ossified from a single nucleus which appears about the time of birth.

Accessory tarsal elements.—As in the carpus, a number of additional elements may occur in the tarsus. The most frequent of these is the **os trigonum**, which has already been noticed. Next in frequency is an additional first cuneiform, resulting from the ossification of the plantar half of that bone independently of the dorsal half, so that the bone is represented by a plantar and a dorsal first cuneiform. Other additional elements may occasionally occur at the upper posterior angle of the sustentaculum tali; at the anterior superior angle of the calcaneus, between that bone and the navicular; in the angle between the first cuneiform and the first and second metatarsals; and in the fibular angle between the fifth metatarsal and the cuboid (**os Vesalianum**).

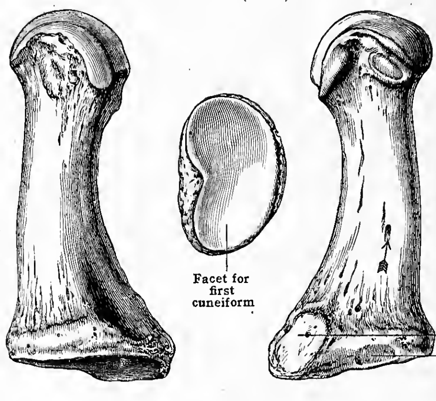
The fibular portion of the navicular is sometimes united to the cuboid and quite separate from the rest of the navicular, the cuboid in such cases articulating with the talus. This condition suggests the recognition of the fibular portion of the navicular as a distinct accessory tarsal element, the *cuboides secundarium*, though it has not yet been observed as an independent bone in the human foot.

THE METATARSUS

The **metatarsus** [ossa metatarsalia] consists of a series of five somewhat cylindrical bones. Articulated with the tarsus behind, they extend forward, nearly parallel with each other, to their anterior extremities, which articulate with the toes, and are numbered according to their position from great toe to small toe. Like the corresponding bones in the hand, each presents for examination a three-sided shaft, a proximal extremity termed the base, and a distal extremity or head. The shaft tapers gradually from the base to the head, and is slightly curved longitudinally so as to be convex on the dorsal and concave on the plantar aspect.

A typical metatarsal bone.—The **shaft** [corpus] is compressed laterally and presents for examination three borders and three surfaces. The two **borders,** distinguished as **medial** and **lateral,** are sharp and commence behind, one on each side of the dorsal aspect of the tarsal extremity, and, gradually approaching in the middle of the shaft, separate at the anterior end to terminate in the corresponding

Fig. 245.—The First (Left) Metatarsal.

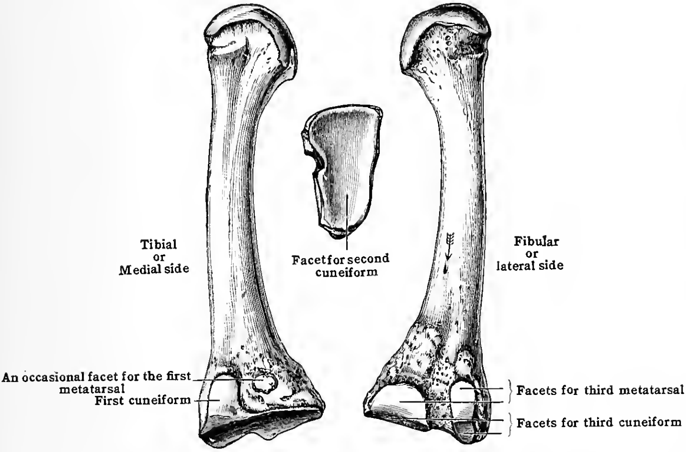


tubercles. The **inferior border** is thick and rounded and extends from the under aspect of the tarsal extremity to near the anterior end of the bone, where it bifurcates, the two divisions terminating in the articular eminences on the plantar aspect of the head. Of the three surfaces, the **dorsal** is narrow in the middle and wider at either end. It is directed upward and is in relation with the extensor tendons. The **medial** and **lateral surfaces,** more extensive than the dorsal, corresponding with the interosseous spaces, are separated above, but meet together at the inferior border; they afford origin to the *interosseous* muscles. The **base** is wedge-shaped, articulating by its terminal surface with the tarsus, and on each side with the adjacent metatarsal bones. The dorsal and plantar surfaces are rough for the attachment of ligaments. The **head** presents a semicircular articular surface for the base of the first phalanx, and on each side a depression, surmounted by a tubercle, for the attachment of the lateral ligaments of the metatarso-phalangeal joint. The inferior surface of the head is grooved for the passage of the flexor tendons and is bounded by two eminences continuous with the terminal articular surface.

The several metatarsals possess distinctive characters by which they can be readily recognised.

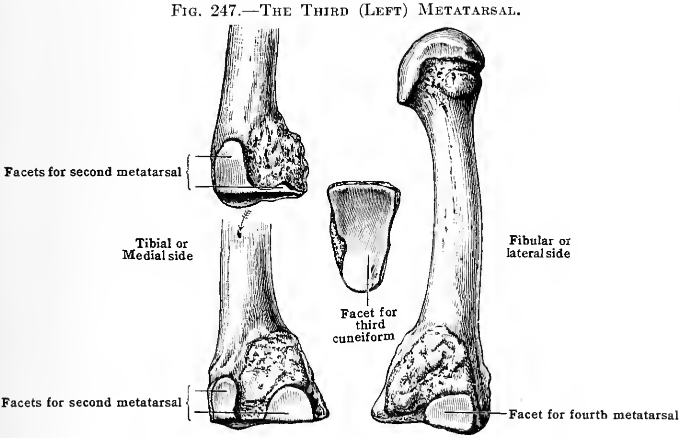
The **first metatarsal** (fig. 245) is the most modified of all the metatarsal bones, and deviates widely from the general description given above. It is the shortest, the thickest, the strongest, and most massive of the series. The **base** presents a large reniform, slightly concave facet for the first cuneiform and projects downward into the sole to form the **tuberosity,** a rough eminence into which the *peroneus longus* and a slip of the *tibialis anterior* are inserted. A little

FIG. 246.—THE SECOND (LEFT) METATARSAL.



above the tuberosity, on its lateral side, there is occasionally a shallow, but easily recognised facet, for articulation with the base of the second metatarsal. The **head** is marked on the plantar surface by two deep grooves, separated by a ridge, in which the two sesamoid bones of the *flexor hallucis brevis* glide. The **shaft** is markedly prismatic. The **dorsal surface** is smooth, broad, and convex, directed obliquely upward; the **plantar surface** is concave longitudinally

FIG. 247.—THE THIRD (LEFT) METATARSAL.



and covered by the *flexor hallucis longus* and *brevis*, whilst the **lateral surface** is triangular in outline, almost vertical, and in relation with the first *dorsal interosseous* and *adductor hallucis obliquus*. A few fibres of the medial head of the first *dorsal interosseous* occasionally arise from the hinder part of the surface adjoining the base, or from the border separating the lateral from the dorsal surface. Somewhere near the middle of the shaft, and on its fibular side, is the nutrient foramen, directed toward the head of the bone.

The second metatarsal (fig. 246) is the longest of the series. Its base is prolonged backward to occupy the space between the first and third cuneiform, and accordingly it is marked by facets for articulation with each of these bones. The tarsal surface is triangular in outline, with the base above and apex below, and articulates with the second cuneiform bone. On the tibial side of the base, near the upper angle, is a small facet for the first cuneiform, and occasionally another for the first metatarsal a little lower down. The fibular side of the base presents an upper and a lower facet, separated by a non-articular depression, and each facet is divided by a vertical ridge into two, thus making four in all. The two posterior facets articulate with the third cuneiform and the two anterior with the third metatarsal. The base gives attachment to a slip of the *tibialis posterior* and the *adductor hallucis obliquus,* whilst from the shaft the first and second *dorsal interosseous* muscles take origin. The nutrient foramen is situated on the fibular side of the shaft near the middle and is directed toward the base of the bone.

Fig. 248.—The Fourth (Left) Metatarsal.

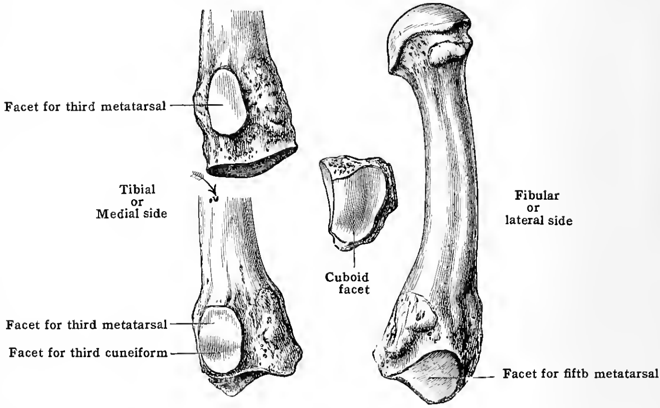


Fig. 249.—The Fifth (Left) Metatarsal.

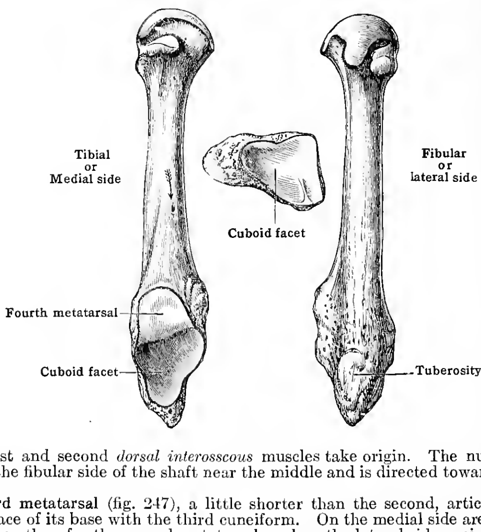


The third metatarsal (fig. 247), a little shorter than the second, articulates by the triangular surface of its base with the third cuneiform. On the medial side are two small facets, one below the other, for the second metatarsal, and on the lateral side, a single large facet for the fourth metatarsal. The base gives attachment to a slip of the *tibialis posterior* and the *adductor hallucis obliquus*, and from the shaft three *interosseous* muscles take origin. The nutrient foramen is situated on the tibial side of the shaft and is directed toward the base.

The **fourth metatarsal** (fig. 248), smaller in size than the preceding, is distinguished by the quadrilateral facet on the base, for the cuboid. The medial side presents a large facet divided by a ridge into an anterior portion for articulation with the third metatarsal and a posterior portion for the third cuneiform. Occasionally the cuneiform part of the facet is wanting. On the lateral side of the base is a single facet for articulation with the fifth metatarsal.

The **fifth metatarsal** (fig. 249), is shorter than the fourth, but longer than the first. It is recognised by the large nipple-shaped process, known as the **tuberosity,** which projects on the lateral side of the base. It constitutes the hindmost part of the bone and gives insertion to the *peroneus brevis* on the dorsal aspect, and *flexor brevis digiti quinti* and the occasional *abductor ossis metatarsi quinti* on the plantar aspect. The fifth metatarsal articulates behind by an obliquely directed triangular facet with the cuboid, and on the medial side with the fourth metatarsal. The plantar aspect of the base is marked by a shallow groove which lodges the tendon of the *abductor digiti quinti*, and the dorsal surface, continuous with the superior surface of the shaft, receives the insertion of the *peroneus tertius*. The **head** is small and turned somewhat laterally in consequence of the curvature of the shaft in the same direction. The **shaft** differs from that of any of the other metatarsals in being compressed from above downward, instead of from side to side, so as to present superior, inferior, and medial surfaces. It gives origin to the lateral head of the fourth *dorsal interosseous* and the third *plantar interosseous* muscles. The nutrient foramen is situated on its tibial side and is directed toward the base.

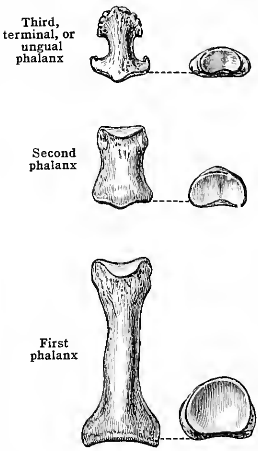
Ossification.—Each metatarsal ossifies from two centres. The primary nucleus for the shaft appears in the eighth week of embryonic life in the middle of the cartilaginous metatarsal. At birth, each extremity is represented by cartilage, and that at the proximal end is ossified by extension from the primary nucleus, except in the case of the first metatarsal. For this, a nucleus appears in the third year.

The distal ends of the four lateral metatarsals are ossified by secondary nuclei which make their appearance about the third year. Very frequently an epiphysis is found at the distal end of the first metatarsal as well as at its base. The shafts and epiphyses consolidate at the twentieth year. The sesamoids belonging to the *flexor hallucis brevis* begin to ossify about the fifth year.

THE PHALANGES

The **phalanges** (fig. 250) are the bones of the toes, and number in all fourteen. Except the great toe, each consists of three phalanges, distinguished as first (proximal), second and third (distal); in the great toe the second phalanx is absent.

FIG. 250.—THE PHALANGES OF THE MIDDLE TOE.



There is thus a similarity as regards number and general arrangement with the phalanges of the fingers. With the exception of the phalanges of the great toe, which are larger than those of the thumb, the bones of the toes are smaller and more rudimentary than the corresponding bones of the fingers. In all the phalanges, the nutrient foramen is directed toward the distal extremity.

The phalanges of the **first** row are constricted in the middle and expanded at either extremity. The shafts are narrow and laterally compressed, rounded on the dorsal and concave on the plantar aspects. The base of each presents a single oval concave facet for the convex head of the corresponding metatarsal, whilst the head forms a pulley-like surface [trochlea phalangis], grooved in the centre and elevated on each side for the second phalanx.

The phalanges of the **second row** are stunted, insignificant bones. Their shafts, besides being much shorter, are flatter than those of the first row. The **bases** have two depressions, separated by a vertical ridge, and the heads present **trochlear** surfaces for the ungual phalanges.

The **third,** or **ungual** phalanges are easily recognised. The bases articulate with the second phalanges; the shafts are expanded, forming the ungual tuberosities which support the nails, and their plantar surfaces are rough where they come into relation with the pulp of the digits.

The muscles attached to the various phalanges may be tabulated thus:—

The **first phalanx of the hallux** gives insertion to the flexor hallucis brevis; abductor hallucis; adductor hallucis transversus and obliquus; extensor digitorum brevis.

The **first phalanx of second toe**: The first and second dorsal interosseous.

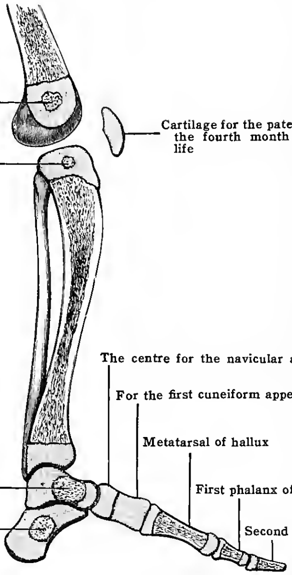
The **first phalanx of third toe**: Third dorsal interosseous; first plantar interosseous.

The **first phalanx of fourth toe**: Second plantar interosseous; fourth dorsal interosseous.

The **first phalanx of fifth toe**: Third plantar interosseous; flexor digiti quinti brevis; and abductor digiti quinti.

The **terminal phalanx of hallux**: Flexor hallucis longus; extensor hallucis longus.

Fig. 251.—A Longitudinal Section of the Bones of the Lower Limb at Birth.



The **second phalanges of the remaining toes**: Dorsal expansion of the extensor tendons, including extensor digitorum longus, extensor digitorum brevis (except in the case of the fifth toe), and expansions from the interossei and lumbricales.

The **third phalanges**: Flexor digitorum longus; dorsal expansion of the extensor tendon with the associated muscles.

Ossification.—Like the corresponding bones of the fingers, the phalanges of the toes ossify from a primary and a secondary nucleus. In each, the centre for the shaft appears during the eighth or ninth week of embryonic life. The secondary centre forms a scale-like epiphysis for the proximal end between the fourth and eighth years, and union takes place in the eighteenth or nineteenth year—i. e., earlier than the corresponding epiphyses in the fingers. The primary centres for the third phalanges appear at the distal extremities of the bones.

Sesamoid Bones

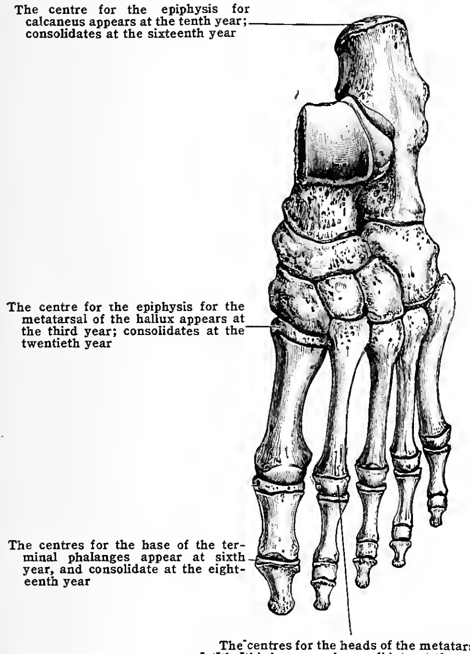
In the foot a pair of sesamoid bones is constant over the metatarso-phalangeal joint of the great toe in the tendons of the flexor hallucis brevis. One sometimes occurs over the iuter-phalangeal joint of the same toe and over the metatarso-phalangeal joints of the second and fifth and rarely of the third and fourth toes.

A sesamoid also occurs in the tendon of the peroneus longus, where it glides over the groove in the cuboid; another may be found, especially in later life, in the tendon of the tibialis anterior over the first cuneiform bone, and another in the tendon of the tibialis posterior over the medial surface of the head of the talus. Further a sesamoid, the fabella, sometimes occurs in the lateral head of the gastrocnemius, and another may be found in the tendon of the ilio-psoas over the pubis.

BONES OF THE FOOT AS A WHOLE

Although the foot is constructed on the same general plan as the hand, there is a marked difference in its architecture to qualify it for the different functions which it is called upon to perform. When in the erect posture, the foot forms a firm basis of support for the rest of the body, and the bones are arranged in an elliptical arch, supported on two pillars, a posterior or *calcaneal* pillar and an

FIG. 252.—THE SECONDARY OSSIFIC CENTRES OF THE FOOT.



anterior or *metatarsal* pillar. It is convenient, however, to regard the anterior part of the arch as consisting of two segments, corresponding to the medial and lateral borders of the foot respectively. The medial segment is made up of the three metatarsal bones, the three cuneiform, the navicular, and talus; the lateral segment is made up of the fourth and fifth metatarsal bones, the cuboid, and the calcaneus, and both segments are supported behind on a common *calcaneal* pillar. The division corresponds to a difference in function of the two longitudinal arches. Both are intimately concerned in ordinary locomotion. In addition, the medial, characterised by its great curvature and remarkable elasticity, sustains the more violent concussions in jumping and similar actions, whereas the lateral, less curved, more rigid, and less elastic arch forms, with the pillars in front and behind, a firm basis of support in the upright posture.

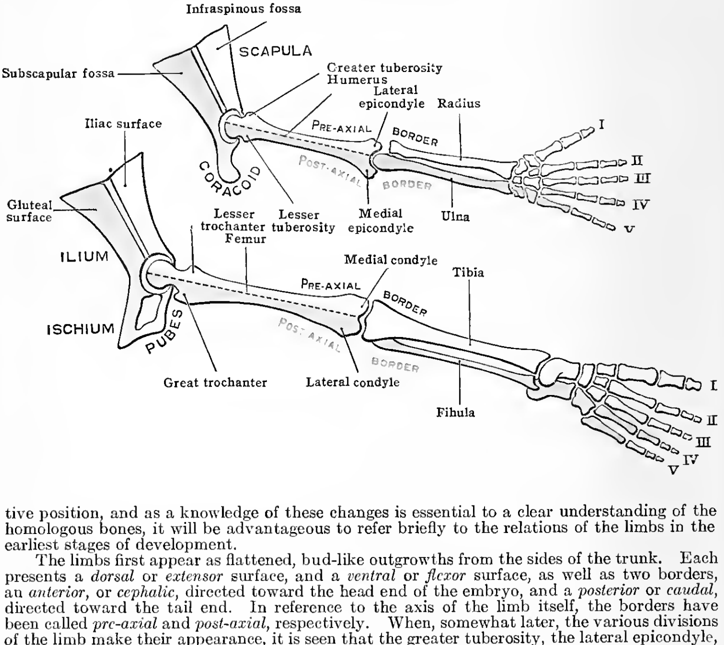
Both arches are completed and maintained by strong ligaments and tendons. The weakest part is the joint between the talus and navicular bone, and special provision is accordingly made, by the addition of a strong calcaneo-navicular ligament, for the support of the head of the talus. This ligament is in turn supported by its union with the deltoid ligament of the ankle, and by the tendon of the *tibialis posterior* which passes beneath it to its insertion.

Besides being arched longitudinally, the foot presents a transverse arch formed by the metatarsal bones in front and the distal row of the tarsus behind. It is produced by the marked elevation of the central portion of the medial longitudinal arch above the ground, whereas the lateral longitudinal arch is much less raised, and at its anterior end becomes almost horizontal. Both the longitudinal and transverse arches serve the double purpose of increasing the strength and elasticity of the foot and of providing a hollow in which the muscles, nerves, and vessels of the sole may lie protected from pressure.

Homology of the Bones of the Limbs

That there is a general correspondence in the plan of construction of the two extremities is apparent to a superficial observer, and this becomes more marked when a detailed examination of the individual bones, their forms and relations, their embryonic and adult peculiarities, is systematically carried out. In each limb there are four segments, the shoulder girdle corresponding to the pelvic girdle, the arm to the thigh, the forearm to the leg, and the hand to the foot. These parts have been variously modified, in adaptation to the different functions of the two limbs, particularly as regards the deviations or changes from what is regarded as their primitive position, and as a knowledge of these changes is essential to a clear understanding of the homologous bones, it will be advantageous to refer briefly to the relations of the limbs in the earliest stages of development.

Fig. 253.—Diagrammatic Representation of the Bones of the Two Limbs, to show Homologous Parts. (Modified from Flower.)



The limbs first appear as flattened, bud-like outgrowths from the sides of the trunk. Each presents a *dorsal* or *extensor* surface, and a *ventral* or *flexor* surface, as well as two borders, an *anterior*, or *cephalic*, directed toward the head end of the embryo, and a *posterior* or *caudal*, directed toward the tail end. In reference to the axis of the limb itself, the borders have been called *pre-axial* and *post-axial*, respectively. When, somewhat later, the various divisions of the limb make their appearance, it is seen that the greater tuberosity, the lateral epicondyle, the radius, and the thumb lie on the pre-axial border of the anterior extremity, and the small trochanter, the medial condyle, the tibia, and the great toe on the pre-axial border of the posterior extremity. Further on the post-axial border of the anterior extremity are seen the lesser tuberosity, the medial epicondyle, the ulna, and little finger, whilst on the corresponding border of the posterior limb are the great trochanter, the lateral condyle, the fibula, and the little toe. The parts now enumerated on the corresponding borders of the two limbs must therefore be regarded as serially homologous (fig. 253).

It is necessary to trace next the further changes which take place in the segments of the limbs up to the time when they assume their permanent positions. They may be arranged in stages as follows:—

(1) Each segment of the limb is bent upon the one above it. The humerus and femur remain unchanged. The forearm segment, however, is bent so that the ventral surface looks medially and the dorsal surface laterally. Moreover, the joints between these segments—i. e., elbow and knee—form marked projections. The terminal segments (hand and foot) are bent in the opposite direction to the middle one, so that the primitive position is retained, and the ends of the digits directed laterally. It will be noticed that in this series of changes the relations of the pre-axial and post-axial borders of the limbs remain as before.

(2) This stage consists in a rotation of the whole limb from the proximal end, though in an exactly opposite direction in each case. The anterior extremity is rotated *backward* so that the humerus lies parallel with the trunk; the elbow is directed toward the caudal end, the pre-axial (radial) border becomes lateral, and the post-axial border medial. The ends of the digits point backward. The posterior extremity undergoes a rotation *forward* to the same extent, so that the femur is also nearly parallel with the trunk; the knee is directed toward the head end, the pre-axial (tibial) border becomes medial, and the post-axial border lateral. The tibia and fibula are parallel, the ends of the digits are directed forward, the great toe is on the pre-axial and the little toe on the post-axial border of the limb, and in this position the posterior extremity remains, the changes being finally completed by the extension of the limb at the hip-joint as the body attains its full development.

(3) This stage affects the anterior extremity alone and consists in a rotation of the radius, carrying the hand round the ulna so that the digits are brought round from the back to the front of the limb, and in many animals the manus is thus placed permanently in the prone position. But in man, in whom the capacity for pronation and supination is highly developed, the hand can assume either position at will. In his case the final change is the extension which takes place at the shoulder-joint with the assumption of the upright posture, the limb dropping loosely at the side of the body, and being endowed with the greatest freedom of movement.

Homological comparison of—

I. The shoulder and pelvic girdles.—Primarily the lateral half of each girdle consists of a curved bar or rod of cartilage placed at right angles to the longitudinal axis of the trunk and divisible into a dorsal segment, and a ventral segment, the point of division corresponding to the place of articulation with the limb-stalk—i. e., the glenoid and acetabular cavities. In the fore-limb the dorsal segment is the scapula, and the ventral segment the coracoid, whilst in the hind-limb the dorsal segment is the ilium and the ventral segment the ischium and pubis.

The dorsal segments of the two girdles—i. e., scapula and ilium—are accordingly regarded as homologous bones, the chief difference being that whereas the scapula is free from articulation with the vertebral column, the ilium is firmly jointed to the rib elements (lateral mass) of the sacrum. But the correspondence is not quite so clear with regard to the ventral segments. In the primitive condition the coracoid articulates with the side of the sternum, an arrangement which persists throughout life in certain animals, such as reptiles and Ornithorhynchus. But in all the higher mammals it undergoes reduction, withdrawing from the side of the sternum, and eventually forming a more or less rudimentary process attached to the scapula. In the more generalised form of shoulder girdle the ventral bar is double, consisting of coracoid and pre-coracoid elements, the latter being situated in front and almost parallel with the coracoid. The pre-coracoid in mammals is largely replaced by the development over it of the clavicle, a dermal or membranous splint-bone which eventually invades the underlying cartilage. Parts, however, remain distinct and form the sternal epiphysis of the clavicle, the inter-articular cartilage between it and the sternum, the supra-sternal bones, and the inconstant inter-articular cartilage in the acromio-clavicular joint.

It has already been noticed that in the hip girdle the ventral segment also consists of two elements, the pubis and ischium. Both take part in the formation of the acetabular cavity, and the pubis meets in the ventral median line the corresponding segment of the opposite side.

It is generally agreed that the coracoid and ischium are homologous structures. The pubic portion of the ventral segment appears to correspond most closely with the pre-coracoid element of reptiles, so that there is no true homologue of the clavicle in the pelvis. If, however, the clavicle corresponds to the reptilian pre-coracoid, as believed by many anatomists, it then becomes the representative of the pubis.

From a consideration of the condition in cranio-cleido-dysostosis, Mr. Fitzwilliams has put forward the following views regarding the homology of the shoulder girdle:—Coracoid bar is represented by (a) medial two-thirds of clavicle; (b) coraco-clavicular ligaments; and (c) sub-coracoid centre of coracoid process. The clavicula, a membranous bone, is represented by the lateral third of adult clavicle. The pre-coracoid bar is represented by:—(a) the coracoid process (less the sub-coracoid centre); and (b) the costo-coracoid ligament. The epi-coracoid is represented by the meniscus of the sterno-clavicular joint.

Moreover, it is possible to establish a comparison between the individual parts of the ilium and scapula. A reference to fig. 253 shows that both the scapula and ilium may be resolved into three-sided prismatic rods, each of which has three surfaces and three borders. In the primitive position of the limb one surface—the *internal*—is turned toward the vertebral column, the remaining surfaces are *external*, and named *pre-axial* and *post-axial*, corresponding to the borders of the limb. The borders separating the internal from the external surfaces are antero-internal (terminating in the acromion or pubis) and postero-internal (terminating in the coracoid or ischium). The two external surfaces are separated by a ridge, terminating below at the upper margin of the glenoid cavity or acetabulum (glenoid and cotyloid borders).

The primitive arrangement is lost by the marked growth of the borders of the rods leading to the formation of fossæ and by the rotation of each rod, the scapula *laterally* and the ilium *medially*, in association with the rotation which takes place in the free part of the limb, so that the inner surface of the one comes to correspond with the outer surface of the other. It results that the primitive vertebral surface of the scapula is now the pre-scapular or supraspinous fossa, and the corresponding surface in the ilium is the sacral, which, on account of its close connection with the vertebral column, undergoes but little change in position. Further, the primitive pre-axial surfaces are the infraspinous fossa and the iliac fossa, which accordingly are to be regarded as homologous, as well as the two post-axial surfaces, the subscapular fossa and the dorsum ilii. The correspondence between the various parts of the scapula and ilium is shown in the appended table (after Flower).

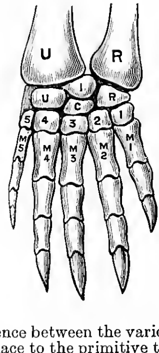
	Scapula	Primitive Arrangement	Ilium
I. Surfaces:	Supraspinous fossa.	Vertebral.	Sacral surface.
	Infraspinous fossa.	Pre-axial.	Iliac fossa.
	Subscapular fossa.	Post-axial.	Gluteal surface.
II. Borders:	Axillary or glenoid.	External.	Cotyloid or anterior border.
	Spine.	Antero-internal.	Terminal line.
	Superior or coracoid.	Postero-internal.	Posterior border.
	Base.	Dorsal extremity.	Crest of ilium.

II. Bones of the arm and thigh, forearm, and leg.—It has already been pointed out in describing the deviation of the limbs from the primitive position that the humerus corresponds to the femur, the radius to the tibia, and the ulna to the fibula; also that in consequence of the rotation backward of the fore-limb, and forward of the hind-limb, the lateral side of the humerus corresponds with the medial side of the femur, the radial border of the forearm to the tibial border of the leg, and the ulnar (border of the forearm) to the fibular border of the leg. The corresponding parts are tabulated below:—

Fore-Limb	Hind-Limb
Humerus	Femur
Greater tuberosity	Lesser Trochanter
Lesser tuberosity	Great Trochanter
Lateral epicondyle and capitulum	Medial Condyle
Medial epicondyle and trochlea	Lateral Condyle
Radius	Tibia
Ulna	Fibula
Not represented	Patella

III. Bones of the hand and foot.—It is obvious that the carpus and tarsus, the metacarpus and metatarsus, and the various digits, commencing at the thumb, in the hand, and at the great toe, in the foot, are serially homologous.

Fig. 254.—Dorsal Surface of the Right Manus of a Water-tortoise, *Chelydra serpentina.* (After Gegenbaur.)



In order to trace the correspondence between the various elements of the carpus and tarsus it is convenient to refer in the first place to the primitive type of hand and foot as found in the water-tortoise and the lizard (fig. 254). In each segment nine elements may be recognised, arranged in a proximal row of three, named respectively *radiale* or *tibiale, intermedium,* and *ulnare,* or *fibulare,* a distal row of five *carpalia,* or *tarsalia,* numbered from one to five, commencing at the pre-axial border, and between the two rows an *os centrale.*

In man the carpus is derived from the typical form in the following manner: The radiale forms the navicular, intermedium the lunate, and the ulnare, the triquetral; carpale I forms the greater multangular, carpale II the lesser multangular, carpale III the capitate, whilst carpalia IV and V coalesce to form the hamate. The os centrale is present in the human carpus at an early stage, but in the second month it joins the navicular. It is occasionally separate—a normal arrangement in most of the primates.

In the tarsus, the tibiale and intermedium coalesce to form the talus, and the fibulare becomes the calcaneus. It is interesting to note that although in the human subject there are three bones in the first row of the carpus and two in the first row of the tarsus, in carnivores the navicular and lunate are united to form a naviculo-lunate bone—the homologue of the talus. In the human tarsus the intermedium occasionally remains distinct as the *os trigonum*.

Tarsale I forms the first cuneiform, tarsale II the second cuneiform, tarsale III the third cuneiform, and tarsale IV and V are joined to form the cuboid. The os centrale forms the navicular.

In addition to the carpal and tarsal elements enumerated above, brief mention must now be made of the sesamoid bones of the two segments, which are regarded by many anatomists as vestiges of suppressed digits. In the hand are the **ulnar** and **radial sesamoids**, the ulnar being represented by the pisiform and the radial probably by the tuberosity of the navicular. (In the mole and other allied species with fossorial habits, the radial sesamoid is greatly developed to form a sickle-shaped bone which has received the name of *os falciforme*.)

The corresponding structures in the foot are the **tibial** and **fibular sesamoids**, the tibial being most nearly represented by the tuberosity of the navicular and the fibular by the tuber of the calcaneus.

TABLE SHOWING THE HOMOLOGOUS BONES OF THE CARPUS AND TARSUS. (*After G. D. Thane in Quain's Anatomy.*)

CARPUS	PRIMITIVE	NAMES	TARSUS
Triquetral	Ulnare	Fibulare	Calcaneus
Pisiform	Ulnar sesamoid	Fibular sesamoid	
Lunate	Intermedium	Intermedium	Talus
Navicular	Radiale	Tibiale	
	Radial sesamoid	Tibial sesamoid	Navicular
	Centrale	Centrale	
Greater multangular	Carpale I	Tarsale I	First cuneiform
Lesser multangular	" II	" II	Second cuneiform
Capitate	" III	" III	Third cuneiform
Hamate	" IV	" IV	Cuboid
	" V	" V

For further references concerning the *adult structure* and *morphology* of the skeleton, the sections on osteology in the larger works on human anatomy by Quain, von Bardeleben, Rauber-Kopsch. Poirier-Charpy, etc., should be consulted. References to the most recent literature may be found in Schwalbe's Jahresbericht, the Index Medicus, and in the various anatomical journals.

SECTION III

THE ARTICULATIONS

REVISED FOR THE FIFTH EDITION

BY FREDERIC WOOD JONES, D.Sc., M.B., B.S.(LOND.), M.R.C.S., L.R.C.P.

HEAD OF THE DEPARTMENT OF ANATOMY AND LECTURER IN THE LONDON SCHOOL OF MEDICINE FOR WOMEN.

THE CONSTITUENTS OF AN ARTICULATION

THE section devoted to the Articulations or Joints deals with the union of the various and dissimilar parts of the human skeleton. The following structures enter into the formation of joints.

Bones constitute the basis of most joints. The long bones articulate by their ends, the flat by their edges, and the short at various parts on their surfaces. The articular ends are usually expanded, and are composed of cancellous tissue, surrounded by a dense and strong shell of compact tissue.

This shell has no Haversian canals (the vessels of the cancellous tissue turn back and do not perforate it), or large lacunæ, and no canaliculi, and is thus well adapted to bear pressure. This "osteoid" layer may represent in part calcified cartilage rather than true bone.

The **cartilage** which covers the articular ends of the bones is called **articular,** and is of the **hyaline variety.** It is firmly implanted on the bone by one surface, while the other is smooth, polished, and free, thus reducing friction to a minimum, while its slight elasticity tends to break jars. It ends abruptly at the edge of the articulation, and is thickest over the areas of greatest pressure.

Another form of cartilage, the **white fibrous,** is also found in joints:—

(i) As *interarticular cartilage* in diarthrodial joints—viz., in the knee, mandibular, sterno-clavicular, radio-carpal, and occasionally in the acromio-clavicular joint. It is interposed between the ends of the bones, partially or completely dividing the synovial cavity into two. It serves to adjust dissimilar bony surfaces, adding to the security of, while it increases the extent of motion at, the joint; it also acts as a buffer to break shocks.

(ii) As *circumferential* or marginal fibro-cartilages, which serve to deepen the sockets for the reception of the heads of bones—e. g., the glenoid ligaments of the shoulder and hip. Another form of marginal plate is seen in the accessory volar ligaments of the fingers and toes, which deepen the articulations of the phalanges and add to their security.

(iii) As *connecting fibro-cartilage.* The more pliant and elastic is the more cellular form, and is found in the intervertebral discs; while the less yielding and more fibrous form is seen in the sacro-iliac and pubic articulations, where there is little or no movement.

The **ligaments** which bind the bones together are strong bands of white fibrous tissue, forming a more or less perfect capsule [capsula articularis], round the articulation. They are pliant but inextensile, varying in shape, strength, and thickness according to the kind of articulation into which they enter. They are closely connected with the periosteum of the bones they unite. In some cases—as the ligamenta flava which unite parts not in contact—they are formed of yellow elastic tissue.

The **synovial membrane** [stratum synoviale] lines the interior of the fibrous ligaments, thus excluding them, as well as the cushions or pads of fatty tissue situate within and the tendons which perforate the fibrous capsule, from the articular cavity. It is a thin, delicate membrane, frequently forming folds and fringes which project into the cavity of the joint; or, as in the knee, stretches across the cavity, forming a so-called synovial ligament. In these folds are often found pads of fatty tissue, which fill up interstices, and form soft cushions between the contiguous bones. The amount of fat that is normally present within a joint varies greatly. It is an old observation that although there is always fat in the hip-and knee-joints, there is usually none within the shoulder-joint. Sometimes these fringes become villous and pedunculated, and cause pain on movement of the joints. They contain fibro-fatty tissue, with an isolated cartilage cell or two. The synovial membrane is well supplied with blood, especially near the margins of the articular cartilages and in the fringes. It secretes a thick, glairy fluid like white of egg, called synovia, which lubricates the joint. Another variety of synovial membrane is seen in the bursæ, which are interposed between various moving surfaces. In some instances bursæ in the neighbourhood of a joint may communicate with the synovial cavity of that joint.

CLASSIFICATION OF ARTICULATIONS

Joints may be classified:—(*a*) From an anatomical point of view, with regard to the substances and the arrangement of the substances by which the constituent parts are united. (*b*) From a physiological standpoint, with regard to the greater or smaller mobility at the seat of union. (*c*) From a physical standpoint, either the shapes of the portions in contact being mainly considered or the axes round which movement can occur. Or again (*d*) a combination of the preceding methods may be adopted, and this is the plan most generally followed. None of the classifications hitherto used is quite satisfactory, but perhaps, on the whole, that suggested by Prof. Alex. Macalister is the least open to objection, and therefore with slight modification it is utilised here.

There are three chief groups of joints:—

1. *Synarthroses.* In joints of this class the bones are united by fibrous tissue.

2. *Synchondroses.* Or joints in which the uniting substance intervening between the bones is cartilage.

3. *Diarthroses.* The constituent parts of joints of this class are (*a*) two or more bones each covered by articular hyaline cartilage; (*b*) a fibrous capsule uniting the bones, and (*c*) a synovial membrane which lines the fibrous capsule and covers any part of bone enclosed in the capsule and not covered with articular cartilage. An interarticular plate of cartilage may or may not be present.

1. **Synarthroses.**—
   - (*a*) *Sutures* or immovable joints, in which the fibrous tissue between the bones is too small in amount to allow movement.
     - (1) *Harmonic.* The edges of the bones are comparatively smooth and are in even apposition, e. g., vertical plate of palate and maxilla.
     - (2) *Squamous.* The margin of one bone overlaps the other, e. g., temporal and parietal.
     - (3) *Serrate.* The opposed edges interlock by processes tapering to a point.
     - (4) *Dentate.* The opposed edges are dovetailed, e. g., occipital and parietal.
     - (5) *Limbous.* The opposed edges alternately overlap, e. g., parietal and frontal.
     - (6) *Schindylesis.* A ridge or flattened process is received into a corresponding socket, e. g., rostrum of sphenoid and vomer.
     - (7) *Gomphosis.* A peg-like process is lodged in a corresponding socket, e. g., the fangs of the teeth.
   - (*b*) *Syndesmoses.* Movable joints in which the fibrous tissue between bones or cartilages is sufficiently lax to allow movement between the connected parts, e. g., thyreo-hyoid membrane. Interosseous membranes of forearm and leg.
2. **Synchondroses.**—In all synchondroses a certain amount of movement is possible, and they are often called amphiarthroses.
   - (1) *True synchondroses.* The cartilage connecting the bones is the remains of the bar in which the bones were ossified, e. g., occipito-sphenoidal joint.
   - (2) *False synchondroses.* The plate of cartilage intervening between and connecting the bones is fibro-cartilage and is not part of the cartilage in which the bones were ossified, but is developed separately, e. g., intervertebral joint and pubic symphysis. The articular end of each bone may be covered with hyaline cartilage and there may be a more or less well-marked cavity in the intervening plate of fibro-cartilage.
3. **Diarthroses.**—In diarthrodial joints the surfaces in contact may be equal and similar or unequal and dissimilar. In the former case the joints are homomorphic; in the latter, heteromorphic.
   - (A) *Homomorphic.*
     - (*a*) *Plane or arthrodial.* Flat surfaces, admitting gliding movement, e. g., intercarpal and acromio-clavicular joints.
     - (*b*) *Ephippial.* Saddle-shaped surfaces placed at right angles to each other, admitting free movement in all directions, e. g., metacarpo-phalangeal joint of thumb.

(B) *Heteromorphic.*
- (*a*) *Enarthrodial.* Ball-and-socket, allowing the most free movement, e. g., hip- and shoulder-joints.
- (*b*) *Condylarthroses.* The convex surface is ellipsoidal, and fits into a corresponding concavity, e. g., wrist and metacarpo-phalangeal joints.
- (*c*) *Ginglymi.* One surface consists of two conjoined condyles or of a segment of a cone or cylinder, and the opposite surface has a reciprocal contour. In these joints movement is only permitted round one axis, which may be transverse; e. g., elbow, ankle; or it may be vertical, in which case the joint is trochoid; e. g., odontoid process of axis with atlas, radius with ulna.

Such a classification should be considered as being purely academic and the student must always remember that it is not enough to discuss a joint by assigning it to a particular class in any scheme; for he must be familiar with the actual conditions present in every joint. No classification, however perfect, must be taken as final, and each joint should be studied as a separate thing altogether apart from any general systematic arrangement.

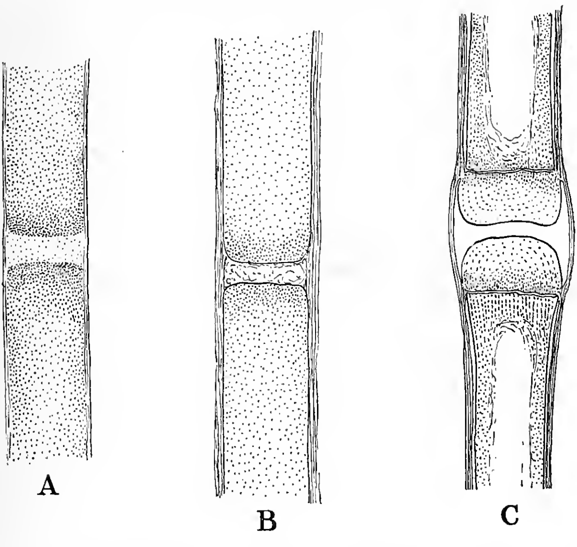
DEVELOPMENT AND MORPHOLOGY OF JOINTS

The arrangement of the various parts which constitute an articulation is best appreciated by a study of the development of the various types of joints. In this way it is easy to recognise a primitive condition typical of each class; but it must be remembered that various modifications take place during growth, that these modifications vary in the individual joints, and produce adult departures from the primitive arrangement which are peculiar to each joint and which must be studied separately.

In the case of bones ossifying in membrane the articulation will be a suture, the ossifications from neighbouring centres extending until they practically come into contact.

Fig. 255.—Development of Joints

A. Stage in which primary embryonic tissue separates the developing cartilages.
B. Primary embryonic tissue transformed into cartilage (synchondrosis), or fibrous connective tissue (syndesmosis).
C. Degeneration of embryonic tissue with production of a joint cavity (diarthrosis).



With cartilage bones the articulation may be either a syndesmosis, a synchondrosis, or a diarthrosis. The embryonic tissue in which the cartilage is to develop is at first continuous; centres of chondrification, corresponding in number to the bony elements which are destined to be formed, appearing in it. As the chondrifications approach each other a small portion of the primary embryonic tissue persists between them (fig. 255), and it is the subsequent fate of this intermediate tissue that determines the nature of the articulation.

(1) When the ossification of the cartilage occurs to form the articulating bones, the intermediate tissue may undergo transformation into cartilage (fig. 255), a **synchondrosis** being thus produced. (2) Or the intermediate tissue may be converted into fibrous connective-tissue

(fig. 255), the result being a **syndesmosis.** (3) Or, finally, the central portion of the intermediate tissue may degenerate, so that an articular cavity is produced, the peripheral portions being converted into connective tissue, forming a sleeve-like capsule surrounding the cavity, continuous at either extremity with the periosteum of the articulating bones (fig. 255). This is the articular capsule, and the connective-tissue cells arranging themselves in a layer upon its inner surface give rise to a synovial membrane. As the result of these processes a **diarthrosis** is produced, and from its mode of formation it is clear that the cavity of such an articulation is completely closed.

In a typical diarthrosis there is therefore a ligamentous capsule which entirely encloses the joint cavity, which is continuous with the periosteum of the bones entering into the articulation but which is not attached to nor reflected onto the cartilaginous ends of the bones which constitute the articulating surfaces. Such a capsule constitutes the primitive bond between the articulating bones and furnishes a complete lubricating bag in which these smooth cartilaginous ends glide over one another. This primitive capsule, however, becomes modified in most adult joints, (1) by unequal development of various parts of the capsule; and (2) by the more or less complete incorporation of other structures which are developmentally separate from the capsule. Under the first heading come specially thickened bands which may be so distinctly marked off from the rest of the capsule as to be named as separate ligaments (e. g., the temporo-mandibular ligament of the mandibular joint). Again certain thickened bands of capsule may, with alteration of joint contour, take up anatomical positions which are apparently separated from the rest of the capsule; advanced examples of this process are, in all probability, seen in the ligamentum teres of the hip-joint and the crucial ligaments of the knee. Under the second heading comes a series of ligaments derived from a great variety of sources; the most common origin being from the divorced or rearranged tendons of the muscles around the joint.

Muscles arising from, or inserted into, bones in the immediate vicinity of a joint tend to become metamorphosed into tendon near their attachments, and a comprehensive study of **myology** in low vertebrate forms indicates that there is associated with this tissue-change a tendency for the muscle to alter its point of attachment; hence a muscle originally inserted below a joint may eventually come to have its insertion above the joint. In the same way, a muscle arising above a joint may, as a result of altered environment, shift its origin to some point below the joint. To this change of position the term **migration of muscles** has been applied. In many instances a portion of the muscle equivalent to the distance between the original and the acquired attachment persists as a fibrous band and fulfils the function of a ligament. This is well seen in the knee-joint, where the *tibial collateral* ligament is derived from the adductor magnus, this muscle having shifted its insertion from the tibia to the femur. In the same way the *fibular collateral* ligament represents the tendon of the peroneus longus, which has migrated from the femur to the head of the fibula.

Among other ligaments derived in a similar way from muscles may be mentioned the *sacro-tuberous* ligament. This was originally the tendon of origin of the biceps femoris. (H. Morris, Med. Times and Gazette, 1877, p. 361.) The *sacro-spinous* is derived from the fibrous retrogression of portions of the coccygeus. The *sacro-coccygeal* ligaments represent the muscles which lift, depress, and wag the tail in those mammals furnished with such an appendage; indeed, these ligaments are occasionally replaced by muscle-tissue.

The *coraco-humeral* ligament is derived from the original tendon of insertion of the pectoralis minor, and not unfrequently the muscle is inserted into the lesser tuberosity of the humerus, the ligament being then replaced by the tendon of the muscle. The *coraco-clavicular, rhomboid*, and *gleno-humeral* ligaments are probably derived from modifications of the subclavius muscle.

Other anatomical structures besides muscles may, when degenerated or functionally altered, form the basis of ligaments in connection with joints. The *spheno-mandibular* ligament is the fibrous remnant of the cartilaginous mandibular bar.

The pulpy substance in the centre of each *intervertebral disc* is derived from the notochord; the *apical ligament* passing from the tip of the dens to the anterior margin of the foramen magnum is a remnant of the sheath of the notochord, and indicates its position as it passed from the vertebral column into the base of the cranium. The *transverse ligament* of the atlas (as pointed out by Professor Cleland) is a persistent and functional form of the posterior conjugal ligament uniting the rib-heads in seals and many other mammals, whilst the *interosseous ligament* of the head of a rib in man is the feeble representative of this structure in the thoracic region of the spine. The *ligamentum conjugale costarum* was described by Mayer in 1834 (Müller's Archiv für Anatomie). According to Luschka's account of this ligament it would seem as though the posterior superior fibres of the capsule of the costo-central joint represented it in man, rather than the interosseous ligament.

THE MOVEMENTS OF JOINTS

The movements which may take place at a joint are either gliding, angular, rotatory, or circumductory.

The **gliding** motion is the simplest, and is common to all diarthrodial joints; it consists of a simple sliding of the apposed surfaces of the bones upon one another, without angular or rotatory motion. It is the only kind of motion permitted in the carpal and tarsal joints, and in those between the articular processes of the vertebræ.

The **angular** motion is more elaborate, and increases or diminishes the angle between different parts. There are four varieties, viz., *flexion* and *extension*, which bend or straighten the various joints, and take place in a forward and backward direction (in a perfect hinge-joint this is the only motion permitted); and *adduction* and *abduction*, which, except in the case of the fingers and toes, signifies an approach to, or deviation from, the median plane of the body. In the case of the hand, the line to or from which adduction and abduction are made is drawn through the middle finger, while in the foot it is through the second toe.

Rotation is the revolution of a bone about its own axis without much change of position. It is only seen in enarthrodial and trochoidal joints. The knee also permits of slight rotation in certain positions, which is a distinctive feature of this articulation.

Circumduction is the movement compounded of the four angular movements in quick succession, by which the moving bone describes a cone, the proximal end of the bone forming the apex, while the distal end describes the base of the cone. It is seen in the hip and shoulder, as well as in the carpo-metacarpal joint of the thumb, which thus approximates to the ball-and-socket joint.

In some situations where a variety of motion is required, strength, security, and celerity are obtained by the combination of two or more joints, each allowing a different class of action, as in the case of the wrist, the ankle, and the head with the spine. Many of the long muscles, which pass over two or more joints, act on all, so tending to co-ordinate their movements and enabling them to be produced with the least expenditure of power. Muscles also act as elastic ligaments to the joints; and when acting as such, are diffusers and combiners, not producers of movement; the short muscles producing movement, the long diffusing it, and thus allowing the short muscles to act on more than one joint.

Muscles are so disposed at their attachments near the joints as never to strain the ligaments by tending to pull the bones apart, but, on the contrary, they add to the security of the joint by bracing the bones firmly together during their action.

The articulations may be divided for convenience of description into those: 1. of the Skull; 2. of the Trunk; 3. of the Upper Limb; and 4. of the Lower Limb.

THE ARTICULATIONS OF THE SKULL

The movable articulations of the skull comprise (1) the mandibular; and (2) those between the skull and the vertebral column, namely (*a*) between the occiput and atlas; (*b*) between the atlas and epistropheus (axis); and (*c*) the ligaments which connect the occiput and epistropheus.

The union of the atlas and epistropheus is described in this section because, (1) there is often a direct communication between the synovial cavity of the transverse epistrophic and the occipito-atlantal joints; (2) the rotatory movements of the head take place around the dens (odontoid process); and (3) important ligaments from the dens pass over the atlas to the occiput.

(1) THE MANDIBULAR ARTICULATION

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

The parts entering into the formation of this joint (figs. 256, 257) are:—the anterior portion of the mandibular fossa and glenoid ridge (eminentia articularis) of the temporal bone above, and the condyle of the lower jaw below. Both are covered with articular cartilage, which extends over the front of the glenoid ridge to facilitate the play of the interarticular cartilage. The ligaments which unite the bones are:

1. Articular capsule.
2. Articular disc.
3. Spheno-mandibular.
4. Stylo-mandibular.

The **articular capsule** is often described as consisting of four portions, anterior, posterior, lateral and medial, which are, however, continuous with one another around the articulation.

1. The **anterior portion** consists of a few stray fibres connected with the anterior margin of the articular disc, and attached below to the anterior edge of the condyle, and above to the front of the articular eminence. Some fibres of insertion of the *external pterygoid* pass between them to be inserted into the margin of the articular disc.

2. The **posterior portion** is attached above, just in front of the *petro-tympanic* (*Glaserian*) fissure, and is inserted into the back of the jaw just below its neck.

3. The **lateral portion** or **temporo-mandibular** (external lateral) **ligament** (fig. 256) is the strongest part of the capsule. It is broader above, where it is attached to the lower edge of the zygoma in nearly its whole length, as well as to the tubercle at the point where the two roots of the zygoma meet. It is inclined downward and backward, to be inserted into the condyle and neck of the mandible laterally. Its fibres diminish in obliquity and strength from before backward, those coming from the tubercle being short and nearly vertical.

4. The **medial portion** (or short internal lateral ligament) (fig. 257) consists of well-defined fibres, having a broad attachment, above to the lateral side of the spine of the sphenoid and medial edge of the mandibular fossa; and below, a narrow insertion to the medial side of the neck

of the condyle. Fatty and cellular tissue separate it from the spheno-mandibular ligament which is medial to it.

The **articular disc** (fig. 258) is an oval plate of fibro-cartilage interposed between and adapted to the two articular surfaces. It is thinner at the centre than at the circumference, and is thicker behind, where it covers the thin bone at the bottom of the mandibular fossa which separates it from the dura mater, than in front, where it covers the articular eminence.

Fig. 256.—Lateral View of the Mandibular Joint.

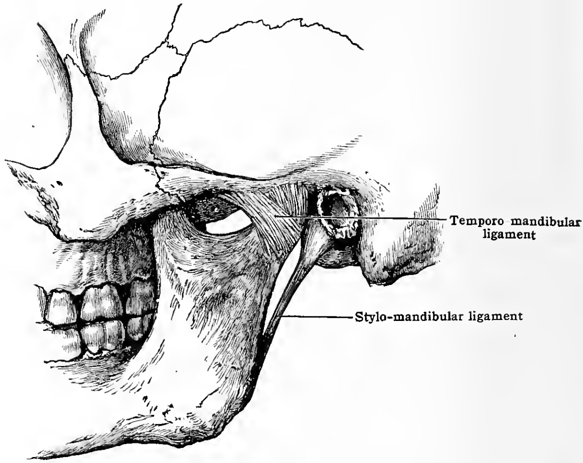


Fig. 257.—Medial View of the Mandibular Joint.

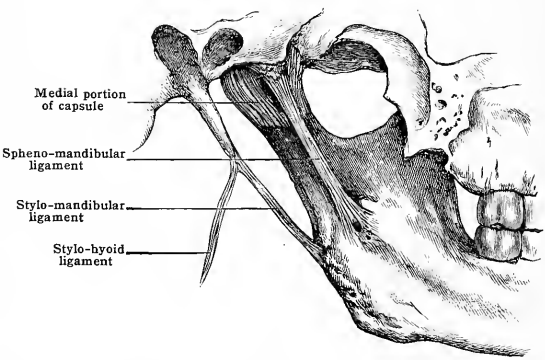


Its *inferior surface* is concave and fits on to the condyle of the lower jaw; while its *superior surface* is concavo-convex from before backward, and is in contact with the articular surface of the temporal bone. It divides the joint into two separate synovial cavities, but is occasionally perforated in the centre, and thus allows them to communicate. It is connected with the articular capsule at its circumference, and has some fibres of the *external pterygoid* muscle inserted into its anterior margin.

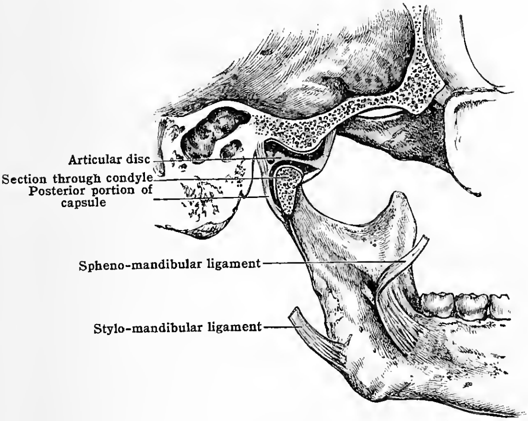
There are usually two **synovial membranes** (fig. 258), the superior being the larger and looser, passing down from the margin of the articular surface above, to the upper surface of the articular disc below; the lower and smaller one passes from the articular disc above to the condyle of the jaw below, extending somewhat further down behind than in front. When the disc is perforated, the two sacs communicate.

The **spheno-mandibular ligament** (long internal lateral) (fig. 257) is a thin, loose band, situated some little distance from the joint. It is attached above to the spine of the sphenoid and contiguous part of the temporal bone, and is inserted into the lingula of the lower jaw.

It covers the upper end of the mylo-hyoid groove, and is here pierced by the *mylo-hyoid* nerve. Its origin is a little medial to, and immediately behind, the origin of the medial portion of the capsule. It is separated from the joint and ramus of the jaw by the *external pterygoid* muscle, the *internal maxillary* artery and vein, the *inferior alveolar* (*dental*) nerve and artery, the *auriculo-temporal* nerve, and the *middle meningeal* artery. It is really the fibrous remnant of a part of the mandibular (Meckelian) bar.

The **stylo-mandibular ligament** (stylo-maxillary) (figs. 256 and 257) is a process of the deep cervical fascia extending from near the tip of the styloid process to the angle and posterior border of the ramus of the jaw, between the *masseter* and *internal pterygoid* muscles. It separates the parotid from the submaxillary gland, and gives origin to some fibres of the *stylo-glossus* muscle.

Fig. 258.—Sagittal Section through the Condyle of Jaw to show the Two Synovial Sacs and the Articular Disc.



The **arterial supply** of the mandibular joint is derived from the temporal, middle meningeal and ascending pharyngeal arteries, and from the latter by its branches to the Eustachian tube.

The **nerves** are derived from the masseteric and auriculo-temporal.

Movements.—The chief movement of this joint is of (i) a **ginglymoid or hinge character,** accompanied by a slight gliding action, as in opening or shutting the mouth. In the opening movement the condyle turns like a hinge on the articular disc, while at the same time the articular disc, together with the condyle, glides forward so as to rise upon the eminentia articularis, reaching as far as the anterior edge of the eminence, which is coated with articular cartilage to receive it; but the condyle never reaches quite so far as the summit of the eminence. Should the condyle, however, by excessive movement (as in a convulsive yawn), glide over the summit, it slips into the zygomatic fossa, the mandible is dislocated, and the posterior portion of the capsule is torn. In the shutting movement the condyle revolves back again, and the articular disc glides back, carrying the condyle with it. This combination of the hinge and gliding motions gives a tearing as well as a cutting action to the incisor teeth, without any extra muscular exertion.

There is (ii) a **horizontal gliding action** in an antero-posterior direction, by which the lower teeth are thrust forward and drawn back again: this takes place almost entirely in the upper compartment, because of the closer connection of the articular disc with the condyle than with the squamosal bone, and also because of the insertion of the *external pterygoid* into both bone and cartilage. In these two sets of movements the joints of both sides are simultaneously and similarly engaged.

The third form of movement is called (iii) the **oblique rotatory,** and is that by which the grinding and chewing actions are performed. It consists in a rotation of the condyle about the vertical axis of its neck in the lower compartment, while the cartilage glides obliquely forward and inward on one side, and backward and inward on the other, upon the articular surface of the squamosal bones, each side acting alternately. If the symphysis be simply moved from the centre to one side and back again, and not from side to side as in grinding, the condyle of that side moves round the vertical axis of its neck, and the opposite condyle and cartilage glide forward and inward upon the mandibular fossa. But in the ordinary grinding movement, one condyle advances and the other recedes, and then the first recedes while the other advances, slight rotation taking place in each joint meanwhile.

Relations.—The chief relations are: Behind, and overlapping the lateral side, the parotid gland. Laterally, the superficial temporal artery. Medially, the internal maxillary artery and auriculo-temporal nerve. In front, the nerve to the masseter muscle.

Muscles acting on the joint.—*Elevators of the mandible.*—temporals, masseters, int. pterygoids.

Depressors.—Mylo-hyoids, digastrics, genio-hyoid, muscles connecting the hyoid bone to lower points. Ext. pterygoids. The weight of the jaw.

Protractors.—Ext. pterygoids, superficial layer of masseters, anterior fibres of temporals.

Retractors.—Posterior fibres of temporals, slightly by the int. pterygoids and deep layer of the masseters.

(2) THE LIGAMENTS AND JOINTS BETWEEN THE SKULL AND VERTEBRAL COLUMN, AND BETWEEN THE ATLAS AND EPISTROPHEUS

(*a*) The Articulation of the Atlas with the Occiput

Class.—*Diarthrosis.* **Subdivision.**—*Double Condylarthrosis.*

This articulation [articulatio atlanto-occipitalis] consists of a pair of joints symmetrically situated on either side of the middle line. The parts entering into their formation are the cup-shaped superior articular processes of the atlas and the condyles of the occipital bone. They are united by the following ligaments:—

1. Anterior atlanto-occipital.
2. Posterior atlanto-occipital.
3. Two articular capsules.
4. Two anterior oblique.

The **anterior atlanto-occipital ligament** [membrana atlanto-occipitalis anterior] (fig. 259) is less than an inch (about 2 cm.) wide, and is composed of densely woven fibres, most of which radiate slightly lateralward as they ascend from the front surface and upper margin of the anterior arch of the atlas to the anterior border of the foramen magnum; it is continuous at the sides with the articular capsules, the fibres of which overlap its edges, and take an opposite direction medially and upward.

The central fibres ascend vertically from the anterior tubercle of the atlas to the pharyngeal tubercle on the occipital bone; they are thicker than the lateral fibres, and are continuous below with the superficial part of the anterior atlanto-epistrophic ligament, and through it with the anterior longitudinal ligament of the vertebral column. It is in relation, in front, with the *recti capitis anteriores;* and behind, with the apical dental or suspensory ligament.

The **posterior atlanto-occipital ligament** (fig. 260) is broader, more membranous, and not so strong as the anterior. It extends from the posterior surface and upper border of the posterior arch of the atlas to the posterior margin of the foramen magnum from condyle to condyle; being incomplete on either side for the passage of the *vertebral artery* into, and *suboccipital nerve* out of, the canal. It is somewhat thickened in the middle line by fibres, which pass from the posterior tubercle of the atlas to the lower end of the occipital crest.

It is not tightly stretched between the bones, nor does it limit their movements; it corresponds with the position of the ligamenta flava, but has no elastic tissue in its composition. It is in relation in front with the dura mater, which is firmly attached to it; and behind with the *recti capitis posteriores minores*, and enters into the floor of the suboccipital triangle. Its lateral margins, which do not reach the occipital bone but terminate on the posterior end of the superior articular processes of the atlas, form the so-called *oblique ligaments of the atlas.* The lateral margins of these ligaments are free and they form the posterior boundaries of the apertures through which the vertebral arteries enter and the suboccipital nerves leave the vertebral canal.

The **atlanto-occipital articular capsules** (figs. 259 and 260) are very distinct and strongly marked, except on the medial side, where they are thin and formed only of short membranous fibres. They are lax, and do not add much to the security of the joint.

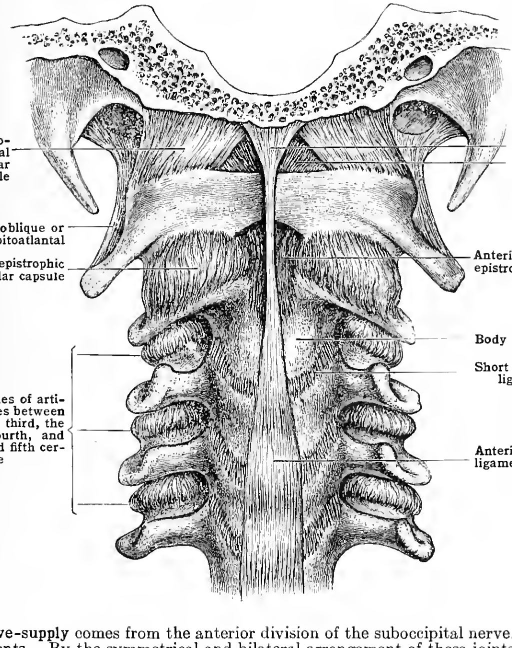
In front, the capsule descends upon the atlas, to be attached, some distance below the articular margin, to the front surface of the lateral mass and to the base of the transverse process; these fibres take an oblique course upward and medialward, overlapping the anterior atlanto-occipital. At the sides and behind, the capsule is attached above to the margins of the occipital condyles; below, it skirts the medial edge of the foramen for the vertebral artery, and behind is attached to the prominent tubercle overhanging the groove for that vessel; these latter fibres are strengthened by a band running obliquely upward and medialward to the posterior margin of the foramen magnum.

The **anterior oblique** or **lateral occipito-atlantal ligament** is an accessory band which strengthens the capsule laterally (fig. 259). It is an oblique, thick band of fibres, sometimes quite separate and distinct from the rest, passing upward and medialward from the upper surface of the transverse process beyond the costo-transverse foramen to the jugular process of the occipital bone.

The **synovial membrane** of these joints occasionally communicates with the synovial sac between the dens (odontoid process) and the transverse ligament.

The arterial supply is derived from twigs of the vertebral, and occasionally from twigs from the meningeal branches of the ascending pharyngeal.

Fig. 259.—Anterior View of the Upper End of the Vertebral Column.



The **nerve-supply** comes from the anterior division of the suboccipital nerve.

Movements.—By the symmetrical and bilateral arrangement of these joints, security and strength are gained at the expense of a very small amount of actual articular surface; the basis of support and the area of action being equal to the width between the most distant borders of the joint.

The principal movement permitted at these joints is of a ginglymoid character, producing flexion and extension upon a transverse axis drawn across the condyles at their slightly constricted parts.

In flexion, the forehead and chin drop, and what is called the nodding movement is made; in extension, the chin is elevated and the forehead recedes.

There is also a slight amount of gliding movement, either **directly lateral**, the lateral edge of one condyle sinking a little within the lateral edge of the socket of the atlas, and that of the opposite condyle projecting to a corresponding degree. The head is thus tilted to one side, and it is even possible that the weight of the skull may be borne almost entirely on one joint, the articular surfaces of the other being thrown out of contact.

Or the movement may be **obliquely lateral,** when the lower side of the head will be a trifle in advance of the elevated side. In this motion, which takes place on the antero-posterior axis, one condyle advances slightly and approaches the middle line, while the other recedes. This is of the nature of rotation, though there is no true rotation round a vertical axis possible between the occiput and atlas.

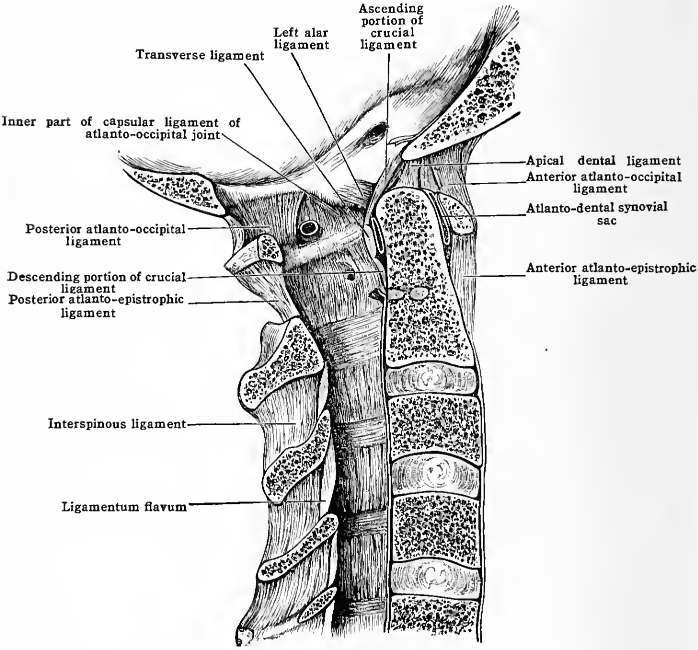
These lateral movements are checked by the alar ligaments and the lateral part of the capsules; extension is checked by the anterior atlanto-occipital and anterior oblique ligaments, and flexion by the posterior part of the capsule and the tectorial membrane.

Muscles acting upon the occipito-atlantal joint.—Flexion whereby the chin is approximated toward the sternum is produced by the weight of the anterior part of the head and by all muscles which are attached to the hyoid bone or to the bones of the skull in front of a transverse axis between the two condyles. These muscles take their fixed point below either from the vertebral column, the sternum, or the bones of the shoulder girdle. Before those connected with the mandible can act that bone must be fixed by the muscles of mastication which, therefore, also take part in the movements. It must be noted that the sterno-mastoid muscles are powerful flexors, although a part of their insertion is behind the transverse axis between the two condyles.

Extension is due to the action of muscles or portions of muscles inserted into the skull behind the transverse axis above mentioned, and connected below either with the vertebral column, shoulder girdle, or sternum.

Lateral movement is produced by the anterior and posterior groups of muscles on the same side acting simultaneously and aided by the rectus capitis lateralis of that side.

Fig. 260.—Median Sagittal Section of Vertebral Column showing Ligaments.



(b) The Articulations between the Atlas and Epistropheus (Axis).

1. The Lateral Atlanto-epistrophic Joints. { **Class.**—*Diarthrosis.* **Subdivision.**—*Arthrodia.*
2. The Central Atlanto-epistrophic Joint or The Atlanto-dental. { **Class.**—*Diarthrosis.* **Subdivision.**—*Trochoides.*

The bones that enter into the formation of the lateral joints are the inferior articular processes of the atlas and the superior of the epistropheus (axis); the central joint is formed by the dens (odontoid process) articulating in front with the atlas, and behind with the transverse ligament.

The ligaments which unite the epistropheus and atlas are:—

1. The anterior atlanto-epistrophic.
2. The posterior atlanto-epistrophic.
3. Two articular capsules (for lateral joints).
4. The transverse ligament.
5. The atlanto-dental articular capsule.

The **anterior atlanto-epistrophic ligament** (figs. 259 and 260) is a narrow but strong membrane filling up the interval between the lateral joints. It is attached above to the front surface and lower border of the anterior arch of the atlas, and below to the transverse ridge on the front of the body of the epistropheus. Its fibres are vertical, and are thickened in the median line by a dense band which is a continuation upward of the anterior longitudinal ligament of the vertebral column.

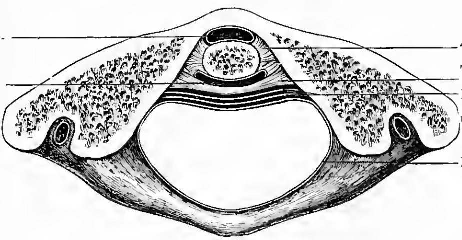
This band is fixed above to the anterior tubercle of the atlas, where it becomes continuous with the central part of the anterior atlanto-occipital ligament (fig. 259); it is sometimes separated by an interval from the deeper ligament, and is often described as the superficial atlanto-epistrophic ligament. It is in relation with the *longus colli* muscle.

The **posterior atlanto-epistrophic ligament** (fig. 260) is a deeper, but thinner and looser membrane than the anterior. It extends from the posterior root of the transverse process of one side to that of the other, projecting laterally beyond the posterior part of the capsules which are connected with it. It is attached above to the posterior surface and lower edge of the posterior arch of the atlas, and below to the superior edge of the laminæ of the epistropheus on their dorsal aspect.

It is denser and stronger in the median line, and has a layer of elastic tissue on its anterior surface like the ligamenta flava, to which it corresponds in position. It is connected in front with the dura mater; behind, it is in relation with the *inferior oblique* muscles, and is perforated at each side by the *second cervical* nerve.

1. The Lateral Atlanto-epistrophic Joints are provided with short, ligamentous fibres, forming **articular capsules** (fig. 259), which completely surround the lateral articular facets. Lateral to the canal they are attached some little distance from the articular margins, extending along the roots of the

Fig. 261.—Horizontal Section through the Lateral Masses of the Atlas and the Top of the Dens (Odontoid Process).



transverse processes of the epistropheus nearly to the tips, but between the roots they skirt the medial edge of the costo-transverse foramina. They are strengthened in front and behind by the atlanto-epistrophic ligaments.

Medially each capsule is thinner, and attached close to the articular margins, being strengthened behind by a strong band of slightly oblique fibres passing upward along the lateral edge of the tectorial membrane from the body of the epistropheus to the lateral mass of the atlas behind the transverse ligament; some of these fibres pass on, thickening and blending with the atlanto-occipital capsule, to be inserted into the margin of the foramen magnum. This band is sometimes called the **accessory band** (fig. 263).

There is a **synovial membrane** for each joint.

2. The Central Atlanto-epistrophic Joint, although usually described as one, is composed of two articulations, which are quite separate from one another:

an anterior between the dens and the arch of the atlas, and a posterior between the dens and the transverse ligament.

The **transverse ligament** (figs. 260, 261, and 263) is one of the most important structures in the body, for on its integrity and that of the alar ligaments our lives largely depend. It is a thick and very strong band, as dense and closely woven as fibro-cartilage, about a quarter of an inch (6 mm.) deep at the sides, and somewhat more in the middle line. Attached at each end to a tubercle on the inner side of the lateral mass of the atlas, it crosses the ring of this bone in a curved manner, so as to have the concavity forward; thus dividing the ring into a smaller anterior portion for the dens and a larger posterior part for the spinal cord and its membranes, and the spinal accessory nerves.

It is flattened from before backward, being smooth in front, and covered by synovial membrane to allow it to glide freely over the posterior facet of the dens. Where it is attached to the atlas it is smooth and well rounded off to provide an easy floor of communication between the transverso-dental and occipito-atlantal joints.

To its posterior surface is added, in the middle line, a strong fasciculus of vertical fibres, passing upward from the root of the dens to the basilar border of the foramen magnum on its cranial aspect. Some of these fibres are derived from the transverse ligament. These vertical fibres give the transverse ligament a cruciform appearance; hence the name, the **crucial ligament** (figs. 260 and 263) applied to the whole.

The **atlanto-dental articular capsule** (fig. 261) is a tough, loose membrane, completely surrounding the apposed articular surfaces of the atlas and dens.

At the dens it blends above with the front of the alar and central occipito-odontoid ligaments, and arises also along the sides of the articular facet as far as the neck of the dens; the fibres are thick, and blend with the capsules of the lateral joint. At the atlas they are attached to the non-articular part of the anterior arch in front of the tubercles for the transverse ligament, blending, above and below the borders of the bone, with the anterior atlanto-occipital and atlanto-epistrophic ligaments, as well as with the medial portion of the articular capsules. It holds the dens to the anterior arch of the atlas after all the other ligaments have been divided.

The **synovial membranes** (figs. 260 and 261) are two in number:—one for the joint between the dens and atlas; and another (transverso-dental) for that between the transverse ligament and the dens. This last often communicates with the atlanto-occipital articulations; it is closed in by membranous tissue between the borders of the transverse ligament and the margin of the facet on the dens, and is separated from the front sac by the atlanto-dental articular capsule.

The **arterial supply** is from the vertebral artery, and the **nerve-supply** from the loop between the first and second cervical nerves.

Movements.—The chief and characteristic movement at these joints is the rotation, in a nearly horizontal plane, of the collar formed by the atlas and transverse ligament, round the dens as a pivot, which is extensive enough to allow of an all-round view without twisting the trunk. Partly on account of its ligamentous attachments, and partly on account of the shape of the articular surfaces, the cranium must be carried with the atlas in these movements. The rotation is checked by the ligaments passing from the dens to the occiput (alar ligaments), and also by the atlanto-epistrophic. Owing to the fact that the facets of both atlas and epistropheus, which enter into the formation of the lateral atlanto-epistrophic articulations, are convex from before backward, and have the articular cartilage thicker in the centre than at the circumference, the motion is not quite horizontal but slightly curvilinear. In the erect position, with the face looking directly forward, the most convex portions of the articular surfaces are alone in contact, there being a considerable interval between the edges; during rotation, therefore, the prominent portions of the condyles of the atlas descend upon those of the epistropheus, diminishing the space between the bones, slackening the ligaments, and thus increasing the amount of rotation, without sacrificing the security of the joint in the central position.

Besides rotation, forward and backward movements and some lateral flexion are permitted between the atlas and epistropheus, even to a greater extent than in most of the other vertebral joints.

The muscles acting upon the atlanto-epistrophic joints.—The muscles capable of producing rotation at the atlanto-epistrophic joints are those which take origin from near the mesial plane either in front or behind and which are attached above either to the atlas or the skull, lateral to the atlanto-epistrophic joints. When the muscles which lie at the back of the joint on one side act they will turn the head to the same side and will be aided by the muscles in front on the opposite side. If the muscles in front and behind on the same side act simultaneously, they will pull down the head to that side and will be aided by muscles which pass more or less vertically from the transverse process of the atlas to points below.

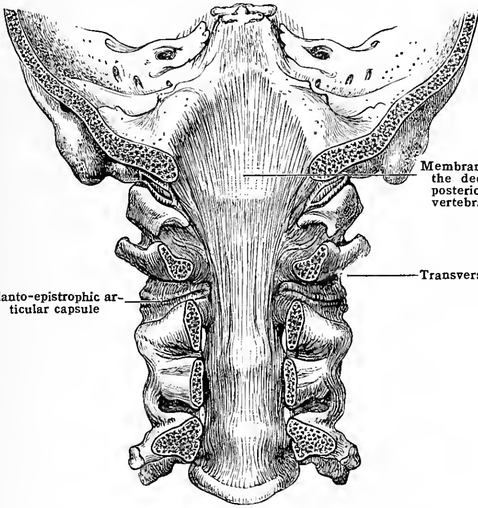
(*c*) The Ligaments uniting the Occiput and Epistropheus

The following ligaments unite bones not in contact, and are to be seen from the interior of the canal after removing the posterior arches of the epistropheus and atlas and posterior ring of the foramen magnum:—

1. The tectorial membrane.
2. The crucial ligament.
3. Two alar (or check) ligaments.
4. The apical dental ligament.

The **tectorial membrane** (occipito-cervical ligament) (figs. 261, 262, and 263) consists of a very strong band of fibres, connected below to the upper part of the body of the third vertebra and lower part of the body of the epistropheus as far as the root of the dens. It is narrow below, but widens out as it ascends, to be fastened to the basilar groove of the occiput. Laterally, it is connected with the accessory fibres of the atlanto-epistrophic capsule. It is really only the upward prolongation of the deep stratum of the posterior longitudinal ligament, the superficial fibres of which run on to the occipital bone without touching the epistropheus, thus giving rise to two strata. It is in relation in front with the crucial ligament.

Fig. 262.—The Superficial Layer of the Posterior Longitudinal Vertebral Ligament has been Removed to show its Deep or Short Fibres. These Deep Fibres form the Tectorial Membrane. Viewed from behind.



The **crucial ligament** has been already described (see p. 222).

The **alar** (or check) **ligaments** (figs. 260 and 263) are two strong rounded cords, which extend from the sides of the apex of the dens, transversely lateralward to the medial edge of the anterior portion of the occipital condyles.

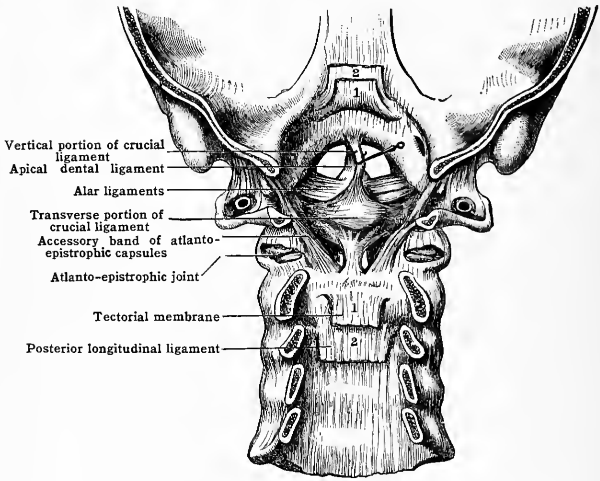
They are to be seen immediately above the upper border of the transverse ligament, which they cross obliquely owing to its forward curve at its attachments to the atlas. Some of their fibres occasionally run across the middle line from one alar ligament to the other. At the dens they are connected with the atlanto-dental capsule, and at the condyles they strengthen the atlanto-occipital articular capsule.

The **apical dental** or suspensory ligament (figs. 260 and 263) consists of a slender band of fibres ascending from the summit of the dens to the lower surface of the occipital bone, close to the foramen magnum. It is best seen from the front, after removing the anterior atlanto-occipital ligament, or from behind by drawing aside the crucial ligament.

The apical ligament is tightened by extension and relaxed by flexion or nodding; the alar ligaments not only limit the rotatory movements of the head and atlas upon the epistropheus, but by binding the occiput to the pivot, round which rotation occurs, they steady the head and prevent its undue lateral inclination upon the vertebral column. (See TRANSVERSE LIGAMENT, p. 222.)

By experiments, it has been proved that the head, when placed so that the orbits look a little upward, is poised upon the occipital condyles in a line drawn a little in front of their middle; the amount of elevation varies slightly in different cases, but the balance is always to be obtained in the human body—it is one of the characteristics of the human figure. It serves to maintain the head erect without undue muscular effort, or a strong ligamentum nuchæ and prominent dorsal spines such as are seen in the lower animals. Disturb this balance, and let the muscles cease to act, the head will either drop forward or backward according as the centre of gravity is in front or behind the balance line. The ligaments which pass over the dens to the occiput are not quite tight when the head is erect, and only become so when the head is flexed; if this were not so, no flexion would be allowed; thus, muscular action, and not ligamentous tension, is employed to steady the head in the erect position. It is through the combination of the joints of the atlas and epistropheus, and occiput and epistropheus (consisting of two pairs of joints placed symmetrically on either side of the median line, while through the median line there passes a pivot, also with a pair of joints), that the head enjoys such freedom and celerity of action, remarkable strength, and almost absolute security against violence, which could only be obtained by a ball-and socket joint; but the ordinary ball-and-socket joints are too prone to dislocations by even moderate twists to be reliable enough when the life of the individual depends on the perfection of the articulation: hence the importance of this combination of joints.

FIG. 263.—CORONAL SECTION OF THE VERTEBRAL COLUMN AND THE OCCIPITAL BONE TO SHOW LIGAMENTS.
(The tectorial membrane (1), though shown as a distinct stratum, is really the deeper part of the posterior longitudinal ligament (2). The upper ends have been reflected upward, the lower downward. Viewed from behind.)



THE ARTICULATIONS OF THE TRUNK

These may be divided into the following sets:—

1. Those of the vertebral column. Joints and ligaments connecting:

   (*a*) The bodies.
   (*b*) The articular processes.
   (*c*) The laminæ.
   (*d*) The spinous processes.
   (*e*) The transverse processes.

2. Vertebral column with the pelvis.
3. Pelvis.

   (*a*) Sacro-iliac
   (*b*) Sacro-coccygeal.
   (*c*) Intercoccygeal.
   (*d*) Symphysis pubis.

4. Ribs with the vertebral column.
5. The articulations at the front of the thorax.

   (*a*) Costal cartilages with the sternum.
   (*b*) Costal cartilages with the ribs.
   (*c*) Sternal.
   (*d*) Certain costal cartilages with each other.

1. THE ARTICULATIONS OF THE VERTEBRAL COLUMN

There are two distinct sets of articulations in the vertebral column:—

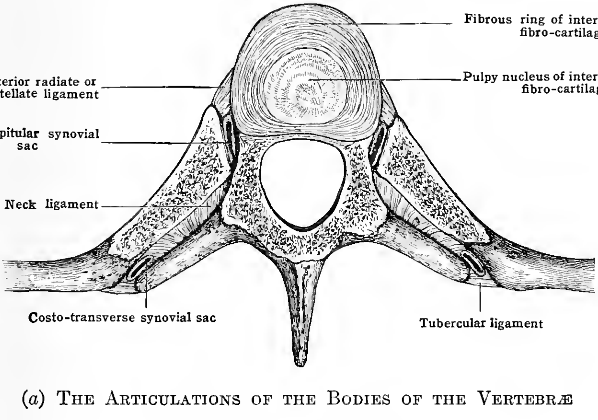
(*a*) Those between the bodies and intervertebral discs which form synchondroses and which are amphiarthrodial as regards movement.
(*b*) Those between the articular processes which form arthrodial joints.

The ligaments which unite the various parts may also be divided into two sets, viz.—**immediate,** or those that bind together parts which are in contact; and **intermediate,** or those that bind together parts which are not in contact.

Immediate.
(*a*) Those between the bodies and discs.
(*b*) Those between the articular processes.

Intermediate.
(*c*) Those between the laminæ.
(*d*) Those between the spinous processes.
(*e*) Those between the transverse processes.

Fig. 264.—Horizontal Section through an Intervertebral Fibro-cartilage and the Corresponding Ribs.



(*a*) The Articulations of the Bodies of the Vertebræ

Class.—*False Synchondrosis.*

The ligaments which unite the bodies of the vertebræ are:—

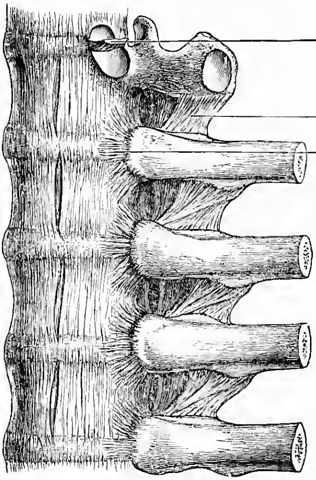
Intervertebral fibro-cartilages.	Anterior longitudinal.
Short lateral ligaments.	Posterior longitudinal.

The **intervertebral fibro-cartilages** (figs. 260 and 264) are tough, but elastic and compressible discs of composite structure, which serve as the chief bond of union between the vertebræ. They are twenty-three in number, and are interposed between the bodies of all the vertebræ from the epistropheus to the sacrum (figs. 260 and 271). Similar discs are found between the segments of the sacrum and coccyx in the younger stages of life, but they undergo ossification at their surfaces and often throughout their whole extent.

Each disc is composed of two portions—a circumferential laminar, and a central pulpy portion; the former tightly surrounds and braces in the latter, and forms somewhat more than half the disc. The **fibrous ring** [annulus fibrosus] or laminar portion consists of alternating layers of fibrous tissue and fibro-cartilage; the component fibres of these layers are firmly connected with two vertebræ, those of one passing obliquely down and to the right, those of the next down and to the left, making an ×-shaped arrangement of the alternate layers. A few of the superficial lamellæ project beyond the edges of the bodies, their fibres being connected with the edges of the anterior and lateral surfaces; and some do not completely surround the rest, but terminate at the intervertebral foramina, so that on horizontal section the circumferential portion is seen to be thinner posteriorly. The more central lamellæ are incomplete, less firm, and not so distinct as the rest; and as they near the pulp they gradually assume its characters, becoming more fibro-cartilaginous and less fibrous, and have cartilage cells in their structure.

The **pulpy nucleus** [nucleus pulposus] or central portion is situated somewhat behind the centre of the disc, forming a ball of very elastic and tightly compressed material, which bulges freely when the confining pressure of the laminar portion is removed by either horizontal or vertical section. Thus, it has a constant tendency to spring out of its confinement in the direction of least resistance, and constitutes a pivot round which the bodies of the vertebræ can twist, tilt, or incline. It is yellowish in colour, and is composed of fine white and elastic

FIG. 265.—THE ANTERIOR LONGITUDINAL LIGAMENT, THE RADIATE, THE INTERARTICULAR, AND THE ANTERIOR COSTO-TRANSVERSE LIGAMENTS.



fibres amidst which are ordinary connective-tissue cells, and peculiar cells of various sizes which contain one or more nuclei. Together with the most central laminæ, it is separated from immediate contact with the bone by a thin plate of articular cartilage. The central pulp of the intervertebral substance is the persistent part of the notochord.

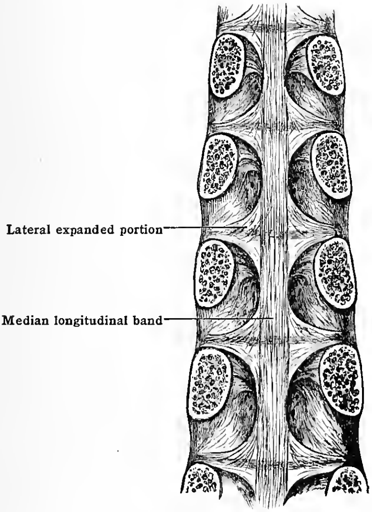
The intervertebral substances vary in shape with the bodies of the vertebræ they unite, and are widest and thickest in the lumbar region. In the cervical and lumbar regions they are thicker in front than behind, and *cause* the convexity forward of the cervical, and *increase* that of the lumbar; the curve in the thoracic region, almost entirely due to the shape of the bodies, is, however, somewhat increased by the discs. Without the discs the column loses a quarter of its length, and assumes a curve with the concavity forward, most marked a little below the mid-thoracic region. Such is the curve of old age, which is due to the shrinking and drying up of the intervertebral substances. The disc between the epistropheus and third cervical is the thinnest of all (fig. 260); that between the fifth lumbar and sacrum is the thickest, and is much thicker in front than behind (fig. 271). The intervertebral discs are in relation, in front with the anterior longitudinal ligament; behind, with the posterior longitudinal ligament; laterally, with the short lateral; and in the thoracic region, with the interarticular and radiate ligaments.

In the cervical region lateral diarthrodial joints are placed one on each side of the intervertebral discs. They are of small extent and are confined to the intervals between the prominent lateral lips of the upper surface of the body below and the bevelled lateral edges of the lower surface of the body above. Situated in front of the issuing spinal nerves and between those parts of the bodies formed from the neural arches, they are homologous with the joints between the atlas and epistropheus, and between the atlas and occipital bone.

The **anterior longitudinal ligament** (figs. 259 and 265) commences as a narrow band attached to the inferior surface of the occipital bone in the median line, just in front of the atlanto-occipital ligament, of which it forms the thickened central portion. Attached firmly to the tubercle of the atlas, it passes down as the central portion of the atlanto-epistrophic ligament, in the mid-line, to the front of the body of the epistropheus. It now begins to widen out as it descends, until it is nearly two inches (5 cm.) wide in the lumbar region. Below, it is fixed to the upper segment of the sacrum, becoming lost in periosteum about the middle of that bone; but is again distinguishable in front of the sacro-coccygeal joint, as the anterior sacro-coccygeal ligament.

Its structure is bright, pearly-white, and glistening. Its lateral borders are separated from the lateral bands by clefts through which blood-vessels pass; they are frequently indistinct and are best marked in the thoracic region. It is thickest in the thoracic region, and thicker in the lumbar than the cervical. It is firmly connected with the bodies of the vertebræ, and is composed of longitudinal fibres, of which the superficial extend over several, while the deeper pass over only two or three vertebræ. It is connected with the tendinous expansion of the prevertebral muscles in the cervical, and the crura of the diaphragm are closely attached to it in the lumbar region.

Fig. 266.—Posterior Longitudinal Ligament. (Thoracic region.)
(Pedicles cut through, and posterior arches of vertebræ removed.)

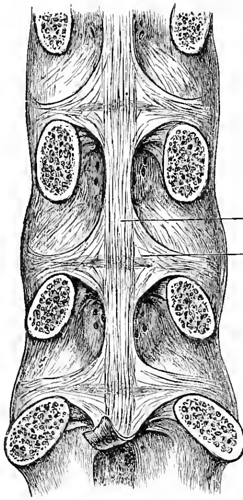


The **posterior longitudinal ligament** (figs. 263, 266, 267, and 274) extends from the occipital bone to the coccyx. It is wider above than below, and commences by a broad attachment to the cranial surface of the basi-occipital. In the cervical region it is of nearly uniform width, and extends completely across the bodies of the vertebræ, upon which it rests quite flat. It does, however, extend slightly further laterally on each side opposite the intervertebral discs. In the thoracic and lumbar regions it is distinctly dentated, being broader over the intervertebral substances and the edges of the bones than over the middle of the bodies, where it is a narrow band stretched over the bones without resting on them, the anterior internal vertebral venous plexus being interposed. The narrow median portion consists of longitudinal fibres, some of which are superficial and pass over several vertebræ; and others are deeper, and extend only from one vertebra to the next but one below.

The dentated or broader portions (fig. 267) are formed by oblique fibres which, springing from the bodies near the intervertebral foramina, take a curved course downward and backward over an intervertebral fibro-cartilage, and reach the narrow portion of the ligament on the centre of the vertebra next below; they then diverge to pass over another intervertebral dics to end on the body of the vertebra beyond, near the intervertebral notch. They thus pass over two discs and three vertebræ. Deeper still are other fibres thickening these expansions of the longitudinal ligament, and extending from one bone to the next.

The last well-marked expansion is situated between the first two segments of the sacrum: below this, the ligament becomes a delicate central band with rudimentary expansions, being more pronounced again over the sacro-coccygeal joint, and losing itself in the ligamentous tissue at the back of the coccyx. The dura mater is tightly attached to it at the margin of the foramen magnum and behind the bodies of the upper cervical vertebræ, but is separated from it in the rest of its extent by loose cellular tissue which becomes condensed in the sacral region to form the sacro-dural ligament. The filum terminale becomes blended with it at the lower part of the sacrum and back of the coccyx.

FIG. 267.—POSTERIOR LONGITUDINAL LIGAMENT. (Lumbar region.)



The **lateral** (or short) **vertebral ligaments** (fig. 265) consist of numerous short fibres situated between the anterior and posterior longitudinal ligaments, and passing from one vertebra over the intervertebral disc, to which it is firmly adherent, to the next vertebra below.

The more superficial fibres are more or less vertical, but the deeper decussate and have a crucial arrangement. They are connected with the deep surface of the anterior longitudinal ligament, and so tie it to the edges of the bodies of the vertebræ and to the intervertebral discs. They blend behind with the expansions of the posterior longitudinal ligament, and so complete the casing round each amphiarthrodial joint. In the thoracic region, they overlie the radiate ligament, and in the lumbar they radiate toward the transverse processes. In the cervical region they are less well marked.

(*b*) THE LIGAMENTS CONNECTING THE ARTICULAR PROCESSES

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The **articular capsules** (fig. 259) which unite these processes are composed partly of yellow elastic tissue and partly of white fibrous tissue. In the cervical region only the medial side of the capsule is formed by the ligamenta flava, which in the thoracic and lumbar regions, however, extend anteriorly to the margins of the intervertebral foramina.

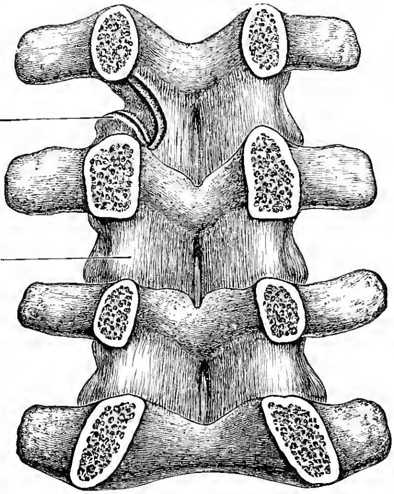
The part formed of white fibrous tissue consists of short, well-marked fibres, which in the cervical region pass obliquely downward and forward over the joint, between the articular processes and the posterior roots of the transverse processes of two contiguous vertebræ. In the thoracic region the fibres are shorter, and vertical in direction, and are attached to the bases of the transverse processes; in the lumbar, they are obliquely transverse. The articular capsules in the cervical region are the most lax, those in the lumbar region are rather tighter, and those in the thoracic region are the tightest.

There is one **synovial membrane** to each capsule.

(c) The Ligaments uniting the Laminæ

The **ligamenta flava** (fig. 268) are thick plates of closely woven yellow elastic tissue, interposed between the laminæ of two adjacent vertebræ. The first connects the epistropheus with the third cervical, and the last the fifth lumbar with

Fig. 268.—Ligamenta Flava in the Lumbar Region, seen from within the Vertebral Canal.



the sacrum. Each ligament extends from the medial and posterior edge of the intervertebral foramen on one side to a corresponding point on the other; above, it is attached close to the inner margin of the inferior articular process and to a well-marked ridge on the inner surface of the laminæ as far as the root of the spine; below, it is fixed close to the inner margin of the superior articular process and to the dorsal aspect of the upper edge of the laminæ.

Thus each ligamentum flavum, besides filling up the interlaminar space, enters into the formation of two articular capsules; they do so to a greater extent in the thoracic and lumbar regions than in the cervical, where the articular processes are placed wider apart. When seen from the front after removing the bodies of the vertebræ, they are concave from side to side, but convex from above downward; they make a more decided transverse curve than the arches between which they are placed. This concavity is more marked in the thoracic, and still more in the lumbar region than in the cervical; in the lumbar region the ligamenta flava extend a short distance between the roots of the spinous process, blending with the interspinous ligament, and making a median sulcus when seen from the front; there is, however, no separation between the two parts. In the cervical region, where the spines are bifid, there is a median fissure in the yellow tissue which is filled up by fibro-areolar tissue. The ligaments are thickest and strongest in the lumbar region; narrow but strong in the thoracic; thinner, broader, and more membranous in the cervical region.

(d) The Ligaments connecting the Spinous Processes

These include supraspinous ligament, interspinous ligaments, and the ligamentum nuchæ.

The **supraspinous ligament** (fig. 270) extends without interruption as a well-marked band of longitudinal fibres along the tips of the spines of the vertebræ from that of the seventh cervical downward till it ends on the median sacral crest.

Fig. 269.—Side View of Ligamentum Nuchæ.

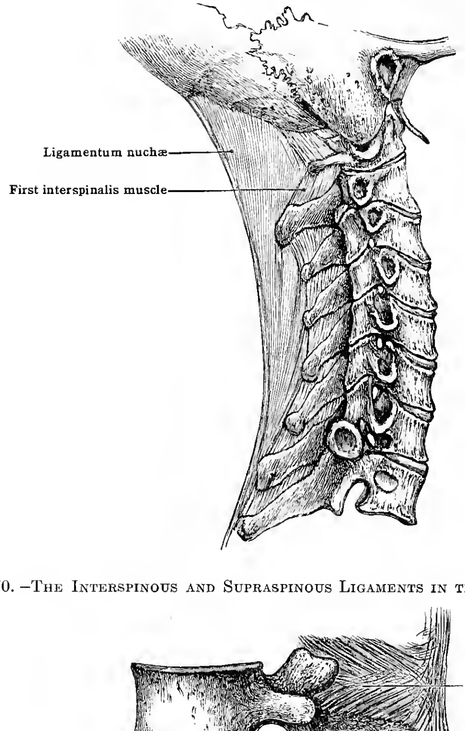


Fig. 270.—The Interspinous and Supraspinous Ligaments in the Lumbar Region.

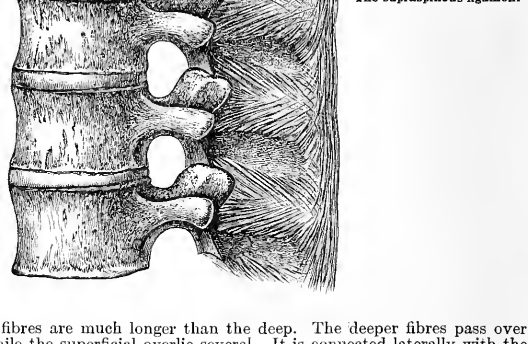


Its more superficial fibres are much longer than the deep. The deeper fibres pass over adjacent spines only, while the superficial overlie several. It is connected laterally with the aponeurotic structures of the back; indeed, in the lumbar region, where it is well marked, it appears to result from the interweaving of the tendinous fibres of the several muscles which are attached to the tips of the spinous processes. In the dorsal region it is a round slender cord which is put on the stretch in flexion and relaxed in extension of the back.

The **ligamentum nuchæ**, or the posterior cervical ligament (fig. 269), is the continuation in the neck of the supraspinous ligament, from which, however, it differs considerably. It is a slender vertical septum of an elongated triangular form, extending from the seventh cervical vertebra to the external protuberance and the crest of the occipital bone. Its anterior border is firmly attached to the tips of the spines of all the cervical vertebræ, including the posterior tubercle of the atlas, as well as to the occiput. Its posterior border gives origin to the trapezii, with the tendinous fibres of which muscle it blends. Its lateral, triangular surfaces afford numerous points of attachment for the posterior muscles of the head and neck.

In man it is rudimentary, and consists of elastic and white fibrous tissues. As seen in the horse, elephant, ox, and other pronograde mammals, it is a great and important elastic ligament, which even reaches along the thoracic part of the spinal column. In these animals it serves to support the head and neck, which otherwise from their own weight would hang down. Its rudimentary state in man is the direct consequence of his erect position.

The **interspinous ligaments** (fig. 270) are thin membranous structures which extend between the spines, and are connected with the ligamenta flava in front, and the supraspinous ligament behind.

The fibres pass obliquely from the root of one spine to the tip of the next; they thus decussate. They are best marked in the lumbar region, and are replaced by the well-developed *interspinales* muscles in the cervical region.

(*e*) The Ligaments connecting the Transverse Processes

The **intertransverse ligaments** are but poorly developed.

In the thoracic region they form small rounded bundles, and in the lumbar they are flat membranous bands, unimportant as bonds of union. They consist of fibres passing between the apices of the transverse processes. In the cervical region they are replaced by the *intertransversarii* muscles.

The **arterial supply** for the column comes from twigs of the vertebral, ascending pharyngeal, ascending cervical, superior and aortic intercostals, lumbar, ilio-lumbar, and lateral sacral.

The **nerve-supply** comes from the spinal nerves of each region.

Movements.—The vertebral column is so formed of a number of bones and intervertebral discs as to serve many purposes. It is the axis of the skeleton; upon it the skull is supported; and with it the cavities of the trunk and the limbs are connected. As a fixed column it is capable of bearing great weight, and, through the elastic intervertebral substances, of resisting and breaking the transmission of shocks. Moreover, it is flexible. Now, the range of movements of the column as a whole is very considerable; but the movements between any two vertebræ are slight, so that motions of the spine may take place without any change in the shape of the column, and without any marked disturbance in the relative positions of the vertebræ. It is about the pulpy part of the intervertebral discs, which form a central elastic pivot or ball, upon which the middle of the vertebræ rest, that these movements take place.

The amount of motion is everywhere limited by the common vertebral ligaments, but it depends partly upon the width of the bodies of the vertebræ, and partly upon the depth of the discs, so that in the loins, where the bodies are large and wide, and the discs very thick, free motion is permitted; in the cervical region, though the discs are thinner, yet, as the bodies are smaller, almost equally free motion is allowed. As the ball-like pulpy part of the intervertebral disc is the centre of movement of each vertebra, it is obvious that the motion would be of a rolling character in any direction but for the articular processes, which serve also to give steadiness to the column and to assist in bearing the superincumbent weight. Were it not for these processes, the column, instead of being steady, endowed with the capacity of movement by muscular agency, would be tottering, requiring muscles to steady it. The influence of the articular processes in limiting the direction of inclination will appear from a study of the movements in the three regions of the spine.

In the **neck** all movements are permitted and are free, except between the second and third cervical vertebræ, where they are slight, owing to the shallow intervertebral disc and the great prolongation of the anterior lip of the inferior surface of the body of the epistropheus, which checks forward flexion considerably. On the whole, however, extension and lateral inclination are more free and extensive in this than in any other region of the column, whilst flexion is more limited than in the lumbar region. Rotatory movements are also free, but take place, on account of the position and inclination of the articular facets, not, as in the thoracic region, round a vertical axis, but round an oblique axis, the articular process of one side gliding upward and forward and that of the opposite side downward and backward.

In the **thoracic region**, especially near its middle, antero-posterior flexion and extension are very slight; and, as the concavity of the curve here is forward, the flat and nearly vertical surfaces of the articular processes prevent anything like sliding in a curvilinear manner of the one set of processes over the sharp upper edges of the other, which would be necessary for forward flexion. A fair amount of lateral inclination would be permitted but for the impediment offered by the ribs; while the position and direction of the articular processes allows rotation round a vertical axis which passes through the centres of the bodies of the vertebræ. This rotation is not very great, and is freer in the upper than in the lower part of the thoracic region.

In the **lumbar region**, extension and flexion are very free, especially between the third and fourth and fourth and fifth vertebræ, where the lumbar curve is sharpest; lateral inclination is also very free between these same vertebræ. It has been stated that the shape and position of the articular processes of the lumbar and the lower two or three dorsal are such as to prevent any rotation in these regions; but, owing to the fact that the inferior articular processes are not tightly embraced by the superior, so that the two sets of articular processes are not in contact on both sides of the bodies at the same time, there is always some space in which horizontal motion can occur round an axis drawn through the central part of the bodies and intervertebral discs, but it is very slight. Thus, the motions are most free in those regions of the column which have a convex curve forward, due to the shape of the intervertebral discs, where there are no bony walls surrounding solid viscera, where the spinal canal is largest and its contents are less firmly attached, and where the pedicles and articular processes are more nearly on a transverse level with the posterior surface of the bodies of the vertebræ.

Nor must the uses of the ligamenta flava be forgotten: these useful structures—(1) complete the roofing-in of the vertebral canal, and yet at the same time permit an ever-changing variation in the width of the interlaminar spaces in flexion and extension; (2) they also restore the articulating surfaces to their normal position with regard to each other after movements of the column; (3) and by forming the medial portion of each articular capsule, they take the place of muscle in preventing it from being nipped between the articular surfaces during movement.

Muscles which take part in the movements of the vertebral column.—Flexors: When acting with their fellows of the opposite side. Rectus abdominis, infra-hyoid muscles (slightly) sterno-mastoid, external oblique, internal oblique, intercostals, scalenus anterior, psoas major and minor, longus colli, longus capitis (rectus capitis anterior major).

Extensors: When acting with their fellows of the opposite side. Sacro-spinalis, quadratus lumborum, semispinalis, multifidus, rotatores, interspinales, serrati posteriores, the splenius, and with the scapula fixed the levator scapulæ and the upper fibres of the trapezius.

Muscles which help to incline the column to their own side.—Sacro-spinalis, quadratus lumborum, semispinalis, multifidus, the intercostals helping to fix the ribs, the external and internal oblique muscles, levatores costarum, serrati posteriores, the scalenes, splenius cervicis, longus colli (oblique part), rotatores, intertransversales, psoas, and with the scapula fixed the levator scapulæ and the upper and lower fibres of the trapezius.

Muscles which rotate the column and turn the body to their own side.—Splenius cervicis, internal oblique (the ribs being fixed), serratus posterior inferior, and with the scapula fixed the lower fibres of the trapezius.

Muscles which rotate the column and turn the body to the opposite side.—Multifidus, semispinalis, external oblique, the lower oblique fibres of the longus colli, and with the scapula and humerus fixed the latissimus dorsi and trapezius.

2. THE SACRO-VERTEBRAL ARTICULATIONS

(*a*) **Class.**—*False Synchondrosis.*

(*b*) **Class.**—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

As in the intervertebral articulations, so in the union of the first portion of the sacrum with the last lumbar vertebra, there are two sets of joints—viz. (*a*) a synchondrosis, between the bodies and intervertebral disc; and (*b*) a pair of arthrodial joints, between the articular processes. The union is effected by the following ligaments, which are common to the vertebral column:—(i) anterior, and (ii) posterior longitudinal; (iii) lateral or short vertebral; (iv) capsular; (v) ligamenta flava; (vi) supraspinous and (vii) interspinous ligaments. Two special accessory ligaments on either side, viz., the sacro-lumbar and the ilio-lumbar, connect the pelvis with the fourth and fifth lumbar vertebræ.

The **sacro-lumbar ligament** (fig. 271) is strong, and triangular in shape. Its apex is above and medial, being attached to the whole of the lower border and front surface of the transverse process of the fifth lumbar vertebra, as well as to the pedicle and body. It is intimately blended with the *ilio-lumbar ligament.* Below, it has a wide, fan-shaped attachment, extending from the edge of the ilio-lumbar ligament forward to the brim of the true pelvis; blending with the periosteum on the base of the sacrum and in the iliac fossa, and with the superior sacro-iliac ligament.

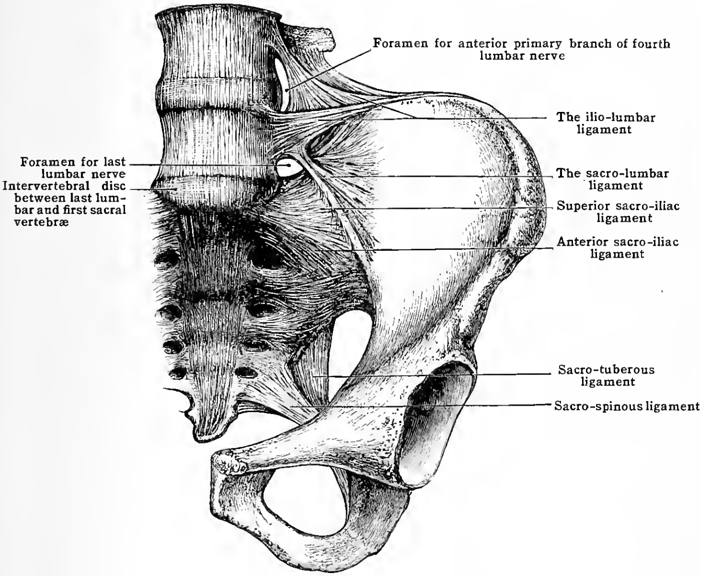
By its sharp medial border it limits laterally the foramen for the *last lumbar nerve.* It is pierced by two large foramina, which transmit arteries to the sacro-iliac synchondrosis. This ligament is in series with the intertransverse ligaments of the spinal column. It is sometimes described as a part of the ilio-lumbar ligament.

The **ilio-lumbar ligament** (fig. 271) is a strong, dense, triangular ligament connecting the fourth and fifth lumbar vertebræ with the iliac crest.

It springs from the front surface of the transverse process of the fifth lumbar vertebra as far as the body, by a strong fasciculus from the posterior surface of the process near the tip, and also from the front surface and lower edge of the transverse process and pedicle of the fourth lumbar vertebra, as far medialward as the body. Between these two lumbar vertebræ it is inseparable from the intertransverse ligament.

At its origin from the transverse process of the fifth lumbar vertebra it is closely interwoven with the sacro-lumbar ligament, and some of its fibres spread downward on to the body of the fifth vertebra, while others ascend to the disc above. At the pelvis it is attached to the inner lip of the crest of the ilium for about two inches (5 cm.). The highest fibres at the column form the upper edge of the ligament at the pelvis, those which come from the posterior portion of the transverse process of the fifth lumbar vertebra forming the lower, while the fibres from the front of the same process pass nearly horizontally lateralward. Near the column the surfaces

FIG. 271.—ANTERIOR VIEW OF THE LIGAMENTS BETWEEN VERTEBRÆ AND PELVIS.



look directly backward and forward, but at the ilium the ligament gets somewhat twisted, so that the posterior surface looks a little upward, and the anterior looks a little downward. The anterior surface forms part of the posterior boundary of the major (false) pelvis, and overlies the upper part of the posterior sacro-iliac ligament; the posterior surface forms part of the floor of the spinal groove, and gives origin to the *multifidus* muscle. Of the borders, the upper is oblique, has the anterior lamella of the lumbar fascia attached to it, and gives origin to the *quadratus lumborum;* the lower is horizontal, and is adjacent to the upper edge of the sacro-lumbar ligament; while the medial is crescentic, and forms the lateral boundary of a foramen through which the *fourth lumbar* nerve passes.

The **arterial supply** is very free, and comes from the last lumbar, ilio-lumbar, and lateral sacral.

The **nerve-supply** is from the sympathetic, as well as from twigs from the fourth and fifth lumbar nerves.

Movements.—The angle formed by the sacrum with the spinal column is called the sacro-vertebral angle. The pelvic inclination does not depend entirely upon this angle, but in great part upon the obliquity of the coxal (innominate) bones to the sacrum, so that in males in whom the average pelvic obliquity is a little greater, the average sacro-vertebral angle is considerably less than in females.

The sacro-vertebral angle in the male shows that there is a greater and more sudden change in direction at the sacro-vertebral union than in the female. A part of this change in direction is due to the greater thickness in the anterior part of the intervertebral fibro-cartilage between the last lumbar vertebra and the sacrum. Owing to the greater thickness of the intervertebral disc here than elsewhere, the movements permitted at this joint are very free, being freer than those between any two lumbar vertebræ. As the diameter of the two contiguous bones is less in the sagittal than in the frontal plane, the forward and backward motions are much freer than those from side to side. The backward and forward motions take place every time the sitting is exchanged for the standing position, and the standing for the sitting posture; in rising, the back is extended on the sacrum at the sacro-lumbar union; in sitting down it is flexed.

The articular processes provide for the gliding movement incidental to the extension, flexion, and lateral movements; they also allow some horizontal movement, necessary for the rotation of the vertebral column on the pelvis, or pelvis on the column. The inferior articular processes of the fifth differ considerably from the inferior processes in the rest of the lumbar vertebræ, and in direction they resemble somewhat those of the cervical vertebræ; while the superior articular processes of the sacrum differ in a similar degree from the superior processes of the lumbar vertebræ. This difference allows for the freer rotation which occurs at this joint.

The sacro-vertebral angle averages 117° in the male, and 130° in the female; while the pelvic inclination averages 155° in the male, and 150° in the female.

As already stated, the movements at the sacro-vertebral joint are the same as those in other parts of the spinal column, but more extensive, and the muscles which produce the movements are those mentioned in the preceding groups which cross the plane of the articulation.

3. THE ARTICULATIONS OF THE PELVIS

This group may again be subdivided into—

(*a*) The **sacro-iliac.**
(*b*) The **sacro-coccygeal.**
(*c*) The **intercoccygeal.**
(*d*) The **symphysis pubis.**

(*a*) The Sacro-iliac Articulation and Sacro-sciatic Ligaments

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

It is now generally admitted that the sacro-iliac joint is a diarthrosis, the articular surface of each bone being covered with a layer of cartilage, whilst the cavity of the joint is a narrow cleft and the capsule is extremely thick posteriorly. The cartilage on the sacrum is much thicker than that on the ilium and the cartilages are sometimes bound together here and there by fibrous strands. The different character of the joint in the two sexes should be noted. Briefly, the female joint has strong ligamentous bonds with but little bony apposition, while the male joint gains its strength by virtue of extensive areas of bony contact and a slighter development of ligaments. This difference is, of course, a physiological one; for some laxity of the joint is demanded during pregnancy and labour. The bones which enter into the joint are the sacrum and ilium, and they are bound together by the following ligaments:—

Anterior sacro-iliac.	Superior sacro-iliac.
Posterior sacro-iliac.	Inferior sacro-iliac.

Interosseous.

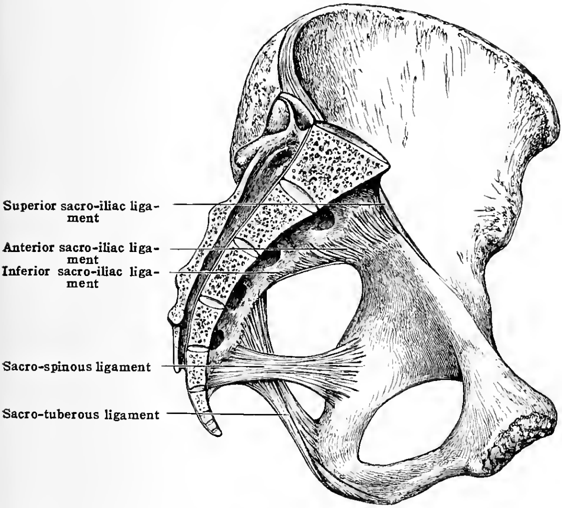
The **anterior sacro-iliac ligament** (figs. 271 and 272) consists of well-marked glistening fibres which pass above into the superior, and below into the inferior, ligaments. It extends from the first three bones of the sacrum to the ilium between the brim of the pelvis minor and the great sciatic notch, blending with the periosteum of the sacrum and ilium as it passes away from the united edges of the bones.

The **superior sacro-iliac ligament** (figs. 271 and 272) extends across the upper margins of the joint, from the ala of the sacrum to the iliac fossa, being well marked along the brim of the pelvis, where it is thickened by some closely packed fibres. Behind, it is far stronger, especially beneath the transverse process of the fifth lumbar vertebra. This ligament is connected with the strong sacro-lumbar ligament, which spreads lateralward and forward over the joint to reach the iliac fossa and terminal line. By some authors it is described as a part of the ilio-lumbar ligament.

The **posterior sacro-iliac ligament** is extremely strong and consists essentially of two sets of fibres, deep and superficial. The deep fibres (short posterior sacro-iliac ligament) pass downward and medialward from the rough area of the ilium behind the auricular surface to the back of the lateral mass of the sacrum, both lateral to and between the upper foramina and to the upper sacral articular process, and the area between it and the first sacral foramen. The deepest fibres of this group constitute the so-called interosseous ligament. The more superficial fibres (long posterior sacro-iliac ligament) are oblique or vertical, and pass from the posterior superior iliac spine to the second, third, and fourth tubercles on the back of the sacrum, a more or less well-defined band which goes to the third and fourth sacral tubercles being called sometimes the oblique sacro-iliac band and sometimes the long straight band.

The **inferior sacro-iliac ligament** (fig. 272) is covered behind by the upper end of the sacro-tuberous ligament; it consists of strong fibres extending from the lateral border of the sacrum below the articular facet to the posterior iliac spines; some of the fibres are attached to the deep surface of the ilium and join the interosseous ligament.

Fig. 272.—Median Sagittal Section of the Pelvis, Showing Ligaments.



The **interosseous ligament** is the strongest of all, and consists of fibres of different lengths passing in various directions between the two bones. Immediately above the interspinous notch of the ilium the fibres of this ligament are very strong, and form an open network, in the interstices of which is a quantity of fat in which the articular vessels ramify.

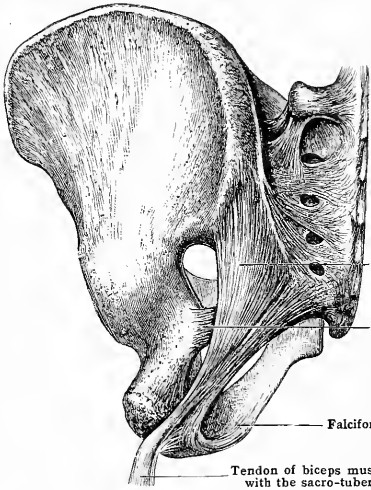
The ear-shaped **cartilaginous plate**, which unites the bones firmly, is accurately applied to the auricular surfaces of the sacrum and ilium. It is about one-twelfth of an inch (2 mm.) thick in the centre, but becomes thinner toward the edges. Though closely adherent to the bones, it tears away from one entirely, or from both partially, on the application of violence, sometimes breaking irregularly so that the greater portion remains connected with one bone, leaving the other bone rough and bare. It is usually one mass, and is only occasionally formed of two plates with a synovial cavity between them.

Because of the occasional presence of a more or less extensive synovial cavity within the fibro-cartilage, and also of a synovial lining to the ligaments passing in front and behind the articulation, the term 'diarthro-amphiarthrosis' has been given to this joint, and also to the symphysis pubis. Testut mentions certain folds of synovial membrane filling up gaps which here and there occur at the margin of the fibro-cartilage but they are not usually seen.

The **sacro-tuberous** (great sciatic) **ligament** (figs. 271, 272, and 273) is attached above to the posterior extremity of the crest of the ilium and the lateral aspect of the posterior iliac spines. From this attachment some of its fibres pass downward and backward to be attached to the lateral borders and posterior surfaces of the lower three sacral vertebræ and upper two segments of the coccyx; while others, after passing for a certain distance backward, curve forward and downward to the ischium, forming the anterior free margin of the ligament where it limits posteriorly the sciatic foramina. These fibres are joined by others which arise from the posterior surfaces of the lower three sacral vertebræ and upper pieces of the coccyx. At the ischium it is fixed to the medial border of the tuberosity, and sends a thin sharp process upward along the ramus of the ischium which is called the **falciform process** (fig. 273), and is a prolongation of the posterior edge of the ligament.

A great many fibres pass on directly into the tendon of the biceps muscle, so that traction on this muscle braces up the whole ligament, and the coccyx is thus made to move on the sacrum. The ligament may not unfairly be described as a tendinous expansion of the muscle, whereby its action is extended and a more advantageous leverage given. It is broad and flat at its attached ends, but narrower and thicker in the centre, looking like two triangular expansions

FIG. 273.—SACRO-TUBEROUS AND SACRO-SPINOUS LIGAMENTS. (Posterior view.)



joined by a flat band, the larger triangle being at the ilium, and the smaller at the ischium The fibres of the ligament are twisted upon its axis at the narrow part, so that some of the superior fibres pass to the lower border.

The posterior surface gives origin to the *gluteus maximus* muscle, and on it ramify the loop; from the posterior branches of the sacral nerves; its anterior surface is closely connected at its origin ,with the sacro-spinous ligament, and some fibres of the *piriformis* muscle arise from its below the *obturator internus* passes out of the pelvis under its cover, and the *internal pudic vessels and nerve* pass in. At the ilium, its posterior edge is continuous with the vertebra. aponeurosis; while to the anterior edge is attached the thick fascia covering the gluteus mediusl The obturator fascia is attached to its falciform edge. It is pierced by the *coccygeal branches of the inferior gluteal* (*sciatic*) *artery* and the *inferior clunial* (*perforating cutaneous*) *nerve* from the *second* and *third sacral*.

The **sacro-spinous** (small sciatic) **ligament** (figs. 271, 272, and 273) is triangular and thin, springing by a broad base from the lateral border of the sacrum and coccyx, from the front of the sacrum both above and below the level of the fourth sacral foramen, and from the coccyx nearly as far as its tip. By its apex it is attached to the front surface and the borders of the ischial spine as far outward as its base. Its fibres decussate so that the lower ones at the coccyx become the highest at the ischial spine; muscular fibres are often seen intermingled with the ligamentous.

The sacro-spinous ligament is situated in front of the sacro-tuberous ligament, with which it is closely connected at the sacrum, and separates the greater from the lesser sciatic foramen.

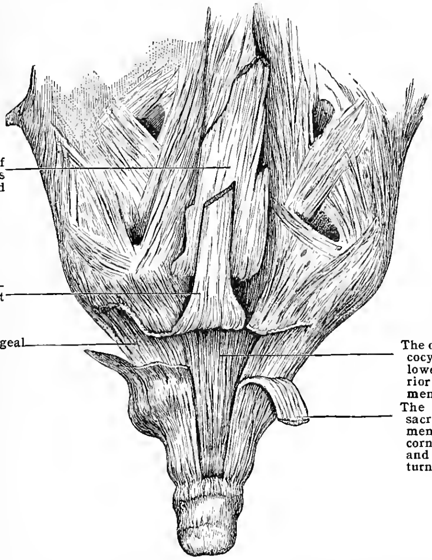
Its front surface gives attachment to the *coccygeus* muscle, which overlies it. Behind, it is connected with, and hidden by, the sacro-tuberous ligament, so that only the lateral inch or less (2 cm.) and a small part of its attachment to the coccyx can be seen; the *internal pudic* nerve also passes over the posterior surface.

The **arterial supply** of the sacro-iliac joint comes from the superior gluteal, ilio-lumbar, and lateral sacral.

The **nerve-supply** is from the superior gluteal, sacral plexus, and external twigs of the posterior divisions of the first and second sacral nerves.

Movements.—Recent investigations have shown that in spite of the interlocking of the articular surfaces and the strong ligaments connecting the bones together a slight amount of movement, both a gliding and rotatory, does occur at the sacro-iliac joint. The gliding movement is both up and down, and forward and backward, and the latter is associated with a slight rotation round a transverse axis which passes through the upper tubercles on the back of the sacrum. The movement is but small in extent, nevertheless as the base of the sacrum moves

FIG. 274.—LIGAMENTS CONNECTING SACRUM AND COCCYX POSTERIORLY.



downward and forward the conjugate (antero-posterior) diameter of the pelvic inlet is diminished and at the same time, as the coccyx moves up and back, the conjugate diameter of the outlet is increased. This rotatory movement is limited principally by the sacro-sciatic (sacro-tuberous and sacro-spinous) ligaments which prevent any extensive upward and backward movement of the coccyx and lower part of the sacrum.

Downward displacement of the sacrum when the body is in the sitting posture is prevented not only by the surrounding ligaments, but also by the wedge-like character of the sacrum, which is broader above than below. Downward and forward displacement of the sacrum in the erect posture is prevented by the ligaments and more particularly by the posterior sacro-iliac bands, while backward displacement would be hindered by the breadth of the anterior as contrasted with the posterior part of the sacrum as well as by the anterior ligaments.

Relations.—The sacro-iliac joint is in relation above with psoas and iliacus. In front it is in relation at its upper part with the hypogastric vessels and obturator nerve, and at its lower part with the piriformis muscle.

(*b*) THE SACRO-COCCYGEAL ARTICULATION

Class.—*False Synchondrosis.*

The last piece of the sacrum and first piece of the coccyx enter into this union [symphysis sacrococcygea] and are bound together by the following ligaments:—

Anterior sacro-coccygeal. Deep posterior sacro-coccygeal.
Superficial posterior sacro-coccygeal. Lateral sacro-coccygeal.
Intervertebral substance.

The **intervertebral fibro-cartilage** is a small oval disc, three-quarters of an inch (about 2 cm.) wide, and a little less from before backward, closely connected with the surrounding ligaments. It resembles the other discs in structure, but is softer and more jelly-like, though the laminæ of the fibrous portion are well marked.

The **anterior sacro-coccygeal ligament** is a prolongation of the glistening fibrous structure on the front of the sacrum. It is really the lower extremity of the anterior longitudinal ligament, which is thicker over this joint than over the central part of either of the bones.

The **posterior sacro-coccygeal ligament** (fig. 274) is divided into two layers of which one (the **deep**) is a direct continuation of the posterior longitudinal ligament of the column, consisting of a narrow band of closely packed fibres, which become blended at the lower border of the first segment of the coccyx with the filum terminale and deep posterior ligament.

The **superficial layer** of the posterior sacro-coccygeal ligament (or supracornual ligament), (fig. 274) is the prolongation of the supraspinous which becomes inseparably blended with the aponeurosis of the *sacro-spinalis* (*erector spinæ*) opposite the laminæ of the third sacral vertebra, and is thus prolonged downward upon the back of the coccyx, passing over and roofing in the lower end of the spinal canal where the laminæ are deficient.

The median fibres (the **supraspinous ligament**) extend over the back of the coccyx to its tip, blending with the deep fibres of the posterior sacro-coccygeal ligament and filum terminale; the deeper fibres run across from the stunted laminæ on one side to the next below on the opposite side, and from the sacral cornua on one side to the coccygeal on the opposite, some passing between the two cornua of the same side, and bridging the aperture through which the fifth sacral nerve passes. Its posterior surface gives origin to the *gluteus maximus* muscle.

The **lateral sacro-coccygeal or intertransverse ligament** (fig. 274) is merely a quantity of fibrous tissue which passes from the transverse process of the coccyx to the lateral edge of the sacrum below its angle. It is connected with the sacrosciatic ligaments at their attachments, and the *fifth sacral* nerve escapes behind it. It is perforated by twigs from the lateral sacral artery and the coccygeal nerve.

The **arterial supply** of the sacro-coccygeal joint is from the lateral sacral and middle sacral arteries.

The **nerves** come from the fourth and fifth sacral and coccygeal nerves.

The **movements** permitted at this joint are of a simple forward and backward, or hinge-like character. In the act of defecation, the bone is pushed back by the fæcal mass, and, in parturition, by the fœtus; but this backward movement is controlled by the upward and forward pull of the levator ani and coccygeus. The external sphincter also tends to pull the coccyx forward.

(*c*) Intercoccygeal Joints

The several segments of the coccyx are held together by the anterior and posterior longitudinal ligaments, which completely cover the bony nodules on their anterior and posterior aspects. Laterally, the sacro-sciatic ligaments, being attached to nearly the whole length of the coccyx, serve to connect them. Between the first and second pieces of the coccyx there is a very perfect amphiarthrodial joint, with a well-marked intervertebral substance.

Movements.—But little movement occurs as a rule at the sacro-coccygeal and intercoccygeal joints, but when the head of the child is passing through the pelvic outlet at birth, the tip of the coccyx is displaced backward, it may be to the extent of one inch.

(*d*) The Symphysis Pubis

Class.—*False Synchondrosis.*

The bones entering into this joint are the pubic portions of the hip-bones. This joint is shorter and broader in the female than in the male. The ligaments, which completely surround the articulation, are:—

Superior.	Anterior.
Arcuate.	Posterior.
Interpubic cartilage.	

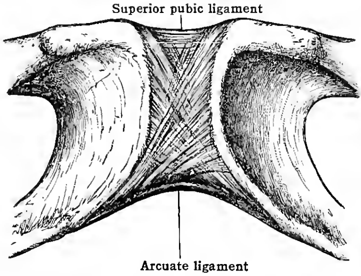
The **superior ligament** (figs. 275 and 276) is a well-marked stratum of yellowish fibres which extends lateralward along the crest of the pubis on each side, blending in the middle line with the interosseous cartilage.

It is continuous in front with the deep traverse fibres of the anterior ligament, and behind with the posterior ligament. It gives origin to the *rectus abdominis* tendon.

The **posterior ligament** (fig. 277) is slight, and, excepting above and below, consists of little more than thickened periosteum.

Near the upper part is a band of strong fibres, reaching the whole width of the pubic bones, and continuous with the thickened periosteal fibres along the terminal line. Below, many of the upper and superficial fibres of the arcuate ligament ascend over the back of the joint, and interlace across the median line with fibres from the opposite side nearly as high as the middle of the symphysis.

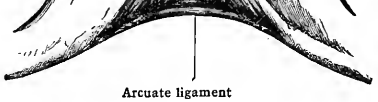
Fig. 275.—Anterior View of the Symphysis Pubis (Male), showing the Decussation of the Fibres of the Anterior Ligament.



The **anterior ligament** (figs. 275 and 276) is thick and strong, and is closely connected with the fascial covering of the muscles arising from the body of the pubis. It consists of several strata of thick, decussating fibres of different degrees of obliquity, the superficial being the most oblique, and extending lowest over the joint.

The most superficial descending fibres extend from the upper border of the pubis, cross others from the opposite side about the middle of the symphysis, and are attached to the ramus of the opposite bone. The most superficial ascending fibres come from the arcuate ligament,

Fig. 276.—Anterior View of the Symphysis Pubis (Female), showing greater Width between the Bones.



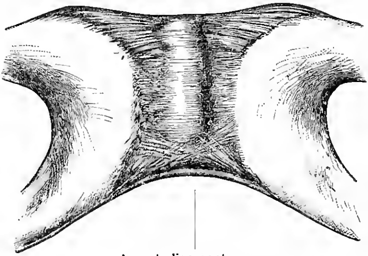
arch upward, and decussate with other fibres across the middle line, and are lost on the opposite side beneath the descending set. There is another deeper set of descending fibres which arise below the angle, but do not descend so far as the superficial; and a deeper set of ascending, which decussate, and reach higher than the superficial set, and are connected with the arcuate ligament. Some few transverse fibres pass from side to side, especially above and below the points of decussation.

The **arcuate** (inferior or subpubic) **ligament** (figs. 275, 276, and 277) is a thick, arch-like band of closely packed fibres which fills up the angle between the pubic rami, and forms a smooth, rounded summit to the pubic arch. On section, it is yellowish in colour and three-eighths of an inch (1 cm.) thick in the middle line; it is inseparably connected with the interpubic cartilage.

Both on the front and back aspects of the joint it gives off decussating fibres, which, by their interlacement over the anterior and posterior ligaments of the symphysis, add very materially to its security. In fact, the ligament may be said to split superiorly into two layers, one passing over the front, and the other over the back, of the articulation.

The **interpubic fibro-cartilage** varies in thickness in different subjects, but is thicker in the female than in the male. It is thicker in front than behind, and projects beyond the edges of the bones, especially posteriorly (see fig. 277), blending intimately with the ligaments at its margins. It is sometimes uninterruptedly woven throughout, but at others has an elongated narrow fissure, partially dividing the cartilage into two plates, with a little fluid in the interspace

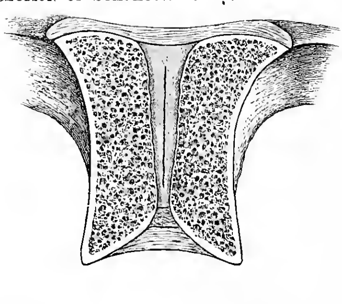
Fig. 277.—Posterior View of the Symphysis Pubis, showing the Decussation of the Fibres from the Arcuate Ligament.



(fig. 278). This is situated toward the upper and posterior aspects, but does not usually reach either; it generally extends about half the length of the cartilage.

When this cavity is large, especially if it reaches or approaches very near to the circumference of the cartilage (which, however, it very rarely does), it is thought by some anatomists that it more nearly resembles a diarthrodial than an amphiarthrodial joint, and it is then classed with the sacro-iliac joint under similar conditions, as 'diarthroamphiarthrosis.' The interosseous cartilage is intimately adherent to the layer of hyaline cartilage which covers the medial surface of each pubic bone; the osseous surface is ridged to give a firmer attachment; and, on forcing the bones apart, it does not frequently split into two plates, but is torn from the bone on one side or the other.

Fig. 278.—Section of Symphysis to show the Synovial Cavity.



The arterial supply of the interpubic joint is from twigs of the internal pudic, pubic branches of the obturator and epigastric, and ascending branches of the internal circumflex and superficial external pudic.

The nerve-supply has not been satisfactorily made out, but it probably comes, in part, from the internal pudic and in part from the ilio-hypogastric and ilio-inguinal.

The movements amount only to a slight yielding of the cartilage; neither muscular force nor extrinsic forces produce any appreciable movement in the ordinary condition. Occasionally, as the result of child-bearing, the joint becomes unnaturally loose, and then walking and standing are painfully unsteady. It is known that, during pregnancy and parturition, the symphyseal cartilage becomes softer and more vascular, so as to permit the temporary enlargement of the pelvis; but it must be remembered that the fibres of the oblique muscles decussate and thus, during labour, while they force the head of the fœtus down, they strengthen the joint by bracing the bones more tightly together.

Relations.—The interpubic joint is in relation above with the linea alba. Behind with the prostate and the anterior border of the bladder. In front with the suspensory ligament of the penis or clitoris and below with the dorsal vein of the penis or clitoris and the upper border of the urogenital trigone (triangular ligament).

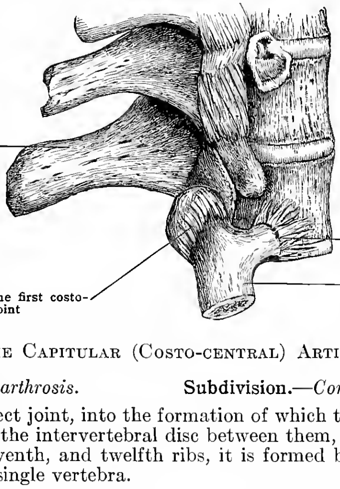
4. THE COSTO-VERTEBRAL ARTICULATIONS

These consist of two sets, viz.:—

(*a*) The **capitular** (costo-central): i. e., the articulation of the head of the rib with the vertebræ.

(*b*) The **costo-transverse,** or the articulation of the tubercle (of each of the first ten ribs) with the transverse process of the lower of the two vertebræ, with which the head of the rib articulates: i. e., the one bearing its own number, as the first rib with the first thoracic vertebra, the second rib with the second thoracic vertebra, and so on.

Fig. 279.—The Capsular Ligaments of the Costo-vertebral Joints.



(*a*) The Capitular (Costo-central) Articulation

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

It is a very perfect joint, into the formation of which the head of the rib and two vertebræ, with the intervertebral disc between them, enter. In the case of the first, tenth, eleventh, and twelfth ribs, it is formed by the head of the rib articulating with a single vertebra.

The **ligaments** are:—

Articular capsule. Interarticular.
Radiate.

The **articular capsule** (fig. 279) consists of short, strong, woolly fibres, completely surrounding the joint, which are attached to the bones and intervertebral substances, a little beyond their articular margins.

At its upper part it reaches through the intervertebral foramen toward the back of the bodies of the vertebræ, being strengthened here by fibres which at intervals connect the anterior with the posterior longitudinal ligaments. The lower fibres extend downward nearly to the demi-facet (costal pit) of the rib below; behind, it is continuous with the neck ligament, and in front is overlaid by the radiate.

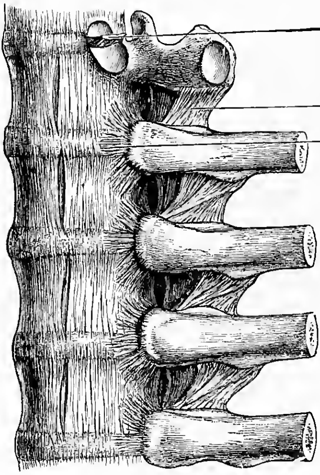
The **interarticular ligament** (fig. 280) consists of short, strong fibres, closely interwoven with the outermost ring of the intervertebral disc, and attached to the transverse ridge separating the articular facets on the head of the rib. It completely divides the articulations into two parts, but does not brace the rib tightly to the spine, being loose enough to allow a moderate amount of rotation on its own axis. There is no interarticular ligament in the costo-vertebral joints of the first, tenth, eleventh, and twelfth ribs.

The **radiate** (or stellate) **ligament,** a thickening of the anterior part of the capsule (figs. 280 and 281), is the most striking of all, and consists of bright, pearly-white fibres attached to the anterior surface, and upper and lower borders of the neck of the rib, a little way beyond the articular facet; from this they radiate upward, forward, and downward, so as to form a continuous layer of distinct and sharply defined fibres.

The middle fibres run straight forward to be attached to the intervertebral disc; the upper ascend to the lower half of the lateral surface of the vertebra above, and the lower descend to the upper half of the vertebra below. The radiate ligament is overlapped on the vertebral bodies by the lateral (short) vertebral ligaments.

In the case of the first, tenth, eleventh, and twelfth ribs, each of which articulates with one vertebra, the ligament is not quite so distinctly radiate, but even in these the ascending fibres reach the vertebra above that with which the rib articulates.

Fig. 280.—Showing the Anterior Longitudinal Ligament, and the Connection of the Ribs with the Vertebræ.



The **synovial membranes** (fig. 281) consist of two closed sacs which do not communicate: one above, and the other below, the interarticular ligament. In the case of the first, tenth, eleventh, and twelfth articulations, there is but one synovial membrane, as these joints have no interarticular ligament.

The **arterial supply** is from the intercostal arteries, the twigs piercing the radiate and capsular ligaments.

The **nerve-supply** comes from the anterior primary branches of the intercostal nerves.

These joints approach most nearly in their movements to the condylarthroses.

The **movements** are ginglymoid in character, consisting of a slight degree of elevation and depression around an obliquely horizontal axis corresponding with the interarticular ligament; there is also a slight amount of forward and backward gliding; and a slight degree of screwing or rotatory movement is also possible. There is a considerable difference in the degree of mobility of the different ribs, for while the first rib is almost immobile except in a very deep inspiration, the mobility of the others increases from the second to the last; the two floating ribs being the most mobile of all. The head of the rib is the most fixed point of the costal arch, and upon it the whole arch rotates; the interarticular ligament allows only a very limited amount of flexion and extension (i. e., elevation and depression), and of gliding. Gliding is checked by the radiate ligament.

In inspiration, the rib is elevated, and glides forward in its socket, too great elevation being checked not only by the ligaments, but also by the overhanging upper edge of the cavity itself. In expiration, the rib is depressed, and glides backward in its cavity.

(b) The Costo-transverse Articulation

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

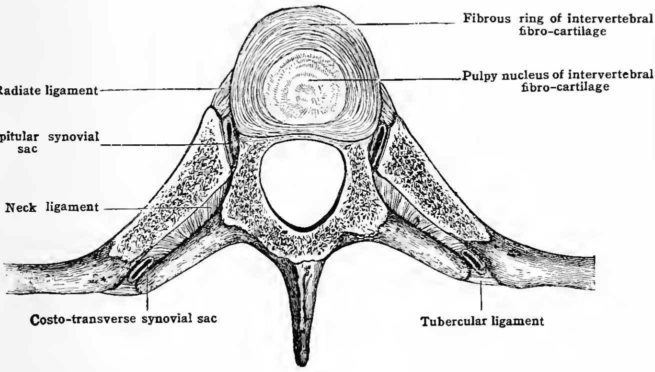
This joint is formed by the tubercle of the rib articulating with the anterior part of the tip of the transverse process. The eleventh and twelfth ribs are devoid of these joints, for the tubercles of these ribs are absent, and the transverse processes of the eleventh and twelfth thoracic vertebræ are rudimentary.

The ligaments of the union are:—

Articular capsule.	Tubercular ligament.
Neck ligament.	Costo-transverse ligaments.

The **articular capsule** (figs. 279 and 281) forms a thin, loose, fibrous envelope to the synovial membrane. Its fibres are attached to the bones just beyond the articular margins, and are thickest below, where they are not strengthened by any other structure. It is connected medially with the neck ligament, above with the costo-transverse, and laterally with the tubercular (posterior costo-transverse) ligaments. The **eleventh** and **twelfth ribs** are unprovided with costo-transverse capsules.

Fig. 281.—Horizontal Section through the Intervertebral Disc and Ribs.



The **neck ligament** [lig. colli costæ] (middle costo-transverse, or interosseous ligament) (fig. 281), consists of short fibres passing between the back of the neck of the rib and front of the transverse process, with which the tubercle articulates. It extends from the capsule of the capitular joint to that of the costo-transverse. It is best seen on horizontal section through the bones. In the **eleventh** and **twelfth** ribs this ligament is rudimentary.

The **tubercular ligament** (posterior costo-transverse) (fig. 281) is a short but thick, strong, and broad ligament, which extends laterally and upward from the extremity of the transverse process to the non-articular surface of the tubercle of the corresponding rib. The **eleventh** and **twelfth** ribs have no posterior ligament.

The (superior) **costo-transverse ligament** (fig. 280) is a strong, broad band of fibres which ascends laterally from the crest on the upper border of the neck of the rib, to the lower border of the transverse process above. A few scattered posterior fibres pass upward and medially from the neck to the transverse process. The costo-transverse ligament is subdivided into a stronger anterior portion (anterior costo-transverse ligament) best seen from the front (fig. 280), and a weaker posterior portion (posterior costo-transverse ligament). Its medial border bounds the foramen through which the posterior branches of the intercostal vessels and nerves pass. To the lateral border is attached the thin aponeurosis covering the *external intercostals*. Its anterior surface is in relation with the intercostal vessels and nerve; the posterior with the *longissimus dorsi*. The **first** rib has no (superior) costo-transverse ligament.

The **synovial membrane** (fig. 281) is a single sac.

The **arterial and nerve supplies** come from the posterior branches of the intercostal arteries and nerves.

The **movements** which take place at these joints are limited to a gliding of the tubercle of the rib upon the transverse process. The exact position of the facet on the transverse process varies slightly from above downward, being placed higher on the processes of the lower vertebræ. The plane of movement in most of the costo-transverse joints is inclined upward and backward in inspiration, and downward and forward in expiration. The point round which these movements occur is the head of the rib, so that the tubercle of the rib glides upon the transverse process in the circumference of a circle, the centre of which is at the capitular joint.

5. THE ARTICULATIONS AT THE FRONT OF THE THORAX

These may be divided into four sets, viz.:—

(*a*) The **intersternal joints,** or the union of the several parts of the sternum with one another.

(*b*) The **costo-chondral joints,** or the union of the ribs with their costal cartilages.

(*c*) The **chondro-sternal joints,** or the junction of the costal cartilages with the sternum.

(*d*) The **interchondral joints,** or the union of five costal cartilages (sixth, seventh, eighth, ninth, and tenth) with one another.

(*a*) The Intersternal Joints

The sternum being composed, in the adult, of three distinct pieces—the manubrium, body, and the xiphoid process—has two articulations, viz., the superior, which unites the manubrium with the body (gladiolus), and the inferior, which unites the body with the xiphoid.

1. The Superior Intersternal Articulation

Class.—*False Synchondrosis.*

The lower border of the manubrium and the upper border of the body of the sternum present oval-shaped, flat surfaces, with their long axes transverse, and covered with a thin layer of hyaline cartilage. An **interosseous fibro-cartilage** is interposed between the bony surfaces: it corresponds exactly in shape and intimately adheres to them. At each lateral border this fibro-cartilage enters into the formation of the second chondro-sternal articulation (fig. 282).

In consistence it varies, being in some cases uniform throughout, in others softer in the centre than at the circumference, and in others again an oval-shaped synovial cavity is found toward its anterior part. When such a cavity exists in the fibro-cartilage this joint has a remote resemblance to the diarthroses, and is classed, with the sacro-iliac joint and the symphysis pubis under similar conditions, as 'diarthro-amphiarthrosis.'

The periosteum passes uninterruptedly over the joint from one segment of the sternum to the other, forming a kind of capsular ligament [membrana sterni]. This capsule is strengthened, especially on its posterior aspect, by longitudinal ligamentous fibres as well as by the radiating and decussating fibres of the chondro-sternal ligaments.

In some instances the fibro-cartilage is replaced by short bundles of fibrous tissue which unite the cartilage-coated articular bony surfaces.

2. The Inferior Intersternal Articulation

Class.—*False Synchondrosis.*

The gladiolus is joined to the xiphoid cartilage by a thick investing membrane, by anterior and posterior longitudinal fibres, and by radiating fibres of the sixth and seventh chondro-sternal ligaments. The **costo-xiphoid ligament** also connects the xiphoid with the anterior surface of the sixth and seventh costal cartilages, and thus indirectly with the gladiolus; and some fine fibro-areolar tissue also connects the xiphoid with the back of the seventh costal cartilage.

The junction of the xiphoid with the sternum is on a level somewhat posterior to the junction of the seventh costal cartilage with the sternum. The union is a synchondrosis, each bone being covered by hyaline cartilage which is connected with the intervening fibro-cartilage plate.

(b) The Costo-chondral Joints

Class.—*Synarthrosis.*

The extremity of the costal cartilage is received into a cup-shaped depression at the end of the rib, which is somewhat larger than the cartilage. The two are joined together by the continuity of the investing membranes, the periosteum of the rib being continuous with the perichondrium of the cartilage.

(c) The Sterno-costal Articulations

Class.—*Diarthrosis.* **Subdivision**—*Ginglymus.*

These articulations are between the lateral borders of the sternum and the ends of the costal cartilages. The union of the first rib with the sternum is *synchondrodial,* and therefore forms an exception to the others. From the second to the seventh inclusive, the articulations have the following ligaments, which together form a complete capsule:—

Radiate (anterior) sterno-costal.	Superior sterno-costal.
Posterior sterno-costal.	Inferior sterno-costal.

The **radiate** (anterior) **sterno-costal ligament** (fig. 282) is a triangular band composed of strong fibres which cover the medial half-inch of the front of the costal cartilage, and radiate upward and downward upon the front of the sternum. Some of the fibres decussate across the middle line with fibres of the opposite ligament. At its upper and lower borders it is in contact with the superior and inferior ligaments respectively.

The **posterior sterno-costal ligament** consists of little more than a thickening of the fibrous envelopes of the bone and cartilage, the joint being completed behind by a continuity of perichondrium with periosteum.

The **superior** and **inferior ligaments** are strong, well-marked bands, which pass from the upper and lower borders respectively of the costal cartilage to the lateral edges of the sternum. The sixth and seventh cartilages are so close that the superior ligament of the seventh is blended with the inferior of the sixth rib.

Deeper than the fibres of these ligaments are short fibres passing from the margins of the sternal facets to the edges of the facets on the cartilages; they are most distinct in the front and lower part of the joint, and may encroach so much upon the synovial cavity as to reduce it to a very small size, or almost obliterate it. This occurs mostly in the case of the sixth and seventh joints, especially the latter.

The **interarticular ligament** (fig. 282) is by no means constant, but is usually present in the second joint on one, if not on both sides of the same subject. It consists of a strong transverse bundle of fibres passing from the ridge on the facet on the cartilage to the fibrous substance between the manubrium and body; sometimes the upper part of the synovial cavity is partially or entirely obliterated by short, fine, ligamentous fibres.

The **costo-xiphoid ligament** (fig. 282) is a strong flat band of fibres passing obliquely upward and laterally from the front surface of the xiphoid cartilage to the anterior surface of the sternal end of the seventh costal cartilage, and most frequently to that of the sixth also.

Synovial membranes.—The union of the first cartilage with the sternum being synchondrodial, it has no synovial membrane; the second has usually two, separated by the interarticular ligament. The rest usually have one synovial membrane, which may occasionally be subdivided into two (fig. 282).

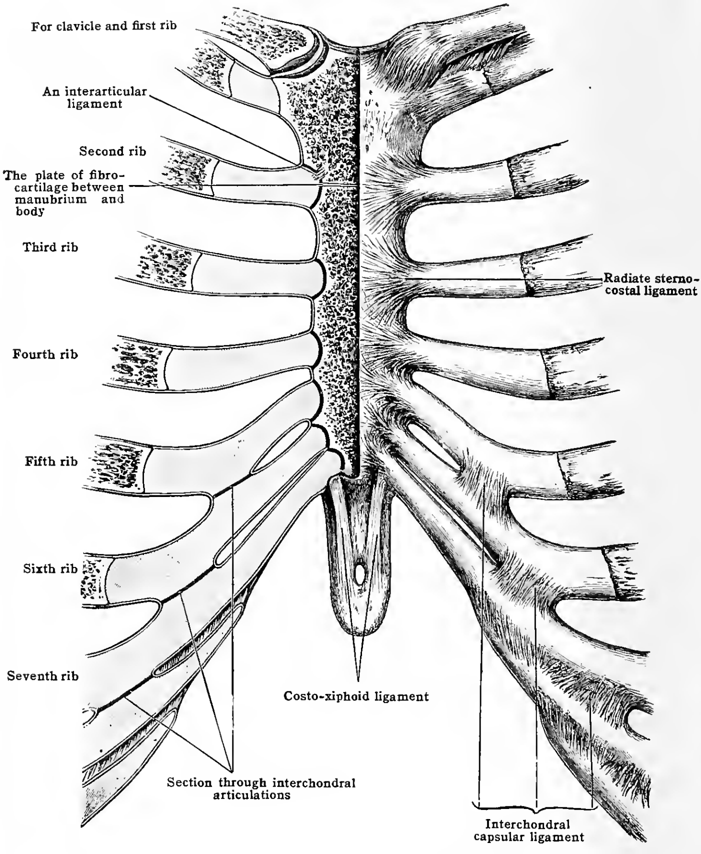
The arterial supply is derived from perforating branches of the internal mammary; and the **nerves** come from the anterior branches of the intercostals.

Movements.—Excepting the first, the chondro-sternal joints are ginglymoid, but the motion of which they are capable is very limited. It consists of a hinge-like action in two directions: first, there is a slight amount of elevation and depression which takes place round a transverse axis, and, secondly, there is some forward and backward movement round an obliquely vertical axis. In inspiration the cartilage is elevated, the lowest part of its articular facet is pressed into the sternal socket, and the sternum is thrust forward so that the upper and front edges of the articular surfaces separate a little; in expiration the reverse movement takes place. Thus the two extremities of the costal arches move in their respective sockets in opposite directions.

This difference results necessarily from the fact that the costal arch moves upon the vertebral column, and, having been elevated, it in its turn raises the sternum by pushing it upward and forward.

The costo-xiphoid ligament tends to prevent the xiphoid cartilage from being drawn backward by the action of the diaphragm.

Fig. 282.—The Articulation at the Front of the Thorax.
(Left side, showing ligaments; right side, the synovial cavities.)



(*d*) The Interchondral Articulations

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

A little in front of the point where the costal cartilages bend upward toward the median line the sixth is united with the seventh, the seventh with the eighth, the eighth with the ninth, and the ninth with the tenth.

At this point each of the cartilages from the sixth to the ninth inclusive is deeper than elsewhere, owing to the projection downward from its lower edge of a broad blunt process, which comes into contact with the cartilage next below. Each of the apposed surfaces is smooth, and they are connected at their margins by ligamentous tissue, which forms a complete capsule for the articulation, and is lined by a synovial membrane (fig. 282). The largest of these cavities is between the seventh and eighth; those between the eighth and ninth, and ninth and tenth, are smaller, and are not free to play upon each other in the whole of their extent, being held together by ligamentous tissue at their anterior margins. Sometimes this fibrous tissue completely obliterates the synovial cavity.

The arteries are derived from the musculo-phrenic, and the nerves from the intercostals.

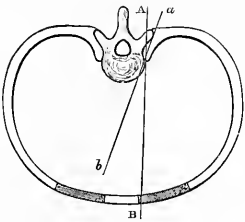
Movements.—By means of the costal cartilages and interchondral joints, strength with elasticity is given to the wall of the trunk at a part where the cartilages are the only firm structures in its composition; while a slight gliding movement is permitted between the costal cartilages themselves, which takes place round an axis corresponding to the long axis of the cartilages. By this means, the outward projection of the lower part of the thoracic wall is increased by deep inspiration.

MOVEMENTS OF THE THORAX AS A WHOLE

Before describing these movements as a whole, it must be premised that there are somt few modifications in the movements of certain ribs resulting from their shape. Thus the firs rib (and to a less extent the second also), which is flat on its upper and lower surfaces, revolves on a transverse axis drawn through the costo-vertebral and costo-transverse joints. During inspiration and expiration, the anterior extremities of the first pair of costal arches play up and down, the tubercles and the heads of the ribs acting in a hinge-like manner, the latter having also a slight screwing motion. By this movement the anterior ends of the costal arches are simply raised or depressed, and the sternum pushed a little forward; it may be likened to the movement of a pump-handle, as in fig. 283, *a*, *b*.

The movements of the other ribs, particularly in the mid-region of the thorax, are more complex, for, besides the elevation of the anterior extremities, the bodies and angles of the

FIG. 283.—DIAGRAM OF AXIS OF RIB-MOVEMENT. (After Kirkes.)



ribs rise nearly as much as the extremities themselves. In this movement the tubercles of the ribs glide upward and backward in inspiration, and downward and forward in expiration; and the movement may be likened to that of a bucket handle, as in fig. 283, A, B.

During inspiration, the cavity of the thorax is increased in every direction. The **antero-posterior diameter** is increased by the thrusting forward of the sternum, caused by the elevation of the costal cartilages and fore part of the ribs, whereby they are brought to nearly the same level as the heads of the ribs. The **transverse diameter** is increased: (i) Behind, by the elevation of the middle part of the ribs; for when at rest the mid-part of the rib is on a lower level than either the costo-vertebral or chondro-sternal articulations. Owing to this obliquity the transverse diameter is increased when the rib is raised, and the increase is proportionate to the degree of obliquity. (ii) By the eversion of the lower border of the costal arch, which turns outward as the arch is raised. (iii) The transverse diameter is increased in front by the abduction of the anterior extremity of the rib at the same time as it is elevated and thrust forward.

The increase in the **vertical diameter** of the thorax is due to the elevation of the ribs, especially the upper ones, and the consequent widening of the intercostal spaces; but the chief increase in this direction is due to the descent of the diaphragm.

The greatest increase both in the antero-posterior and transverse diameters takes place where the ribs are longest, most oblique, and most curved at their angles, and where the bulkiest part of the lung is enclosed. This is on a level with the sixth, seventh, and eighth ribs.

At the lower part of the thorax, where the ribs have no relation to the lungs, and do not affect respiration directly by their movements, it is important that the costal arches should be thrown well outward in order to counteract the compression of the abdominal viscera by the contraction of the diaphragm.

By widening and steadying the lower part of the thorax during inspiration, the attachments of]the muscular fibres of the diaphragm are widened, and their power increased.

Muscles which take part in the movements of inspiration.—(*a*) *Ordinary inspiration;* The scalenes, serratus posterior superior, the external and internal (?) intercostals, the diaphragm; the quadratus lumborum and serratus posterior inferior fixing the lower ribs, possibly the posterior fibres of the external oblique also helping to fix the lower ribs. (*b*) *Extraordinary inspiration:* The superior extremities are raised and fixed. The cervical part of the vertebral column and the head are extended, and in addition to the muscles of ordinary inspiration, the following muscles also come into play: The pectoralis minor, the muscles which extend the head and the cervical part of the vertebral column, the sterno-mastoid and the supra- and infra-hyoid muscles, the lower fibres of the pectoralis major, some of the lower fibres of the serratus anterior, and, when the clavicle is fixed, the subclavius.

Expiration is produced by the elasticity of the lungs and the weight of the thorax, aided by the elastic reaction and contraction of the external and internal oblique muscles, the recti and pyramidales, the transversus abdominis, and the levatores ani and coccygei. In forcible expiration all muscles which depress the ribs and reduce the dimensions of the abdomen are thrown into action. The internal intercostals probably tend to contract the thorax, excepting the parts between the costal cartilages, which tend to expand the thorax.

THE ARTICULATIONS OF THE UPPER EXTREMITY

The articulations of the upper extremity are the following:—

1. The **sterno-costo-clavicular.**
2. The **scapulo-clavicular union.**
3. The **shoulder-joint.**
4. The **elbow-joint.**
5. The **radio-ulnar union.**
6. The **radio-carpal** or **wrist-joint.**
7. The **carpal joints.**
8. The **carpo-metacarpal joints.**
9. The **intermetacarpal joints.**
10. The **metacarpo-phalangeal joints.**
11. The **interphalangeal joints.**

1. THE STERNO-COSTO-CLAVICULAR ARTICULATION

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

At this joint the large medial end of the clavicle is united to the superior angle of the manubrium sterni, the first costal cartilage also assisting to support the clavicle. It is the only joint between the upper extremity and the trunk, and takes part in all the movements of the upper limb. Looking at the bones, one would say that they were in no way adapted to articulate with one another, and yet they assist in constructing a joint of security, strength, and importance. The bones are nowhere in actual contact, being completely separated by an articular disc. The interval between the joints of the two sides varies from one inch to an inch and a half (2.5–4 cm.). The ligaments of this joint are:—

(1) Articular capsule.
(2) Interclavicular.
(3) Articular disc.
(4) Costo-clavicular.

The **articular capsule** (fig. 284) consists of fibres, having varying directions and being of various strength and thickness, which completely surround the articulation, and are firmly connected with the edges of the interarticular fibro-cartilage.

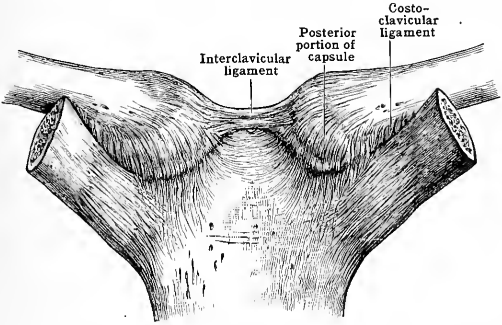
The fibres at the back of the joint, sometimes styled the **posterior sterno-clavicular ligament,** are stronger than those in front or below, and consist of two sets: a superficial, passing upward and laterally from the manubrium sterni, to the projecting posterior edge of the end of the clavicle, a few being prolonged onward upon the posterior surface of the bone. A deeper set of fibres, especially thick and numerous below the clavicle, connect the interarticular cartilage with the clavicle and with the sternum, but do not extend from one bone to the other. The fibres in front, the **anterior sterno-clavicular ligament,** are well marked, but more lax and less tough than the posterior, and are overlaid by the tendinous sternal origin of the *sterno-mastoid,* the fibres of which run parallel to those of the ligament. They extend obliquely upward and laterally from the margin of the sternal facet to the anterior surface of the clavicle some little distance from the articular margin. The fibres which cover in the joint **below** are short, woolly, and consist more of fibro-areolar tissue than true fibrous tissue; they extend from the upper border of the first costal cartilage to the lower border of the clavicle just lateral to the articular margin, and fill up the gap between it and the costo-clavicular ligament. The **superior portion** consists of short tough fibres passing from the sternum to the articular disc; and of others welding the fibro-cartilage to the upper edge of the clavicle, only a few of them passing from the clavicle direct to the sternum.

The **interclavicular ligament** (fig. 284) is a strong, concave band, materially strengthening the superior portion of the capsule. It is nearly a quarter of an inch (6 mm.) deep with the concavity upward, its upper border tapering to a narrow, almost sharp edge. It is connected with the posterior superior angle of the sternal extremity of each clavicle, and with the fibres which weld the inter-articular cartilage to the clavicle; and then passes across from clavicle to clavicle along the posterior aspect of the upper border of the manubrium sterni. The lowest fibres are attached to the sternum, and join the posterior fibres of the capsule of each joint. In the middle line, between the ligament and the sternum, there is an aperture for the passage of a small artery and vein.

In addition to the interclavicular ligament Mr. Carwardine ("Journal of Anatomy and Physiology," vol. 7, new series, p. 232) has described a special band of the upper portion of the sterno-clavicular capsule which he proposes to name the 'suprasternal ligament.' It descends from the upper border of the sternal end of the clavicle to the upper border of the sternum, and is of special importance as it encloses the suprasternal bones, when these rudiments are present.

The **costo-clavicular** or rhomboid **ligament** (fig. 284) is a strong dense band, composed of fine fibres massed together into a membranous structure. It extends from the upper (medial) border of the first costal cartilage (and rib),

FIG. 284.—POSTERIOR VIEW OF THE STERNO-COSTO-CLAVICULAR JOINT.



upward, backward, and distinctly laterally to the costal tuberosity on the under surface of the medial extremity of the clavicle, to which it is attached just lateral to the lower part of the capsule. Frequently some of the lateral fibres pass upward and medially behind the rest, and give the appearance of decussating. It is from half to three-quarters of an inch (1.5–2 cm.) broad.

The **articular disc** (fig. 285) is a flattened disc of nearly the same size and outline as the medial articular end of the clavicle, which it fairly accurately fits. It is attached above to the upper border of the posterior edge of the clavicle; and below to the cartilage of the first rib at its union with the sternum, where it assists in forming the socket for the clavicle. At its circumference it is connected with the articular capsule, and this connection is very strong behind, and still stronger above, where it is blended with the interclavicular ligament.

It is usually thinnest below, where it is connected with the costal cartilage. It varies in thickness in different parts, sometimes being thinner in the centre than at the circumference sometimes the reverse, and is occasionally perforated in the centre. It divides the joint into two compartments.

There are two **synovial membranes** (fig. 285); a lateral one, which is reflected from the clavicle and capsule over the lateral aspect of the disc and is looser than the medial one; the medial is reflected from the sternum over the medial side of the articular disc, costal cartilage, and capsule. Occasionally a communication takes place between them.

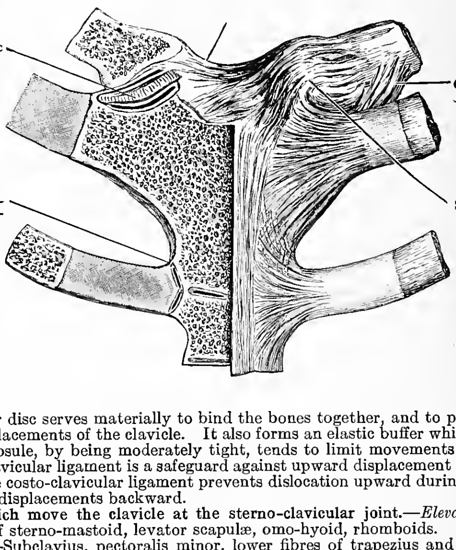
The **arterial supply** is derived from branches—(1) from the internal mammary; (2) from the superior thoracic branch of the axillary; (3) twigs of a muscular branch often arising from the subclavian artery pass over the interclavicular notch; (4) twigs of the transverse scapular (suprascapular) artery.

The **nerve-supply** is derived from the nerve to the *subclavius* and sternal descending branch of the cervical plexus.

Relations.—In front of the joint is the sternal head of the sterno-mastoid. Behind it are the sterno-hyoid and sterno-thyreoid muscles. Still further back, on the right side, are the innominate and internal mammary arteries, and, on the left side, the left common carotid, the left subclavian, and the internal mammary arteries. Above and behind, between the sterno-mastoid and sterno-hyoid muscles, the anterior jugular vein passes back and laterally toward the posterior triangle.

The movements permitted at this joint are various though limited, owing to the capsular ligament being moderately tense in every position of the clavicle. Motion takes place in nearly every direction—viz., upward, downward, forward, backward, and in a circumductory manner. The upward and downward motions occur between the clavicle and the articular disc; during elevation of the arm the upper edge of the clavicle with its attached articular disc is pressed into the sternal socket, and the lower edge glides away from the disc; during depression of the limb, the lower edge of the clavicle presses on to the disc, while the rest of the articular surface of the clavicle inclines laterally, bringing with it to a slight degree the upper edge of the articular disc. These movements occur on an antero-posterior axis drawn through the outer compartment of the joint. The forward and backward motions take place between the articular disc and sternum, the clavicle with the disc gliding backward upon the sternum when the shoulder is brought forward, and forward when the shoulder is forced backward; these movements occur round an axis drawn nearly vertically through the sternal socket.

Fig. 285.—Anterior View of Sterno-costo-clavicular Joint, with Section showing Cavities opened on the Right Side.



The articular disc serves materially to bind the bones together, and to prevent the media and upward displacements of the clavicle. It also forms an elastic buffer which tends to break shocks. The capsule, by being moderately tight, tends to limit movements in all directions, while the interclavicular ligament is a safeguard against upward displacement during depression of the arm. The costo-clavicular ligament prevents dislocation upward during elevation of the arm, and resists displacements backward.

Muscles which move the clavicle at the sterno-clavicular joint.—*Elevators.*—Trapezius, clavicular part of sterno-mastoid, levator scapulæ, omo-hyoid, rhomboids.

Depressors.—Subclavius, pectoralis minor, lower fibres of trapezius and serratus anterior (magnus). Depression is aided by the weight of the upper extremity.

Protractors.—Pectoralis major and minor. Serratus anterior (magnus).

Retractors.—Latissimus dorsi, trapezius.

2. THE SCAPULO-CLAVICULAR UNION

The scapula is connected with the clavicle by a synovial joint with its ligaments at the acromio-clavicular articulation; and also by a set of ligaments passing between the coracoid process and the clavicle. So that we have to consider—

(*a*) The **acromio-clavicular articulation.**
(*b*) The **coraco-clavicular ligaments.**
(*c*) The **proper scapular ligaments** are also best described in this section—viz., the **coraco-acromial** and **transverse.**

(*a*) The Acromio-clavicular Joint

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The acromio-clavicular joint is surrounded by an articular capsule and frequently contains an articular disc.

The **articular capsule** (figs. 287 and 290) completely surrounds the articular margins, and is composed of strong, coarse fibres arranged in parallel fasciculi, of fairly uniform thickness, which are attached to the borders as well as the surfaces of the bones. It is somewhat lax in all positions of the joint, so that the clavicle is not tightly braced to the acromion. The fibres extend three-quarters of an inch (2 cm.) along the clavicle posteriorly, but only a quarter of an inch (6 mm.) anteriorly. Superiorly, they are attached to an oblique line joining these two points, while inferiorly they reach to the ridge for the trapezoid ligament with which they blend.

At the acromion they extend half way across the upper and lower surfaces, but at the anterior and posterior limits of the joint they are attached close to the articular facet. The anterior fibres become blended with the insertion of the coraco-acromial ligament. The fibres are strengthened above by the aponeuroses of the *trapezius* and *deltoid* muscles; and all run from the acromion to the clavicle medially and backward.

The **articular disc** is occasionally present, but is usually imperfect, only occupying the upper part of the joint; it may completely divide the joint into two cavities, or be perforated in the centre. It is usually thicker at the edge than in the centre, and some of the fibres of the articular capsule are blended with its edges.

The **synovial membrane** lining the joint is occasionally either partially or entirely divided into two by the articular disc.

Relations.—Superiorly skin and fascia and the tendinous intersection between the deltoid and the trapezius. Inferiorly, the coraco-acromial ligament and supraspinatus. Anteriorly, part of the origin of the deltoid. Posteriorly, part of the insertion of the trapezius.

Movements.—A certain amount of gliding movement occurs at this joint, but the most important movement is a rotation of the scapula whereby the glenoid cavity is turned forward and upward, or downward. As these movements occur the inferior angle of the scapula moves forward as the glenoid cavity turns upward and the superior angle recedes.

The forward movement of the inferior angle is produced mainly by the inferior fibres of the serratus anterior (magnus), aided by the inferior fibres of the trapezius, and it is by this movement that the arm is raised above the level of the shoulder forward.

The reverse movement is produced mainly by the rhomboideus major aided by the latissimus dorsi.

(*b*) The Coraco-clavicular Union

The **coraco-clavicular ligament** (figs. 286, 287, and 290) consists of two parts, the conoid and the trapezoid ligaments.

The **conoid ligament** is the medial and posterior portion, and passes upward and laterally from the coracoid process to the clavicle.

It is a very strong and coarsely fasciculated band of triangular shape, the apex being fixed to the medial and posterior edge of the root of the coracoid process just in front of the scapular notch, some fibres joining the transverse ligament. Its base is at the clavicle, where it widens out, to be attached to the posterior edge of the inferior surface, as well as to the coracoid tubercle. It is easily separated from the trapezoid, without being absolutely distinct. A small bursa often exists between it and the coracoid process; medially, some of the fibres of the *subclavius* muscle are often attached to it.

The **trapezoid ligament** is the anterior and lateral portion of the coraco-clavicular ligament. It is a strong, flat, quadrilateral plane of closely woven fibres, the surfaces of which look upward and medially toward the clavicle, and downward and laterally over the upper surface of the coracoid process.

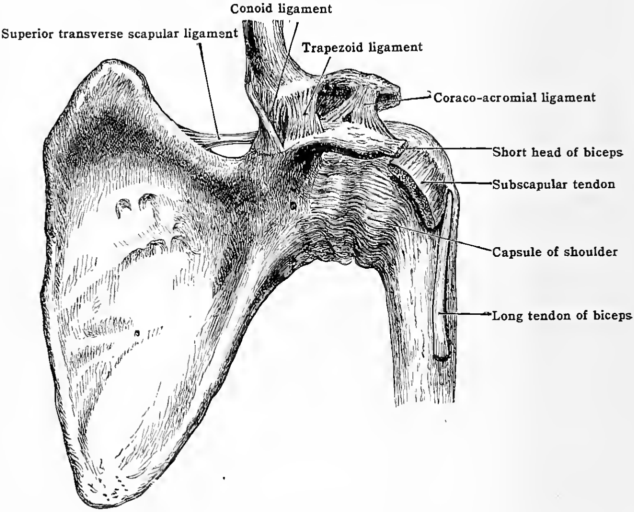
At the coracoid it is attached for about an inch (2.5 cm.) to a rough ridge which runs forward from the angle, along the anterior border of the process. At the clavicle it is attached to the oblique ridge which runs laterally and forward from the coracoid tubercle, reaching as far as, and blending with the inferior part of the acromio-clavicular ligament. Its anterior edge is free, and overlies the coraco-acromial ligament; the posterior edge is shorter than the anterior, and is in contact with the posterior and lateral portion of the conoid ligament.

The **arterial supply** is derived from the transverse scapular (suprascapular), acromial branches of the thoraco-acromial, and the anterior circumflex.

The **nerve-supply** is derived from the suprascapular and axillary (circumflex) nerves.

Movements.—In the movements of the shoulder girdle, the scapula moves upon the lateral end of the clavicle, and the clavicle, in turn, carried by the uniting ligaments, moves upon the sternum; so that the entire scapula moves in the arc of a circle whose centre is at the sterno-clavicular joint, and whose radius is the clavicle. The scapula, in moving upon the clavicle, also moves upon the thorax forward and backward, upward and downward, and also in a rotatory direction upon an axis drawn at right angles to the centre of the bone. Throughout these movements the inferior angle and base of the scapula are kept in contact with the ribs by the

Fig. 286.—Anterior View of Shoulder, showing also Coraco-clavicular and Coraco-acromial Ligaments.



latissimus dorsi, which straps down the former, and the *rhomboids* and *serratus anterior* (*magnus*), which brace down the latter. The glenoid cavity could not have preserved its obliquely forward direction had there been no acromio-clavicular joint, but would have shifted round a vertical axis, and thus the shoulder would have pointed medialward when the scapula was advanced, and lateralward when it was drawn backward. By means of the acromio-clavicular joint, the scapula can be forcibly advanced upon the thorax, the glenoid cavity all the time keeping its face duly forward. Thus the muscles of the shoulder and forearm can be with advantage combined, as, for example, in giving a direct blow. The acromio-clavicular joint also permits the lower angle of the scapula to be retained in contact with the chest wall during the rising and falling of the shoulder, the scapula turning in a hinge-like manner round the horizontal axis of the joint.

There are no actions in which the scapula moves on a fixed clavicle, or the clavicle on a fixed scapula; the two bones, bound together by their connecting ligament, must move in unison.

(c) The Proper Scapular Ligaments

There are three proper ligaments of the scapula, which pass between different portions of the bone, viz.—

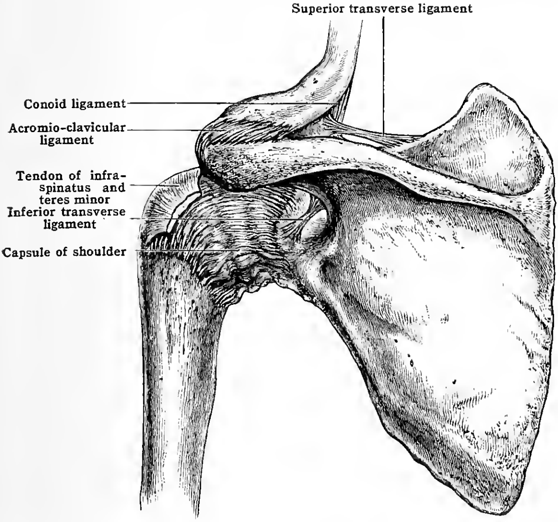
Coraco-acromial. Superior transverse.
Inferior transverse.

The **coraco-acromial ligament** (figs. 286 and 290) is a flat, triangular band with a broad base, attached to the lateral border of the coracoid process, and a blunt apex which is fixed to the tip of the acromion. It is made up of two broad marginal bands, and a smaller and thinner intervening portion. The **anterior band,** which arises from the anterior portion of the coracoid process, is the stronger, and some of its marginal fibres can often be traced into the short head of the biceps, which can then make tense this edge of the ligament. The **posterior band,** coming from the posterior part of the coracoid process, is also strong.

The intermediate part, of variable extent, is thin and membranous, containing but few ligamentous fibres; it is often incomplete near the coracoid process, leaving a small gap (fig. 286).

The superior surface of the ligament looks upward and a little forward, and is covered by the *deltoid* muscle; the inferior looks downward and a little backward, and is separated from the capsule of the shoulder-joint by a bursa and the tendons of the *supraspinatus* and *subscapularis* muscles. At the coracoid process it overlies the coraco-humeral ligament. It is barely one-third of an inch (8 mm.) above the capsule of the shoulder, and in the undissected state there is scarcely a quarter of an inch (6 mm.) interval. The anterior band projects over the centre of the head of the humerus, and is continued into a tough fascia under the deltoid; the posterior band is continuous with the fascia over the supraspinatus muscle. It binds the

FIG. 287.—POSTERIOR VIEW OF THE SHOULDER-JOINT, SHOWING ALSO THE ACROMIO-CLAVICULAR JOINT AND THE SPECIAL LIGAMENTS OF THE SCAPULA.



two processes firmly together, and so strengthens each; it holds the deltoid off the capsule of the shoulder, and protects the joint from slight injuries directed downward and backward against it.

The **superior transverse** (coracoid, or suprascapular) **ligament** (figs. 286, 287, and 288) is a small triangular band of fibrous tissue, the surfaces of which look forward and backward; and its edges, which are thin and sharp, are turned upward and downward. It continues the superior border of the scapula, bridging over the scapular notch.

It is broader medially, where it springs from the upper border of the scapula on its dorsal surface; and narrow laterally, where it is attached to the base of the coracoid process; some of its fibres are inserted under the edge of the trapezoid ligament, and others pass upward with the conoid to reach the clavicle. The *transverse scapular* (*suprascapular*) *artery* passes over it, and the *suprascapular nerve* beneath it. Medially, some fibres of the *omo-hyoid* muscle arise from it.

The **inferior transverse** (spino-glenoid) **ligament** (fig. 287) reaches from the lateral border of the spine of the scapula to the margin of the glenoid cavity, and so forms a foramen under which the *transverse scapular* (*suprascapular*) *vessels* and *suprascapular nerve* gain the infraspinous fossa. It is usually a weak membranous structure with but few ligamentous fibres.

3. THE SHOULDER-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Enarthrodia.*

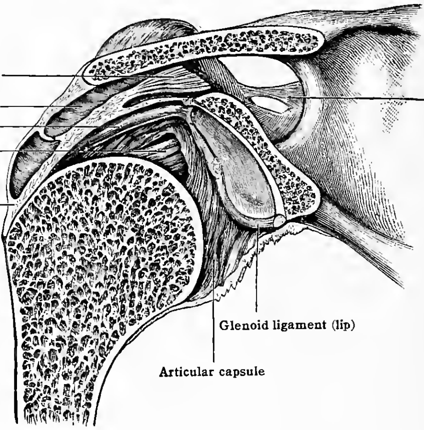
The shoulder [articulatio humeri] is one of the most perfect and most movable of joints, the large upper end of the humerus playing upon the shallow glenoid cavity. Like the hip, it is a ball-and-socket joint. It is retained in position much less by ligaments than by muscles, and, owing to the looseness of its capsule, as well as to all the other conditions of its construction and position, it is exceedingly liable to be displaced; on the other hand, it is sheltered from violence by the two projecting processes—the acromion and coracoid.

The ligaments of the shoulder-joint are:—

Articular capsule.	Coraco-humeral.
Gleno-humeral.	Glenoid:

The **articular capsule** (figs. 286, 287, and 288) is a loose sac, insufficient in itself to maintain the bones in contact. It consists of fairly distinct but not coarse fibres, closely woven together, and directed, some straight, others obliquely, between the two bones, a few circular ones being interwoven amongst them. At the scapula, it is fixed on the dorsal aspect to the prominent rough

FIG. 288.—VERTICAL SECTION THROUGH THE SHOULDER-JOINT TO SHOW THE GLENO-HUMERAL LIGAMENT.
(The joint is opened from behind.)



surface around the margin of the glenoid cavity, reaching as far as the neck of the bone. Superiorly, it is attached to the root of the coracoid process; anteriorly, to the ventral surface, at a variable distance from the articular margin, often reaching half an inch (12 mm.) upon the neck of the bone, and thus allowing the formation of a pouch; it may not, however, extend for more than a quarter of an inch (6 mm.) beyond the articular margin; inferiorly, it blends with the origin of the long head of the triceps. At the humerus, the superior half is fixed to the anatomical neck, sending a prolongation downward between the two tuberosities which attenuates as it descends, and covers the transverse humeral ligament. The lower half of the capsule descends upon the humerus further from the articular margin, some of the deeper fibres being reflected upward so as to be attached close to the articular edge, thus forming a kind of fibrous investment for the neck of the humerus. This ligament is more uniform in thickness than that of the hip.

Gleno-humeral bands of the capsule (figs. 288 and 289).—There are three accessory bands, known as the *superior, middle* and *inferior gleno-humeral bands,* which project toward the interior of the joint from the fore part of the capsule and are consequently best seen when the joint is opened from behind.

The **middle** band reaches from the anterior margin of the glenoid cavity along the lower border of the subscapularis tendon to the lower border of the lesser tuberosity, and the **inferior** band from the inferior part of the glenoid cavity to the inferior part of the neck of the humerus.

The superior band, known also as the gleno-humeral ligament, runs from the edge of the glenoid cavity at the root of the coracoid process, just medial to the origin of the long tendon of the biceps, and, passing laterally and downward at an acute angle to the tendon, for which it forms a slight groove or sulcus, is fixed to a depression, the fovea capitis humeri, above the lesser tuberosity of the humerus. It is a thin, ribbon-like band, of which the superior surface is attached to the capsule, while the inferior is free and turned toward the joint. In the fœtus it is often, and in the adult occasionally, quite free from the capsule, and may be as thick as the long tendon of the biceps (fig. 289).

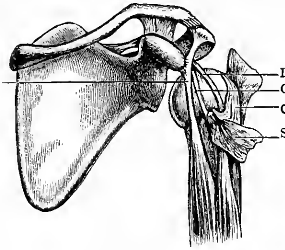
The tendons of the *supra-* and *infra-spinatus, teres minor*, and *subscapularis* muscles strengthen and support the capsule, especially near their points of insertion, and can be with difficulty dissected off from it. The long head of the *triceps* supports and strengthens the capsule below. The capsule also receives an upward slip from the *pectoralis major*. The *supraspinatus* often sends a slip into the capsule from its upper edge (fig. 288).

The **coraco-humeral ligament** (fig. 290) is a strong broad band, which is attached above to the lateral edge of the root and horizontal limb of the coracoid process nearly as far as the tip. From this origin it is directed backward along the line of the biceps tendon to blend with the capsule, and is inserted into the greater tuberosity of the humerus.

Seen from the back, it looks like an uninterrupted continuation of the capsule, while from the front it looks like a fan-shaped prolongation from it overlying the rest of the ligament. At its origin there is sometimes a bursa between it and the capsule.

The **glenoid ligament** or **lip** [labrum glenoidale] (figs. 288 and 292) is a narrow rim of dense fibro-cartilage, which surrounds the edge of the glenoid socket and deepens it. It is about a quarter of an inch (6 mm.) wide above and below, but less at its sides. Its peripheral edge is inseparably welded, near the bone, with

Fig. 289.—Fœtal Shoulder-joint, showing the Gleno-humeral Ligament, and also the Short Head of the Biceps, being continuous with the Coraco-acromial Ligament.



the articular capsule. Its structure is almost entirely fibrous, with but few cartilage cells intermixed. At the upper part of the fossa the **biceps tendon** is prolonged into the glenoid ligament, the tendon usually dividing and sending fibres right and left into the ligament, which may wind round nearly the whole circumference of the socket. It may, however, send fibres into one side only, usually into the lateral.

The **articular cartilage** covering the glenoid fossa is thicker at the circumference than in the centre, thus tending to deepen the cavity. It is usually thickest at the lower part of the fossa; over the head of the humerus the cartilage is thickest at and below the centre.

The **synovial membrane** lines the glenoid ligament, and is then reflected over the capsule as far as its attachment to the humerus, from which it ascends as far as the edge of the articular cartilage. The tendon of the *biceps* receives a long tubular sheath, which is continuous with the synovial membrane, both at its attached extremity and at the bicipital groove, but is free in the rest of its extent. The synovial cavity almost always communicates with the bursa under the *subscapularis*, and sometimes with one under the infraspinatus muscle.

It also sends a pouch-like prolongation beneath the coracoid process when the fibrous capsule is attached wide of the margin of the glenoid fossa. A few fringes are seen near the edge of the glenoid cavity, and there is often one which runs down the medial edge of the biceps tendon, extending slightly below it and making a slight groove for the tendon to lie in.

The **transverse humeral ligament** (fig. 290) is so closely connected with the capsule of the shoulder that, although it is a proper ligament of the humerus, it may well be described here. It is a strong band of fibrous tissue, which extends

Fig. 290.—Lateral View of the Shoulder-joint, showing the Coraco-humeral and Transverse Humeral Ligaments.

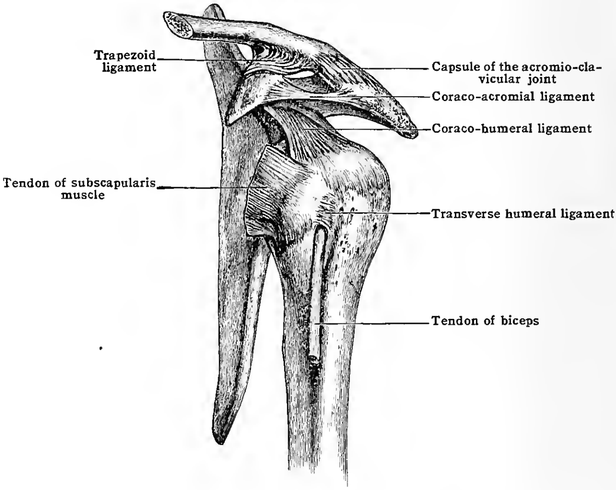


Fig. 291.—The Upper Extremity of the Humerus, Anterior View, to Show the Relation of the Articular Capsule of the Shoulder-joint (in red) to the Epiphysial Line.

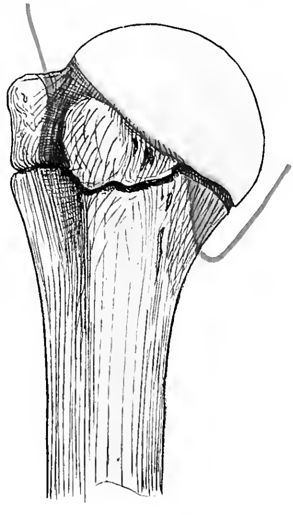


between the two tuberosities, roofing in the intertubercular (bicipital) groove. It is covered by a thin expansion of the capsule. It is limited to the portion of the bone above the line of the epiphysis.

Relations.—The following muscles are in contact with the capsule of the shoulder-joint. In front, the subscapularis; above, the supraspinatus; above and behind, the infraspinatus; behind, the teres minor; below, the long head of the triceps and the teres major. In the interval between the subscapularis and the supraspinatus the subacromial bursa is close to the capsule and occasionally its cavity communicates with the cavity of the joint.

The axillary (circumflex) nerve and posterior circumflex artery pass beneath the capsule in the interval between the long head of the triceps, the humerus, and the teres major. When the arm is abducted, the long head of the triceps and the teres major are drawn into closer relation with the capsule and help to prevent dislocation of the humerus.

The axillary vessels, the great nerves of the axilla, the short head of the biceps, and the coraco-brachialis are separated from the joint by the subscapularis, whilst the deltoid forms a kind of cap, which extends from the front to the back over the more immediate relations.

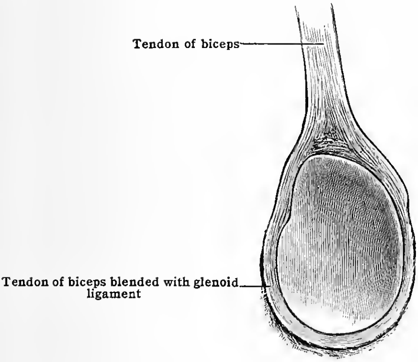
The **arterial supply** is derived from the transverse scapular (suprascapular), anterior and posterior circumflex, subscapular, circumflex scapular (dorsalis scapulæ), and a branch from the second portion of the axillary artery.

The **nerve-supply** is derived from the suprascapular, by branches in both fossæ; and from the axillary (circumflex) and subscapular nerves.

The **movements** of the shoulder-joint consist of flexion, extension, adduction, abduction, rotation and circumduction.

Flexion is the swinging forward, extension the swinging backward, of the humerus; abduction is the raising of the arm from, and adduction depression of the arm to, the side. In flexion and extension the head of the humerus moves upon the centre of the glenoid fossa round an

FIG. 292.—BICEPS TENDON, BIFURCATING AND BLENDING ON EACH SIDE WITH THE GLENOID LIGAMENT.



oblique line corresponding to the axis of the head and neck of the humerus, flexion being more free than extension, and in extreme flexion the scapula follows the head of the humerus, so as to keep the articular surfaces in apposition. In extension the scapula moves much less, if at all.

In abduction and adduction the scapula is fixed, and the humerus rolls up and down upon the glenoid fossa; during abduction the head descends until it projects beyond the lower edge of the glenoid cavity, and the greater tuberosity impinges against the arch of the acromion; during adduction, the head of the humerus ascends in its socket, the arm at length reaches the side, and the capsule is completely relaxed.

In circumduction, the humerus, by passing quickly through these movements, describes a cone, whose apex is at the shoulder-joint, and the base at the distal extremity of the bone or limb.

Rotation takes place round a vertical axis drawn through the extremities of the humerus from the centre of the head to the inner condyle; in rotation forward (that is, medialward) the head of the bone rolls back in the socket as the great tuberosity and shaft are turned forward; in rotation backward (that is, lateralward) the head of the bone glides forward, and the tuberosity and shaft of the humerus are turned backward, i. e., lateralward.

Great freedom of movement is permitted at the shoulder, and this is increased by the mobility of the scapula. Restraint is scarcely exercised at all upon the movements of the shoulder by the ligaments, but chiefly by the muscles of the joint.

In abduction, the lower part of the capsule is somewhat, and in extreme abduction considerably, tightened; and in rotation medialward and lateralward, the upper part of the capsule is made tense, as is also, in the latter movement, the coraco-humeral ligament.

The movements of abduction and extension have a most decided and definite resistance offered to them other than by muscles and ligaments, for the greater tuberosity of the humerus, by striking against the acromion process and coraco-acromial ligament, stops short any further advance of the bone in these directions, and thus abduction ceases altogether as soon as the arm is raised to a right angle with the trunk, and extension shortly after the humerus passes the line of the trunk.

Further elevation of the arm beyond the right angle, in the abducted or extended position, is effected by the rotation of the scapula round its own axis by the action of the trapezius and serratus anterior muscles upon the sterno-clavicular and acromio-clavicular joints respectively.

The acromion and coracoid process, together with the coraco-acromial ligament, form an arch, which is separated by a bursa and the tendon of the *supraspinatus* from the capsule of the shoulder. Beneath this arch the movements of the joint take place, and against it the head and tuberosities are pressed when the weight of the trunk is supported by the arms; the greater tuberosity and the upper part of the shaft impinge upon it when abduction and extension are carried to their fullest extent.

No description of the shoulder-joint would be complete without a short notice of the peculiar relation which the biceps tendon bears to the joint. It passes over the head of the humerus a little to the medial side of its summit, and lies free within the capsule, surrounded only by a tubular process of synovial membrane. It is flat, with the surfaces looking upward and downward, until it reaches the intertubercular (bicipital) groove, when it assumes a rounded form. It strengthens the articulation along the same course as the coraco-humeral ligament, and tends to prevent the head of the humerus from being pulled upward too forcibly against the inferior surface of the acromion. It also serves the purpose of a ligament by steadying the head of the humerus in various movements of the arm and forearm, and to this end is let into a groove at the upper end of the bone, from which it cannot escape on account of the abutting tuberosities and the strong transverse humeral ligament which binds it down. Further, it acts like the four shoulder muscles which pass over the capsule, to keep the head of the humerus against the glenoid socket; and, moreover, it resists the tendency of the *pectoralis major* and *latissimus dorsi* muscles, in certain actions when the arm is away from the side of the body, to pull the head of the humerus below the lower edge of the cavity.

Muscles which act upon the shoulder-joint.—*Flexors or protractors.*—Deltoid (anterior fibres), pectoralis major (clavicular fibres), coraco-brachialis, biceps (short head), subscapularis (upper fibres).

Extensors or retractors.—Latissimus dorsi, deltoid (posterior fibres), teres major, teres minor, infraspinatus (lower fibres).

Abductors.—Deltoid, supraspinatus, biceps (long head).

Adductors.—Pectoralis major, latissimus dorsi, subscapularis, infraspinatus, teres major, teres minor, coraco-brachialis, biceps (short head), triceps (lower head).

Medial rotators.—Pectoralis major, latissimus dorsi, teres major, subscapularis, deltoid (anterior fibres).

Lateral rotators.—Deltoid (posterior fibres), infraspinatus, teres minor.

Circumductors.—The above groups acting consecutively.

4. THE ELBOW-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

The elbow [articulatio cubiti] is a complete hinge, and, unlike the knee, depends for its security and strength upon the configuration of its bones rather than on the number, strength, or arrangement of its ligaments. The bones composing it are the lower end of the humerus above, and the upper ends of the radius and ulna below; the articular surface of the humerus being received partly within the semilunar notch (great sigmoid cavity) of the ulna, and partly upon the cup-shaped area (fovea) of the radial head. The ligaments form one large and capacious capsule [capsula articularis], which, by blending with the annular ligament, and then passing on to be attached to the neck of the radius, embraces the elbow and the superior radio-ulnar joints, uniting them into one. Laterally, it is considerably strengthened by superadded fibres arising from the epicondyles of the humerus and inseparably connected with the capsule. For convenience of description it will be spoken of as consisting of four portions:—

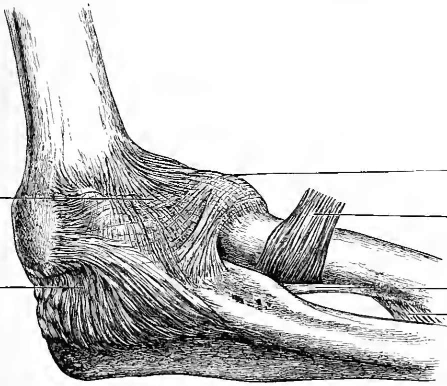
Anterior.	Medial.
Posterior.	Lateral.

The **anterior portion** (fig. 293) is attached to the front of the humerus above the articular surface and coronoid fossa, in an inverted **V**-shaped manner, to two very faintly marked ridges which start from the front of the medial and lateral epicondyles, and meet a variable distance above the coronoid fossa. Below, it is fixed, just beyond the articular margin, to the front of the coronoid process and it is intimately blended with the front of the annular ligament, a few fibres passing on to the neck of the radius.

It varies in strength and thickness, being sometimes so thin as barely to cover the synovial membrane; at others, thick and strong, and formed of coarse decussating fibres, the majority of which descend from the medial side laterally to the radius.

The **posterior portion** (fig. 294), thin and membranous, is attached superiorly to the humerus, in much the same inverted **V**-shaped way as the anterior; ascending from the medial epicondyle, along the medial side of the olecranon fossa nearly to the top; then, crossing the bottom of the fossa, it descends on the lateral side, skirting the lateral margin of the trochlear surface, and turns laterally along the posterior edge of the capitulum. Inferiorly, it is attached to a slight groove

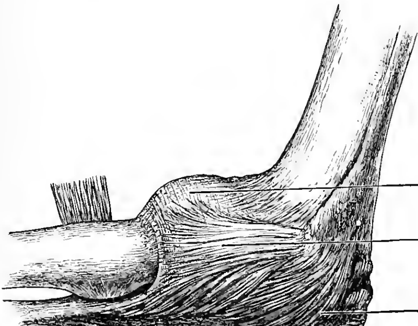
Fig. 293.—Medial View of the Elbow-joint.



along the superior and lateral surfaces of the olecranon, and the rough surface of the ulna just beyond the radial notch, and to the annular ligament, a few fibres passing on to the neck of the radius.

It is composed of decussating fibres, most of which pass vertically or obliquely downward, a few taking a transverse course at the summit of the olecranon fossa where the ligament is usually thinnest.

Fig. 294.—Lateral View of the Elbow-joint.



The **medial portion,** the **ulnar collateral ligament** (fig. 293), is thicker, stronger, and denser than either the anterior or posterior portions. It is triangular in form, its apex being attached to the anterior and under aspect of the medial epicondyle, and to the condyloid edge of the groove between the trochlea and the condyle. The fibres radiate downward from this attachment, the anterior passing forward to be fixed to the rough overhanging medial edge of the coronoid process; the middle descend less obliquely to a ridge running between the coronoid and olecranon processes, while the posterior pass obliquely backward to the medial edge of the olecranon just beyond the articular margin.

Fig. 295.—Lower Extremity of the Humerus, to show the Relation of the Articular Capsule of the Elbow-joint (in red) to the Epiphysial Lines.

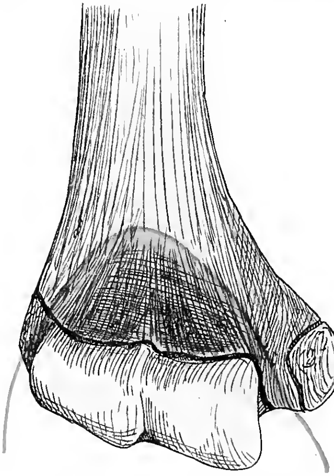


Fig. 296.—The Upper Extremity of the Ulna, to show the Relation of the Articular Capsule of the Elbow-joint (in red) to the Epiphysial Lines.

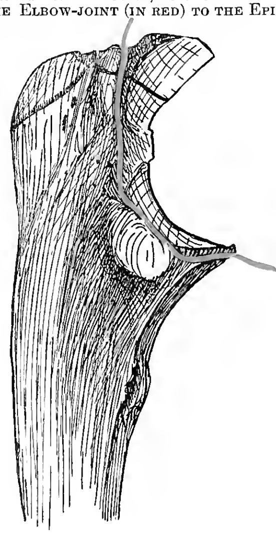


An oblique band (the oblique ligament of Sir Astley Cooper) connects the margin of the olecranon process with the margin of the coronoid process. It lies superficial to the posterior fibres of the ulnar collateral ligament. The anterior fibres are the thickest, strongest, and most pronounced.

The **lateral portion**, the **radial collateral ligament** (fig. 294), is attached above to the lower part of the lateral epicondyle, and from this the fibres radiate to their attachment into the lateral side of the annular ligament, a few fibres being prolonged to reach the neck of the radius. The anterior fibres reach further forward than the posterior do behind. It is strong and well-marked, but less so than the medial portion.

The **synovial membrane** lines the whole of the capsule, and extends into the superior radio-ulnar joint, lining the annular ligament.

Outside the synovial membrane, but inside the capsule, are often seen some pads of fatty tissue; one is situated on the medial side at the base of the olecranon, another is seen on the lateral side projecting into the cavity between the radius and ulna; this latter, with a fold of synovial membrane opposite the front of the lateral lip of the trochlea, suggests the division of the joint into two parts—one medially for the ulna, and another laterally for the radius. There are also pads of fatty tissue at the bottom of the olecranon and coronoid fossæ, and at the tip of the olecranon process.

The **arterial supply** is derived from each of the vessels forming the free anastomosis around the elbow, and there is also a special branch to the front and lateral side of the joint, from the brachial artery, and the arterial branch to the *brachialis* also feeds the front of the joint.

The **nerve-supply** comes chiefly from the musculo-cutaneous; the ulnar, median, and radial (musculo-spiral) also give filaments to the joint.

Relations.—In front of the joint, and in immediate relation with the capsule, are the brachialis, the superficial and deep branches of the radial (musculo-spiral) nerve, the radial recurrent artery, and the brachio-radialis. The brachial artery, the median nerve, and the pronator teres are separated from the capsule by the brachialis. Directly behind the capsule are the triceps, the anconeus, and the posterior interosseous recurrent artery. On the medial side are the ulnar nerve, the superior ulnar collateral (posterior ulnar recurrent) artery, and the upper parts of the flexor carpi ulnaris and flexor digitorum sublimis. On the lateral side lie the extensor carpi radialis longus and the upper part of the common tendon of origin of the superficial extensors of the wrist and fingers.

The **movements** permitted at the elbow are those of a true hinge joint, viz., flexion and extension. These movements are oblique, so that the forearm is inclined medially in flexion, and laterally in extension; they are limited by the contact respectively of the coronoid and olecranon processes of the ulna with their corresponding fossæ on the humerus, and their extent is determined by the relative proportion between the length of the processes and depth of the fossæ which receive them, rather than by the tension of the ligaments, or the bulk of the soft parts over them. The anterior and posterior portions of the capsule, together with the corresponding portions of the collateral ligament, are not put on the stretch during flexion and extension; but, although they may assist in checking the velocity, and thus prevent undue force of impact, they do not control or determine the extent of these movements. The limit of extension is reached when the ulna is nearly in a straight line with the humerus; and the limit of flexion when the ulna describes an angle of from 30° to 40° with the humerus.

The obliquity of these movements is due to the lateral inclination of the upper and back part of the trochlear surface, and the greater prominence of the medial lip of the trochlea below; thus the plane of motion is directed from behind forward and medially, and carries the hand toward the middle third of the clavicle. The obliquity of the joint, the twist of the shaft of the humerus, and the backward direction of its head, all tend to bring the hand toward the midline of the body, under the immediate observation of the eye, whether for defence, employment, or nourishment. This is in striking contrast to the lower limb, where the direction of the foot diverges from the median axis of the trunk, thus preventing awkwardness in locomotion. In flexion and extension, the cup-like depression of the radial head glides upon the capitulum, and the medial margin of the radial head travels in the groove between the capitulum and the trochlea. This allows the radius to rotate upon the humerus while following the ulna in all its movements. In full extension and supination, the head of the radius is barely in contact with the inferior surface of the capitulum, and projects so much backward that its posterior margin can be felt as a prominence at the back of the elbow. In full flexion the anterior edge of the radial head is received into, and checked against, the depression above the capitulum; while in mid-flexion the cup-like depression is fairly received upon the capitulum, and in this position, the radius being more completely steadied by the humerus than in any other, pronation and supination take place most perfectly.

Muscles which act upon the elbow-joint.—*Flexors.*—Brachialis, biceps, brachio-radialis, pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis, flexor carpi ulnaris.

Extensors.—Triceps, anconeus, and the muscles which spring from the lateral epicondyle

5. THE UNION OF THE RADIUS WITH THE ULNA

The radius is firmly united to the ulna by two joints, and an intermediate fibrous union, viz.:—

(*a*) **The superior radio-ulnar**—whereat the head of the radius *rotates* within the radial notch and annular ligament.

(*b*) The **union of the shafts**—the **mid radio-ulnar union.**

(*c*) The **inferior radio-ulnar**—whereat the lower end of the radius *rolls round* the head of the ulna.

(*a*) The Superior Radio-ulnar Joint

Class.—*Diarthrosis.* **Subdivision.**—*Trochoides.*

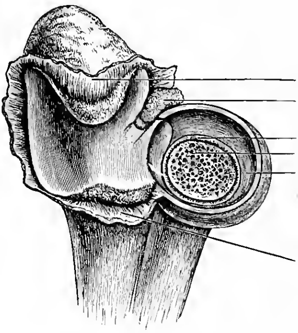
The bones which enter into this joint (which is often included with the elbow-joint) are, the ulna by its radial notch and the radius by the smooth vertical border or rim on its head. There is but one ligament special to the joint, viz.:—

Annular.

The **annular ligament** consists of bands of strong fibres, somewhat thicker than the capsule of the elbow-joint, which encircle the head of the radius, retaining it against the side of the ulna. The bulk of these fibres forms about three-fourths of a circle, and they are attached to the anterior and posterior margins of the radial notch; some few are continued round below the radial notch, and form a complete ligamentous circle.

The ligament is inseparably connected along its upper edge and lateral (i. e., its non-articular) surface with the anterior, posterior, and lateral portions of the capsule of the elbow, a few of the fibres of these portions, especially of the lateral, descending to be attached to the neck of the radius. The lower part of the articulation is covered in anteriorly, posteriorly, and laterally by a thin independent membranous layer, which passes from the lower edge of the annular ligament to the neck of the radius, strengthened on the lateral side by those fibres passing down from the capsule. They are loose enough to allow the bone to rotate upon its

Fig. 297.—Annular Ligament.
(The head of the radius removed to show the membranous connection of this ligament with the radius.)



own axis (fig. 297). Medially and below the cavity is closed in by a loose membrane, the ligamentum quadratum, which passes from the lower border of the radial notch to the neck of the radius.

The **synovial membrane** is the same as that of the elbow-joint, and, after lining the annular ligament, passes on to the neck of the radius, and thence up to the lower margin of the articular cartilage.

The arterial and nerve-supply are the same as those to the lateral part of the elbow-joint.
Relations.—Behind lies the anconeus and in front the lateral border of the brachialis.

(*b*) The Mid Radio-ulnar Union

Class.—*Synarthrosis.* **Subdivision.**—*Syndesmosis.*

There are two interosseous ligaments which pass betweeen the shafts of the bones and unite them firmly together, viz.:—

Oblique cord. Interosseous membrane.

The **oblique cord** [chorda obliqua] (figs. 293 and 298) is a fairly strong, narrow band, which passes from the lower end of the rough lateral border of the coronoid process, downward and laterally to be attached to the posterior edge of the lower end of the tuberosity of the radius and the vertical ridge running from it to the medial border of the bone.

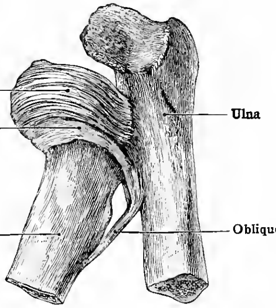
Some of its fibres blend with the fibres of insertion of the biceps tendon; behind, it is in close contact with the *supinator;* below, a thin membrane passes off from it to the upper edge of the interosseous membrane; the posterior interosseous vessels pass in the space between it and the interosseous membrane; occasionally a slip is continued into the annular ligament of the superior radio-ulnar articulation (see fig. 298).

The **interosseous membrane** (fig. 293) is attached to the ulna at the lowest part of the ridge in front of the depression for the supinator, and along the whole length of the interosseous border as far as the inferior radio-ulnar articulation, approaching the front of the bone in the lower part of its attachment. To the radius it is attached along the interosseous border, from an inch (2.5 cm.) below the tuberosity to the ulnar notch for the lower end of the ulna.

It is strongest and broadest in the centre, where the fibres are dense and closely packed; it is also well marked beneath the *pronator quadratus*, and thickens considerably at the lower end, forming a strong band of union between the two bones. Its fibres pass chiefly downward and medially, from the radius to the ulna, though some take the opposite direction; at the lower end some are transverse. On the posterior surface are one or two bands, which pass downward and laterally from the ulna to the radius, and frequently there is a strong bundle as large as the

FIG. 298.—UPPER PORTIONS OF LEFT ULNA AND RADIUS, TO SHOW AN OCCASIONAL SLIP FROM THE OBLIQUE CORD TO THE LOWER PART OF THE ANNULAR LIGAMENT. This condition is present in the spider monkey (*Ateles*), which has no external thumb but only rudimentary bones of one.

(From a dissection by Mr. W. Pearson, Royal College of Surgeons, England.)



oblique cord; this, which may be called the **inferior oblique ligament** (fig. 303), stretches from the ulna, an inch and a half above its lower extremity, downward and laterally to the ridge above and behind the ulnar notch of the radius.

At its attachment to the bones, the interosseous membrane blends with the periosteum. Its upper border is connected with the oblique cord by a thin membrane, which is pierced by the posterior interosseous vessels; and the lower border, which stretches across between the two bones just above the inferior radio-ulnar articulation, assists in completing the capsule of that joint. Its anterior surface is in relation with the *flexor digitorum profundus and flexor pollicis longus* in the upper three-quarters, the lower fourth being in relation with the *pronator quadratus*. The anterior interosseous vessels and nerve descend along the middle of the membrane, the artery being bound down to it. About an inch from the lower end it is pierced by the anterior interosseous artery. The posterior surface is in relation with the *supinator, abductor pollicis longus* (*extensor ossis metacarpi pollicis*), *extensor pollicis longus* and *brevis*, and the *extensor indicis proprius;* at its lower part, also with the posterior branch of the anterior interosseous artery, and the deep branch of the radial nerve (posterior interosseous).

(c) THE INFERIOR RADIO-ULNAR JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Trochoides.*

This is, in one respect, the reverse of the superior; for the radius, instead of presenting a circular head to rotate upon the facet on the ulna, presents a concave facet which rolls round the ulna. The articulation may be said to consist of two parts at right angles to each other; one between the radius and ulna, and the other between the ulna and the articular disc (triangular fibro-cartilage).

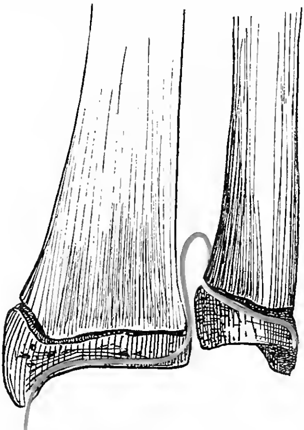
The ligaments are:—

Anterior radio-ulnar. Posterior radio-ulnar.
Articular disc.

The **articular disc** (triangular fibro-cartilage) (figs. 303 and 304) assists the radius in forming an arch under which is received the first row of carpal bones. Its base is attached to the margin of the radius, separating the ulnar notch from the articular surface for the carpus, while its apex is fixed to the fossa at the base of the styloid process of the ulna. It gradually and uniformly diminishes in width from base to apex, becoming rounded where it is fixed to the ulna; it is joined by fibres of the ulnar collateral ligament of the wrist.

The articular disc is about three-eighths of an inch (1 cm.) wide, and the same from base to apex; thicker at the circumference than in the centre; smooth and concave above to adapt itself to the ulna, and smooth and slightly concave below to fit over the triquetral bone. Its anterior and posterior borders are united to the anterior and posterior radio-ulnar and radio-carpal ligaments. It is the most important structure in the inferior radio-carpal articulation, as it is a very firm bond of union between the lower ends of the bones, and serves to limit their movements upon one another more than any other structure in either the upper or lower radio-ulnar joints. Its structure is fibrous at the circumference, while in the centre there is a preponderance of cells. It differs from all other fibro-cartilages in entering into two distinct articulations; and separates entirely the synovial membrane of the radio-ulnar joint from that of the wrist.

FIG. 299.—LOWER EXTREMITIES OF THE RADIUS AND ULNA TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE WRIST JOINT (in red) TO THE EPIPHYSIAL LINES. Note the upward extension of the membrana sacciformis.



The lower end of the **interosseous membrane** extends between the ulna and radius immediately above their points of contact. Transverse fibres between the two bones form a sort of arch above the concave articular facet of the radius, and, joining the anterior and posterior radio-ulnar ligaments, complete the **articular capsule** of the inferior radio-ulnar joint. The ligaments represent merely thickenings of the capsule.

The anterior radio-ulnar ligament (fig. 300) is attached by one end to the anterior edge of the ulnar notch of the radius, and by the other to the rough bone above the articular surface of the ulna as far medially as the notch, as well as into the anterior margin of the trianguar cartilage from base to apex.

The posterior radio-ulnar ligament (fig. 301) is similarly attached to the posterior margin of the ulnar notch at one end, and at the other to the rough bone above the articular surface of the extremity of the ulna as far medially as the groove for the *extensor carpi ulnaris*, with the sheath of which it is connected, as well as into the whole length of the posterior margin of the articular disc. Both the radio-ulnar ligaments consist of thin, almost scattered, fibres.

The **synovial membrane**, sometimes called **the membrana sacciformis**, is large and loose in proportion to the size of the joint. It is not only interposed between the radial and ulnar articular surfaces, but lines the terminal articular surface of the ulna and the upper surface of the articular disc.

The **arterial supply** is derived from the volar interosseous artery and branches of the volar carpal rete.

The **nerve-supply** comes from the volar interosseous of the median, and the deep branch of the radial (posterior interosseous).

Relations.—Behind lies the tendon of the extensor digiti quinti proprius and in front the flexor digitorum profundus.

The movements of the radius.—The upper end of the radius rotates upon an axis drawn through its own head and neck within the collar formed by the radial notch and the annular ligament, while the lower end, retained in position by the articular disc, rolls round the head of the ulna. This rotation is called *pronation*, when the radius from a position nearly parallel to the ulna turns medialward so as to lie obliquely across it; and *supination*, when the radius turns back again, so as to uncross and lie nearly parallel with the ulna. In these movements the radius carries with it the hand, which rotates on an axis passing along the ulnar side of the hand; thus, the hand when pronated lies with its dorsum upward, as in playing the piano, while when supinated, the palm lies upward—the attitude of a beggar asking alms. Ward thus expresses the relations of the two extremities of the radius in pronation and supination: 'The head of the radius is so disposed in relation to the sigmoid cavity (ulnar notch) at the lower end that the axis of the former if prolonged falls upon the centre of the circle of which the latter is a segment;' the axis thus passes through the lower end of the ulna at a point at which the articular disc is attached, and if prolonged further, passes through the ring finger. Thus the radius describes, in rotating, a blunt-pointed cone whose apex is the centre of the radial head, and whose base is at the wrist; partial rotation of the bone being unaccompanied by any hinge-like or antero-posterior motion of its head, and pronation and supination occurring without disturbance to the parallelism of the bones at the superior radio-ulnar joint. Associated with this rotation in the ordinary way, there is some rotation of the humero-ulnar shaft, which causes lateral shifting of the hand from side to side; thus, with pronation there is some abduction, and with supination some adduction combined, so that the hand can keep on the same superficies in both pronation and supination. The power of supination in man is much greater than pronation, owing to the immense power and leverage obtained by the curve of the radius, and by the attachment of the biceps tendon to the back of the tuberosity. For this reason all our screw-driving and boring tools are made to be used by supination movements.

In the undissected state, the amount of rotation it is possible to obtain is about 135°, so that neither the palm nor the fore part of the lower end of the radius can be turned completely in opposite directions; yet in the living subject this amount can be greatly increased by rotation of the humero-ulnar shaft at the shoulder-joint.

Pronation is checked in the living subject by (a) the posterior inferior radio-ulnar ligament, which is strengthened by the connection of the sheath of the extensor tendons with it; (b) the lowermost fibres of the interosseous membrane; (c) the back part of the ulnar collateral and adjacent fibres of the posterior ligament of the wrist, and (d) the meeting of the soft parts on the front of the forearm.

Supination is checked mainly (a) by the medial ulnar collateral ligaments of the wrist, but partly also by (b) the oblique cord; (c) the anterior inferior radio-ulnar ligament, and (d) the lowest fibres of the interosseous membrane.

The interosseous membrane serves, from the direction of its fibres downward and medially from the radius to the ulna, to transmit the weight of the body from the ulna to the radius in the extended position of the elbow, as in pushing forward with the arms extended, or in supporting one's own weight on the hands, the ulna being in intimate contact with the humerus, but not at all with the carpus; while the area of contact of the radius with the humerus is small, and that of the radius with the carpus large. Hence the weight transmitted by the ulna is communicated to the radius by the tightening of the interosseous membrane. Conversely, in falls upon the hand with the arm extended, the interosseous membrane acts as a sling to break the violence of the shock, and prevents the whole force of the impact from expending itself directly upon the capitulum.

Muscles which act upon the radio-ulnar joints.—*Pronators.*—Pronator teres, pronator quadratus, flexor carpi radialis, palmaris longus.

Supinators.—Biceps, supinator, extensor pollicis longus.

The brachio-radialis is chiefly a flexor of the elbow-joint, but it takes part in the initiation of the movement of supination when the hand is fully pronated and of pronation when the hand is fully supinated.

6. THE RADIO-CARPAL OR WRIST-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

The wrist-joint is formed by the union of the radius and articular disc above, articulating with the navicular, lunate, and triquetral bones below; the ulna being excluded by the intervention of the articular disc. The radius and disc together present a smooth surface, slightly concave both from before backward, and from side to side, whilst the three bones of the carpus present a smooth, convex surface, made uniformly even by the interosseous ligaments which bind them together.

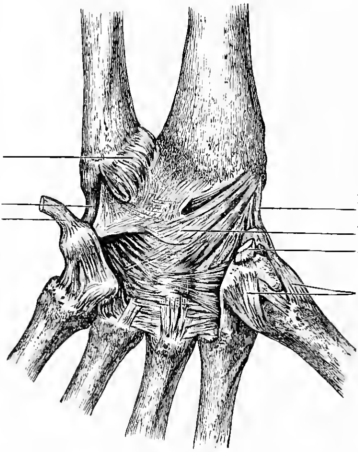
The capsule of the wrist-joint has been usually described as four separate ligaments, and it will be convenient for the sake of a complete description to follow this method; but it must be understood that these four portions are continuous around the joint, extending from styloid process to styloid process on both its aspects.

The four portions are:—

Volar radio-carpal.	Ulnar collateral.
Dorsal radio-carpal.	Radial collateral.

The **volar** (or anterior) **radio-carpal** (fig. 300) is a thick strong ligament, attached superiorly to the radius immediately above the anterior margin of the terminal articular facet, to the curved ridge at the root of the styloid process of the radius, and to the anterior margin of the articular disc, blending with some fibres of the capsule of the inferior radio-ulnar joint. It passes downward and in a medial direction to be attached to both rows of carpal bones, especially the second, and to the volar intercarpal ligament.

Fig. 300.—Anterior View of Wrist.



The strongest and most oblique fibres arise from the root of the styloid process of the radius, and pass obliquely over the navicular, with which only a few fibres are connected, to be inserted into the lunate, capitate, and triquetral bones. Another set, less oblique, passes from the margin of the facet for the lunate to be attached to the adjacent parts of the capitate, hamate, and triquetral bones. Between the two sets of fibres, small vessels pass into the joint.

The **dorsal** (or posterior) **radio-carpal ligament** (fig. 301) is attached above to the dorsal edge of the lower end of the radius, the back of the styloid process, and the posterior margin of the fibro-cartilage. It passes downward and in a medial direction to be connected with the first row of the carpal bones, chiefly with the lunate and triquetral, and the dorsal intercarpal ligament. This ligament is thin and membranous.

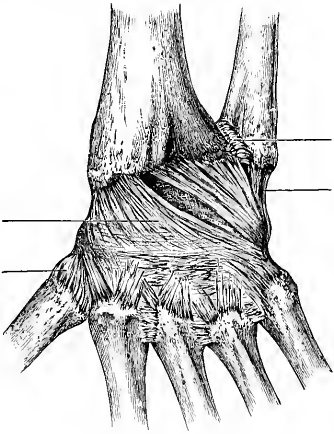
It is strengthened by (i) strong fibres passing from the back of the articular disc where they are blended with the posterior inferior radio-ulnar ligament, and, from the edge of the radius just behind the ulnar notch, to the triquetral bone; (ii) from the ridge and groove for the extensor pollicis longus to the back of the lunate and triquetral bones; and (iii) from the groove for the radial extensors to the back of the navicular and lunate. It is in relation with, and strengthened by, the extensor tendons which pass over it.

The **ulnar collateral ligament** (fig. 301) is fan-shaped, with its apex above, at the styloid process of the ulna, to which it is attached on all sides, blending with the apex of the articular disc. Some of the fibres pass forward and laterally to the base of the pisiform bone and to the medial part of the upper border of the transverse carpal ligament, where it is attached to the pisiform bone; they form a thick, rounded fasciculus on the front of the wrist. Other fibres descend vertically to the medial side of the triquetral bone, and others again laterally to the dorsal surface of the triquetral. The tendon of the *extensor carpi ulnaris* is posterior to, and passes over, part of the fibres of the ligament.

The **radial collateral ligament** (fig. 300) consists of fibres which radiate from the fore part and tip of the styloid process of the radius. Some pass downward and medially, in front, to the navicular and adjacent edge of the capitate; some downward, a little forward and medially, to the tubercle of the navicular and ridge of the greater multangular; and others downward and laterally to the rough dorsal surface of the navicular.

The fibres of this ligament are not so long and strong, nor do they radiate so much as those of the ulnar collateral ligament. It is in relation with the *radial artery*, and the *abductor pollicis longus* (*extensor ossis metacarpi pollicis*) and *extensor pollicis brevis*, the artery separating the tendons from the ligament.

Fig. 301.—Posterior View of Wrist.



The **synovial membrane** is extensive, but does not usually communicate with the synovial membrane of the inferior radio-ulnar joint, being shut out by the articular disc. It is also excluded, in almost every instance, from that of the carpal joints by the interosseous ligaments between the first row of carpal bones. The styloid process of the radius is cartilage-covered medially, and forms part of the articular cavity, while that of the ulna does not.

The **arterial supply** is derived from the anterior and posterior carpal rami, the dorsal division of the volar interosseous, and from twigs direct from the radial and ulnar arteries.

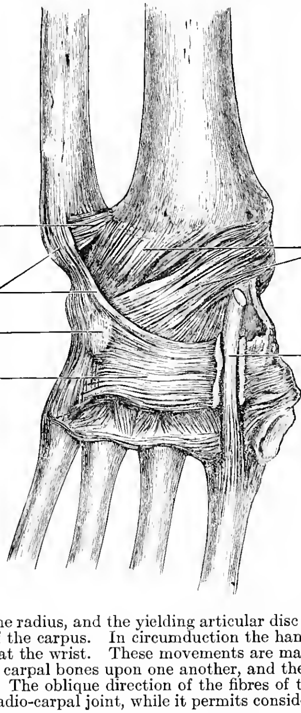
The **nerve-supply** is derived from the ulnar and median in front, and the deep branch of the radial (posterior interosseous) behind.

Relations.—In front of the radio-carpal joint are the tendons of the flexor muscles of the wrist and fingers, the synovial sheaths associated with them, the radial and ulnar arteries, and the median and ulnar nerves.

Behind the joint are the majority of the tendons of the extensor muscles of the wrist and fingers, with their synovial sheaths, the terminal part of the anterior and posterior interosseous arteries, and the deep branch of the radial nerve (posterior interosseous). On the radial side lie the tendons of the abductor pollicis longus (*extensor ossis metacarpi pollicis*) and the extensor pollicis brevis. On the ulnar side the joint is subcutaneous and it is crossed by the dorsal cutaneous branch of the ulnar nerve.

Movements.—The wrist is a condyloid joint, the carpus forming the condyle. It allows of movements upon a transverse axis, i. e., flexion and extension; and around an antero-posterior axis, i. e., abduction and adduction; together with a combination of these in quick succession—circumduction. Lacking only rotation on a vertical axis, it thus possesses most of the movements of a ball-and-socket joint, without the weakness and liability to dislocation which are peculiar to these joints. This deficiency of rotation is compensated for by the movements of the radius at the radio-ulnar joints, viz., supination and pronation. Its strength depends chiefly upon the number of tendons which pass over it, and the close connection which exists between the fibrous tissue of their sheaths and the capsule of the wrist; also upon the proximity of the medio-carpal and carpo-metacarpal joints, which permits shocks and jars to be shared and distributed between them; another source of strength is the absence of any long bone on the distal side of the joint. In flexion and extension the carpus rolls backward and forward, respectively, beneath the arch formed by the radius and articular disc; flexion being limited by the dorsal ligament and dorsal portions of the collateral; extension by the volar, and volar portions of the collateral ligaments. In adduction and abduction the carpal bones glide from the ulnar to the radial side and from the radial to the ulnar side, respectively. Abduction is more limited than adduction, and is checked by the ulnar collateral ligament and by contact of the styloid process of the radius with the greater multangular; adduction is checked by the radial collateral ligament alone. One reason for adduction being more free than abduction is that the ulna does

Fig. 302.—Front of Wrist with Transverse Carpal Ligament.



not reach so low down as the radius, and the yielding articular disc allows of greater movement upward of the ulnar end of the carpus. In circumduction the hand moves so as to describe a cone, the apex of which is at the wrist. These movements are made more easy and extensive by the slight gliding of the carpal bones upon one another, and the comparatively free motion at the medio-carpal joint. The oblique direction of the fibres of the collateral ligaments prevents any rotation at the radio-carpal joint, while it permits considerable freedom of abduction and adduction.

Muscles which act upon the radio-carpal joint.—*Flexors.*—The flexors of the carpus and the long flexors of the fingers and the thumb, and the palmaris longus. *Extensors.*—The extensors of the carpus and fingers. *Abductors.*—Extensor carpi radialis longus, the abductor pollicis longus (extensor ossis metacarpi pollicis. *Adductors.*—Flexor carpi ulnaris, extensor carpi ulnaris.

7. THE CARPAL JOINTS

The joints of the carpus may be subdivided into—

(*a*) The **joints of the first row.**

(*b*) The **joints of the second row.**

(*c*) The **medio-carpal,** or junction of the two rows with each other.

(a) The Joints of the First Row of Carpal Bones

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The bones of the first row, the pisiform excepted, are united by two sets of ligaments and two interosseous fibro-cartilages.

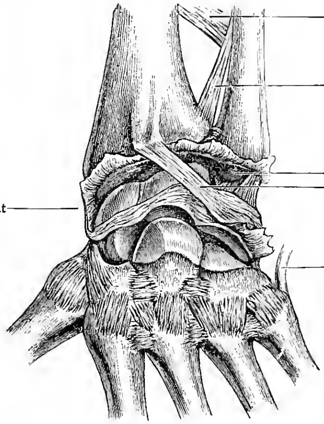
Dorsal. Volar.
Interosseous.

The two **dorsal intercarpal ligaments** extend transversely between the bones, and connect the navicular with the lunate, and the lunate with the triquetral. Their posterior surfaces are in contact with the posterior ligament of the wrist.

The two **volar intercarpal ligaments** extend nearly transversely between the bones connecting the navicular with the lunate, and the lunate with the triquetral. They are stronger than the dorsal ligaments, and are placed beneath the anterior ligament of the wrist.

The two **interosseous intercarpal ligaments** (fig. 304) are interposed between the navicular and lunate, and the lunate and triquetral bones, reaching from the dorsal to the volar surfaces,

Fig. 303.—Posterior View of the Wrist, with Capsule cut to show Articular Surfaces.



and being connected with the dorsal and volar ligaments. They are narrow fibro-cartilages which extend between small portions only of the osseous surfaces. They help to form the convex carpal surface of the radio-carpal joint, and are somewhat wedge-shaped, their bases being toward the wrist, and their thin edges between the adjacent articular surfaces of the bones.

The **synovial membrane** is a prolongation from that of the medio-carpal joint.

The **arterial** and **nerve-supplies** are the same as for the medio-carpal joint.

The Joint of the Pisiform Bone with the Triquetral

This is an arthrodial joint which has a loose fibrous **capsule** attached to both the pisiform and triquetral bones just beyond the margins of their articular surfaces.

It is lined by a separate synovial membrane. Two strong rounded or flattened bands pass downward from the pisiform, one to the process of the hamate [lig. pisohamatum], and the other [lig. pisometacarpeum] to the bases of the third to fifth metacarpals; these are regarded as prolongations of the tendon of the *flexor carpi ulnaris*, and the pisiform bone may be looked upon in the light of a sesamoid bone developed in that tendon.

(b) The Joints of the Second Row of Carpal Bones

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The four bones of this row are united by three dorsal, three palmar, and three interosseous ligaments.

The **three dorsal ligaments** (fig. 303) extend transversely and connect the greater with the lesser multangular, the lesser multangular with the capitate, and the capitate with the hamate.

The **three volar ligaments** are stronger than the dorsal, and are deeply placed beneath the mass of flexor tendons; they extend transversely between the bones in a similar manner to the dorsal ligaments.

Three interosseous ligaments connect the bones of the lower row of the carpus together. Two are connected with the capitate, one uniting it with the hamate (fig. 304) and the other binding it to the lesser multangular. The third ligament joins the greater and lesser multangular.

The **synovial membrane** is a prolongation of that lining the medio-carpal joint.

The **arterial** and **nerve-supplies** are the same as for the medio-carpal joint.

(*c*) The Medio-carpal Joint, or the Union of the Two Rows of the Carpus with each other

(I) **Class.**—*Diarthrosis.* **Subdivision.**—*Arthrodia.*
(II) **Class.**—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

The inferior surfaces of the bones of the first row are adapted to the superior articular surfaces of the bones of the second row. The line of this articulation is concavo-convex from side to side, and is sometimes described as having the course of a Roman S placed horizontally, ∽, a resemblance by no means strained. (i) The lateral part of the first row consists of the navicular alone; it is convex, and bears the greater and lesser multangulars. (ii) Then follows a transversely elongated socket formed by the medial part of the navicular, the lunate, and triquetral, into which are received—(*a*) the head of the capitate, which articulates with the navicular and lunate; (*b*) the upper and lateral angle of the hamate, which articulates with the navicular; and (*c*) the upper convex portion of the medial surface of the hamate, which articulates with the lateral and concave portion of the inferior surface of the triquetral. (iii) The medial part of the inferior surface of the triquetral bone is convex, and turned a little backward to fit into the lower portion of the medial surface of the hamate, which is a little concave and turned forward to receive it. The central part, which forms a socket for the capitate and hamate, has somewhat the character of a condyloid joint, the capitate and hamate being the condyle, to fit into the cavity formed by the navicular, lunate, and triquetral; the other portions are typically arthrodial. The ligaments are:—(1) **radiate or anterior medio-carpal**; (2) **posterior medio-carpal**; (3) **transverse dorsal.**

The **radiate**, anterior or volar medio-carpal is a ligament of considerable strength, consisting mostly of fibres which radiate from the capitate to the navicular, lunate, and triquetral; some few fibres connect the greater and lesser multangular with the navicular, and others pass between the hamate and triquetral. It is covered over and thickened by fibrous tissue derived from the sheaths of the flexor tendons and the fibres of origin of the small muscles of the thumb and little finger.

The posterior or **dorsal medio-carpal ligament**, consists of fibres passing obliquely from the bones of the first row to those of the second. It is stronger on the ulnar side than on the radial, but is not so strong as the volar ligament.

The **transverse dorsal ligament** (fig. 303) is an additional band, well marked and often of considerable strength, which passes across the head of the capitate from the navicular to the triquetral bone; besides binding down the head of the capitate, it serves to fix the upper and lateral angle of the hamate in the socket formed by the first row.

The dorsal ligaments, like the volar, are strengthened by a quantity of fibrous tissue belonging to the sheaths of the extensor tendons, and by an extension of some of the fibres of the capsule of the wrist. There are no proper collateral medio-carpal ligaments; they are but prolongations of the collateral ligaments of the wrist.

The **synovial membrane** (fig. 304) of the carpus is common to all the joints of the carpus, and extends to the bases of the four medial metacarpal bones. Thus, besides lining the inter- or medio-carpal joint, it sends two processes upward between the three bones of the first row, and three downward between the contiguous surfaces of the lesser and greater multangular, the lesser multangular and capitate, and capitate and hamate. From these latter, prolongations extend to the four medial carpo-metacarpal joints and the three intermetacarpal joints.

The **arterial supply** is derived from—(*a*) the volar and dorsal carpal rami of the radial and ulnar arteries; (*b*) the carpal branch of the volar interosseous; (*c*) the recurrent branches from the deep palmar arch. The terminal twigs of the volar and dorsal interosseous arteries supply the joint on its dorsal aspect.

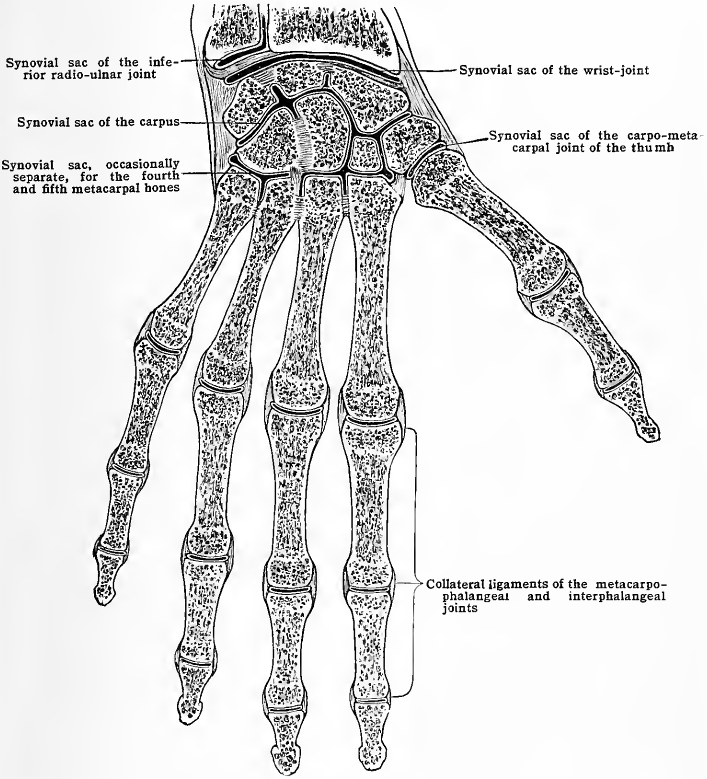
The **nerve-supply** comes from the ulnar on the ulnar side, the median on the radial side, and the deep branch of the radial (posterior interosseous) behind.

Relations.—The relations of this joint are practically the same as those of the radio-carpal joint, except that the flexor carpi ulnaris does not cross the front, the ulnar artery is separated from it by the transverse carpal ligament, and the radial artery passes across its lateral border instead of in front.

The **movements** of the carpal articulations between bones of the same row are very limited and consist only of slight gliding upon one another; but, slight as they are, they give elasticity to the carpus to break the jars and shocks which result from blows or falls upon the hand.

The movements of one row of bones upon the other at the medio-carpal joint are more extensive, especially in the direction of flexion and extension, so that the hand enjoys a greater range of these movements than is permitted at the wrist-joint alone. At the wrist, extension is more free than flexion; but this is balanced by the greater freedom of flexion than of extension at the medio-carpal joint, and by flexion at the carpo-metacarpal joint, so that on the whole the range of flexion of the hand is greater than that of extension.

Fig. 304.—Synovial Membranes of Wrist, Hand, and Fingers.



A slight amount of side to side motion accompanied by a limited degree of rotation also takes place; this rotation consists in the head of the capitate and the superior and lateral angle of the hamate bone rotating in the socket formed by the three bones of the upper row, and in a gliding forward and backward of the greater and lesser multangular upon the navicular.

In addition to the ligaments, the undulating outline and the variety of shapes of the apposed facets render this joint very secure.

Bearing in mind the mobility of this medio-carpal joint and of the carpo-metacarpal, we see at once the reason for the radial and ulnar flexors and extensors of the carpus being prolonged down to their insertion into the base of the metacarpus, for they produce the combined effect of motion at each of the three transverse articulations:—(1) at the wrist; (2) at the medio-carpal; (3) at the carpo-metacarpal joints.

Muscles which act upon the mid-carpal joint.—The muscles which act upon this joint are the same as those which act upon the radio-carpal joint, except the flexor carpi ulnaris, which is inserted into the pisiform bone.

8. THE CARPO-METACARPAL JOINTS

These may be divided into two sets, namely:—

(*a*) The **carpo-metacarpal joints of the four medial fingers.**
(*b*) The **carpo-metacarpal joints of the thumb.**

The inferior surfaces of the bones of the second row of the carpus present a composite surface for the four medial metacarpal bones; the greater multangular presents in addition a distinct and separate saddle-shaped surface for the base of the metacarpal bone of the thumb.

(*a*) The Four Medial Carpo-metacarpal Joints

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

These joints exist between the greater and lesser multangular, capitate, and hamate bones above, and the four medial metacarpal bones below. The ligaments which unite them are, dorsal, volar, and interosseous.

The dorsal ligaments (fig. 303).—Three dorsal ligaments pass to the second metacarpal bone: one from each of the carpal bones with which it articulates, viz., the greater and lesser multangular, and capitate. Two dorsal bands pass from the capitate to the third metacarpal bone. Two dorsal bands pass to the fourth bone: viz., one from the hamate, and another from the capitate; the latter is sometimes wanting. The fifth bone has only one band passing to it from the hamate.

The volar ligaments (fig. 300).—One strong band passes from the second metacarpal bone to the greater multangular medial to the ridge for the transverse carpal ligament; it is covered by the sheath of the *flexor carpi radialis.*

Three bands pass from the third metacarpal: one laterally to the greater multangular, a middle one upward to the capitate, and a third medially over the fourth to reach the fifth metacarpal and the hamate bones.

One ligament connects the fourth bone to the hamate.

One ligament connects the fifth bone to the hamate, the fibres extending medially, and connecting the dorsal and volar ligaments. The ligament to the fifth bone is strengthened in front by the prolonged fibres of the *flexor carpi ulnaris* and the strong medial slip of the ligament of the third metacarpal bone; and posteriorly, by the tendon of the *extensor carpi ulnaris.*

The interosseous ligament (fig. 304) is limited to one part of the articulation, and consists of short fibres connecting the contiguous angles of the hamate and capitate with the third and fourth metacarpal bones toward their volar aspect. There is, however, a thick strong ligament connecting the edge of the greater multangular with the lateral border of the base of the second metacarpal bone; it helps to separate the carpo-metacarpal joint of the thumb from the common carpo-metacarpal joint, and to close in the radial side of the latter joint.

The synovial membrane is a continuation of the medio-carpal joint; occasionally there is a separate membrane between the hamate and fourth and fifth metacarpal bones (fig. 304); while that between the fourth and capitate is lined by the synovial sac of the common joint.

The arteries to the four medial carpo-metacarpal joints are as follows:—

(1) For the index finger: twigs are supplied by the trunk of the radial on the dorsal and volar aspects, and by the dorsal and volar metacarpal branches.

(2) For the middle finger: the first dorsal metacarpal by the branch which passes upward to join the dorsal carpal arch, and a branch from the deep volar arch which joins the volar carpal arch.

(3) For the ring finger: the deep volar arch and recurrent twigs from the second dorsal metacarpal in the same manner as for the middle finger.

(4) For the little finger: the ulnar and its deep branch; also twigs from the second dorsal metacarpal.

The nerves are supplied to these joints by the deep volar branch of the ulnar, the deep branch of the radial (posterior interosseous), and the median.

Relations.—In front of the four medial carpo-metacarpal joints are the flexors of the fingers with their synovial sheath. The flexor carpi radialis crossing in front of the lateral part of the joint and the fibres of the oblique adductor pollicis which spring from the capitate and lesser multangular are also anterior relations. Behind the joints are the extensors of the wrist and fingers with their synovial sheaths and the dorsal metacarpal arteries. At the lateral border of the joints between the index and lesser multangular lies the radial artery.

The movements permitted at these joints, though slight, serve to increase those of the medio-carpal and wrist-joints. The joint between the fifth metacarpal and the hamate bones approaches somewhat in shape and mobility the first carpo-metacarpal joint; it has a greater range of flexion and extension, but its side to side movement is nearly as limited as that of the three other metacarpal bones; the process of the hamate bone limits its flexion. Motion toward the ulnar side is checked by the strong palmar band which unites the base of the fifth metacarpal to the base of the third, and the strong transverse ligament at the head of the bones. The mobility of the second, third, and fourth metacarpal bones is very limited, and consists almost entirely of a slight gliding upon the carpal bones, i. e., flexion and extension; that of the third and fourth bones is extremely slight, as there is no long flexor attached to either; but, owing to the close connection of the bases of the metacarpal bones, the radial and ulnar flexors and extensors of the carpus act on all by their pull on the particular bone into which they are inserted.

Abduction, or movement toward the radial side, is prevented by the impaction of the second bone against the greater multangular; a little adduction is permitted, and is favoured by the slope given to the hamate and fifth metacarpal bones.

There is also a slight gliding between the fourth and fifth bones, when the concavity they present toward the palm is deepened to form the 'cup of Diogenes.'

Muscles which act upon the four medial carpo-metacarpal joints are the flexors and extensors of the wrist and fingers, except the flexor carpi ulnaris.

(*b*) The Carpo-metacarpal Joint of the Thumb

Class.—*Diarthrosis.* **Subdivision.**—*Saddle-shaped Arthrodia.*

The bones entering into this joint are the base of the first metacarpal and the greater multangular. The first metacarpal bone diverges from the other four, contrasting very strongly with the position of the great toe. It is due to this divergence that the thumb is able to be opposed to each and all the fingers. The ligament which unites the bones is the

Articular capsule.

The **articular capsule** (figs. 300 and 301) consists of fibres which pass from the margin of the articular facet on the greater multangular, to the margin of the articular facet at the base of the first metacarpal bone.

The fibres are stronger on the dorsal than on the palmar aspect. They are not tense enough to hold the bones in close contact, so that while they restrict they do not prevent motion in any direction. The medial fibres are stronger than the lateral.

The **synovial membrane** is lax, and distinct from the other synovial membranes of the carpus.

The **arteries** of the carpo-metacarpal joint of the thumb are derived from the trunk of the radial, the first volar metacarpal, and the dorsalis pollicis.

The **nerves** are supplied by the branches of the median to the thumb.

Relations.—Behind are the long and short extensor tendons of the thumb, and behind and laterally the tendon of the abductor pollicis longus (extensor ossis metacarpi pollicis). The tendon of the flexor pollicis longus is in front and fibres of the flexor pollicis brevis and opponens pollicis muscles are also anterior relations. To the medial side is the radial artery as it passes forward into the palm of the hand.

The **movements** of this joint are regulated by the shape of the articular surfaces, rather than by the ligaments, and consist of flexion, extension, abduction, adduction, and circumduction, but not rotation. In flexion and extension the metacarpal bone slides to and fro upon the multangular; in abduction and adduction it slides from side to side or, more correctly, revolves upon the antero-posterior axis of the joint. The power of opposing the thumb to any of the fingers is due to the forward and medial obliquity of its flexion movement, which is by far its most extensive motion. Abduction is very free, while adduction is limited on account of the proximity of the second metacarpal bone. The movement of the greater multangular upon the rest of the carpus somewhat increases the range of all the movements of the thumb.

Muscles which act upon the carpo-metacarpal joint of the thumb.—*Flexors.*—Flexor pollicis brevis, flexor pollicis longus, opponens pollicis. *Extensors.*—Extensores pollicis brevis and longus and abductor pollicis longus. *Abductors.*—Abductores pollicis longus and brevis. *Adductors.*—The transverse and oblique adductor pollicis, opponens, first dorsal interosseous. *Muscles producing opposition.*—Opponens, flexor brevis, oblique adductor.

9. THE INTERMETACARPAL ARTICULATIONS

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The metacarpal of the thumb is not connected with any other metacarpal bone. The second, third, fourth, and fifth metacarpal bones are in actual contact at their bases, and are held firmly together by the following ligaments (in addition to the articular capsule):—

Dorsal. Volar.
Interosseous ligaments.

The **dorsal ligaments** (fig. 302) are layers of variable thickness of strong, short fibres, which pass transversely from bone to bone, filling up the irregularities on the dorsal surfaces.

The **volar ligaments** are transverse layers of ligamentous tissue passing from bone to bone; they cannot be well differentiated from the other ligaments and fibrous tissue covering the bones.

The **interosseous ligaments** (fig. 304) pass between the apposed surfaces of the bones, and are attached to the distal sides of the articular facets, so as to close in the synovial cavities on this aspect; where there are two articular facets, the fibres extend upward between them nearly as far as their carpal facets. That between the fourth and fifth is the weakest.

The synovial membrane is prolonged downward from the common carpal sac.

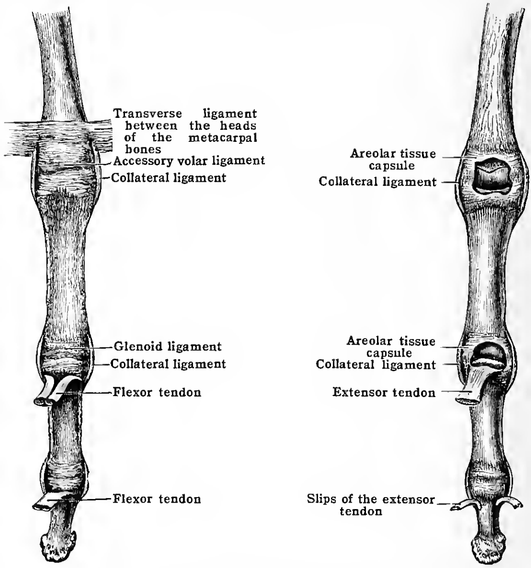
The arteries to the intermetacarpal joints are twigs from the volar and dorsal metacarpal arteries; the twigs pass upward between the interosseous muscles.

The nerves are derived from the ulnar and the deep branch of radial (posterior interosseous).

The Union of the Heads of the Metacarpal Bones

The distal extremities of these bones are connected together on their palmar aspects by what is called the transverse ligament [lig. capitulorum]. This consists of three short bands of fibrous tissue, which unite the second and third, third and fourth, and the fourth and fifth bones. They are rather more than 6 mm. ($\frac{1}{4}$ in.) deep, and rather less in width, and limit the distance to which the metacarpal bones can be separated. They are continuous above with the fascia covering the interosseous muscles; below, they are connected with the subcutaneous tissue of the web of the hand. They are on a level with the front surface of the bones, and are blended on either side with the edges of the glenoid ligament in front, with the lateral ligaments

Fig. 305.—Anterior and Posterior Views of Ligaments of the Fingers.



of the metacarpo-phalangeal joint, and also with the sheaths of the tendons. In front, a *lumbrical* muscle passes with the digital arteries and nerves; while behind, the *interossei* muscles pass to their insertions.

10. THE METACARPO-PHALANGEAL JOINTS

(*a*) The Metacarpo-phalangeal Joints of the Four Medial Fingers

Class.—*Diarthrosis*. **Subdivision.**—*Condylarthrosis*.

In these joints the cup-shaped extremity of the base of the first phalanx fits on to the rounded head of the metacarpal bone, and is united by the following ligaments (in addition to the articular capsule):—

Collateral. Volar accessory.

The volar accessory (or glenoid) ligament (fig. 305) is a fibro-cartilaginous plate which seems more intended to increase the depth of the phalangeal articular facet in front, than to unite the two bones. It is much more firmly attached to the margin of the phalanx than to the metacarpal bone, being only loosely connected with the palmar surface of the latter by some loose areolar tissue which covers in the synovial membrane, here prolonged some little distance upon the surface of the bone. At the sides, it is connected with the collateral ligaments and the transverse metacarpal ligament. It corresponds to the sesamoid bones of the thumb; a sesamoid bone sometimes exists at the medial border of the joint of the little finger.

The **collateral ligaments** (304 and 305) are strong and firmly connect the bones with one another; each is attached above to the corresponding tubercle, and to a depression in front of the tubercle, of the metacarpal bone. From this point the fibres spread widely as they descend on either side of the base of the phalanx; the anterior fibres are connected with the glenoid ligament; the posterior blend with the tendinous expansion at the back of the joint.

The joint is covered in posteriorly by the expansion of the extensor tendon, and some loose areolar tissue passing from its under surface to the bones (fig. 305).

The **synovial membrane** is loose and capacious, and invests the inner surface of the ligaments which connect the bones.

The **arteries** come from the digital or volar metacarpal vessels of the deep arch.

The **nerves** are derived from the digital branches, or from twigs of the branches of the ulnar to the interosseous muscles.

Relations.—I. The metacarpo-phalangeal joints of the middle three digits. In front, the tendons of the flexor profundus and flexor sublimis digitorum. On the radial side, a lumbrical, an interosseous muscle, and digital nerves and vessels; on the ulnar side, an interosseous muscle and digital vessels and nerves. Behind, the common extensor tendon and in the case of the index digit the tendon of the extensor indicis.

II. The metacarpo-phalangeal joint of the little finger. In front, the flexor quinti digiti brevis and the tendons of the flexor profundus and sublimis digitorum muscle which go to this digit. Behind, the extensor digiti quinti to a slip of the extensor digitorum communis sometimes. On the radial side, a lumbrical, the third palmar interosseous muscle, digital vessels and nerves. On the ulnar side, digital vessels and nerves.

The **movements** permitted at these joints are flexion, extension, abduction, adduction, and circumduction. Flexion is the most free of all and may be continued until the phalanx is at a right angle with the metacarpal bone. It is on this account that the articular surface of the head of the bone is prolonged so much further on the palmar aspect, and that the synovial membrane is here so loose and ample. Extension is the most limited of the movements, and can only be carried to a little beyond the straight line. Abduction and adduction are fairly free, but not so free as flexion. Flexion is associated with adduction, and extension with abduction. This may be proved by opening the hand, when the fingers involuntarily separate as they extend, while in closing the fist they come together again. The free abduction, adduction, and circumduction which are permitted at these joints are due to the fact that the long axes of the articular facets are at right angles to one another.

Muscles acting on the middle three digits.—*Flexors.*—Flexor digitorum profundus, flexor digitorum sublimis. *Extensors.*—Extensor digitorum communis and on the index digit the extensor indicis. *Abductors.*—Dorsal interossei. *Adductors.*—Volar interossei.

Muscles acting on the metacarpo-phalangeal joint of the little finger.—*Flexors.*—Flexor quinti digiti brevis, flexor digitorum sublimis, flexor digitorum profundus. *Extensors.*—Extensor digitorum communis, extensor quinti digiti. *Abductor.*—Abductor quinti digiti. *Adductor.*—Third volar interosseous.

(*b*) The Metacarpo-phalangeal Joint of the Thumb

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

The head of the metacarpal bone of the thumb differs considerably from the corresponding ends of the metacarpal bones of the fingers. It is less convex, wider from side to side, the palmar edge of the articular surface is raised and irregular, and here on either side of the median line are the two facets for the sesamoid bones. The base of the first phalanx of the thumb, too, is more like the base of the second phalanx of one of the other fingers. The ligaments are:—

Collateral. Dorsal.
Articular capsule.

The **collateral ligaments** are short, strong bands of fibres, which radiate from depressions on either side of the head of the metacarpal bone to the base of the first phalanx and sesamoid bones. As they descend they pass a little forward, so that the greater number are inserted in front of the centre of motion.

The **dorsal ligament** consists of scattered fibres which pass across the joint from one collateral ligament to the other, completing the **articular capsule** and protecting the synovial sac.

The **sesamoid bones** are two in number, situated on either side of the middle line, and connected together by strong transverse fibres which form the floor of the groove for the *long flexor tendon;* they are connected with the base of the phalanx and head of the metacarpal bone by strong fibres. Anteriorly they give attachment to the short muscles of the thumb, and posteriorly are smooth for the purpose of gliding over the facets. The collateral ligaments are partly inserted into their sides.

The **arteries** and **nerves** come from the digital branches of the thumb.

Relations.—Of the metacarpo-phalangeal joint of the thumb: In front and externally abductor pollicis brevis and superficial head of flexor pollicis brevis. In front and medially oblique and transverse adductors and deep head of flexor pollicis brevis. Directly in front flexor pollicis longus and terminal branches of first volar metacarpal artery. Behind, extensor pollicis brevis and longus tendons. On either side, the dorsal digital vessels and the digital nerves.

The **movements** are chiefly flexion and extension, very little side to side movement being permitted, and that only when the joint is slightly bent. Thus this joint more nearly approaches the simple hinge character than the corresponding articulations of the fingers. The thumb gets its freedom of motion at the carpo-metacarpal joint; the fingers get theirs at the metacarpo-phalangeal, but they are not endowed with so much freedom as the thumb enjoys.

Muscles which act upon the metacarpo-phalangeal joint of the thumb.—*Flexors.*—Flexor pollicis brevis, flexor pollicis longus. *Extensors.*—Extensor pollicis brevis, extensor pollicis longus.

11. THE INTERPHALANGEAL ARTICULATIONS

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

The ligaments which unite the phalanges of the thumb and of the fingers are (in addition to the articular capsule):—

Accessory volar. Collateral.

The **accessory volar** (or glenoid) **ligament** (fig. 305), sometimes called the sesamoid body, is very firmly connected with the base of the distal bone, and loosely, by means of fibro-areolar tissue, with the head of the proximal one. It blends with the collateral ligaments at the sides, and over it pass the flexor tendons. Occasionally a sesamoid bone is developed in the cartilage of the interphalangeal joint of the thumb.

The **collateral ligaments** (figs. 304 and 305) are strong bands which are attached to the rough depressions on the sides of the upper phalanx, and to the projecting margins of the lower phalanx of each joint. They are tense in every position, and entirely prevent any side to side motion; they are connected posteriorly with the expansion of the extensor tendon.

Dorsally (fig. 305) the joint is covered in by the deep surface of the extensor tendon, and a little fibro-areolar tissue extends from the tendon, and thickens the posterior portion of the synovial sac, completing the **articular capsule.**

The **synovial membrane** is loose and ample, and extends upward a little way along the shaft of the proximal bone.

The **arteries** and **nerves** come from their respective digital branches.

The **relations** of the interphalangeal joints are the flexor and extensor tendons and the digital vessels and nerves.

The **movements** are limited to flexion and extension. Flexion is more free, and can be continued till one bone is at a right angle to the other, and is most free at the junction of the first and second bones; the second phalanx can be flexed on the first through 110° to 115° when the latter is not flexed. The greater freedom of flexion is due to the greater extent of the articular surface in front of the heads of the proximal bones, and to the direction of the fibres of the collateral ligaments, which pass a little forward to their insertion into the distal bone.

The muscles which act upon the interphalangeal joints are the extensors and flexors of the digits.

THE ARTICULATIONS OF THE LOWER LIMB

The articulations of the lower limb are the following:—

1. The **hip-joint.**
2. The **knee-joint.**
3. The **tibio-fibular union.**
4. The **ankle-joint.**
5. The **tarsal joints.**
6. The **tarso-metatarsal joints.**
7. The **intermetatarsal joints.**
8. The **metatarso-phalangeal joints.**
9. The **interphalangeal joints.**

1. THE HIP-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Enarthrodia.*

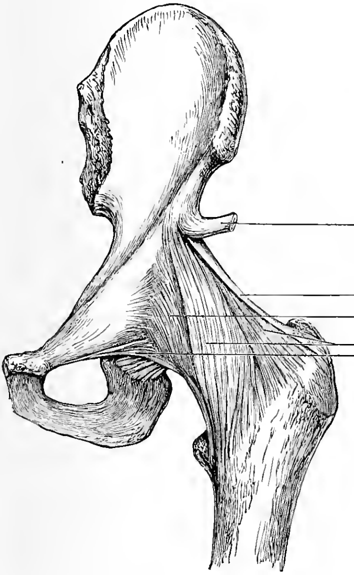
The hip is the most typical example of a ball-and-socket joint in the body, the round head of the femur being received into the cup-shaped cavity of the acetabulum. Both articular surfaces are coated with cartilage, that covering the head of the femur being thicker above where it has to bear the weight of the body, and thinning out to a mere edge below; the pit for the ligamentum teres is the only part uncoated, but the cartilage is somewhat heaped up around its margin. Covering the acetabulum, the cartilage is horseshoe-shaped, and thicker above than below, being deficient over the depression at the bottom of the acetabulum, where a mass of fatty tissue—the so-called synovial or Haversian gland—is lodged.

The ligaments of the joint are:—

Articular capsule.	Ligamentum teres.
Transverse.	Glenoid lip.

The **articular capsule** is one of the strongest ligaments in the body. It is large and somewhat loose, so that in every position of the body some portion of it is relaxed. At the **pelvis** it is attached, superiorly, to the base of the anterior inferior iliac spine; curving backward, it becomes blended with the deep surface of the reflected tendon of the *rectus femoris;* posteriorly, it is attached a few millimetres from the acetabular rim; and below, to the upper edge of the groove between the acetabulum and tuberosity of the ischium. Thus it reaches the

Fig. 306.—Anterior View of the Articular Capsule of the Hip-joint.



transverse ligament, being firmly blended with its outer surface, and frequently sends fibres beyond the notch to blend with the obturator membrane. Anteriorly it is attached to the pubis near the obturator notch, to the ilio-pectineal eminence and thence backward to the base of the inferior iliac spine.

A thin strong stratum is given off from its superficial aspect behind; this extends beneath the gluteus minimus and small rotators, to be attached above to the dorsum of the ilium higher than the reflected tendon of the rectus, and posteriorly to the ilium and ischium nearly as far as the sciatic notch. As this expansion passes over the long tendon of the *rectus*, the tendon may be described as being in part contained within the substance of the capsule.

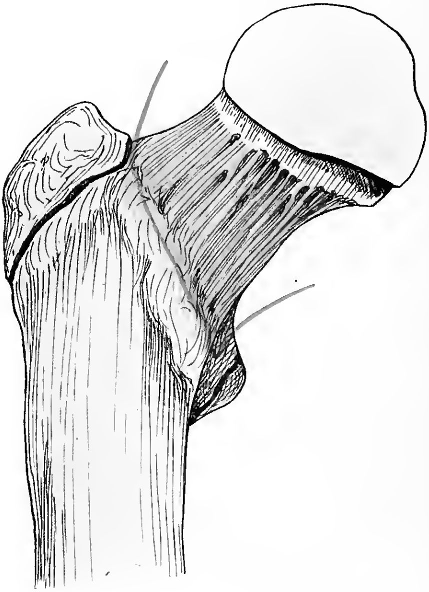
At the **femur,** the capsule is fixed to the anterior portion of the upper border of the great trochanter and to the cervical tubercle. Thence it runs down, the intertrochanteric line as far as the medial border of the femur, where it is on a level with the lower part of the lesser trochanter. It then runs upward and backward along an oblique line about 1.6 cm. ($\frac{2}{3}$ in.) in front of the lesser trochanter, and continues its ascent along the back of the neck nearly parallel to the intertrochanteric crest, and from 12 to 16 mm. ($\frac{1}{2}$ to $\frac{2}{3}$ in.) above it; finally, it passes along the medial side of the trochanteric fossa to reach the anterior superior angle of the great trochanter.

On laying open the capsule, some of the deeper fibres are seen reflected upward along the neck of the femur, to be attached much nearer the head: these are the **retinacula**. One corresponds to the upper, and another to the lower, part of the intertrochanteric line; a third is seen at the upper and back part of the neck. They form flat bands,which lie on the femoral neck.

Superadded to the capsule, and considerably strengthening it, are three auxiliary bands, whose fibres are intimately blended with, and in fact form part of, the capsule, viz., the ilio-femoral, ischio-capsular, and pubo-capsular ligaments.

The **ilio-femoral ligament** (fig. 306) is the longest, widest, and strongest of the bands. It is of triangular shape, with the apex attached above to a curved line on the ilium immediately below and behind the anterior inferior spine, and its base below to the anterior edge of the greater trochanter and to the spiral line as far as the medial border of the shaft. The highest or most lateral fibres are coarse, almost straight, and shorter than the rest; the most medial fibres are also thick and strong, but oblique. This varying obliquity of the fibres, and their accumulation at the borders, explain why this band has been described as the **Y**-shaped ligament; but it

Fig. 307.—Upper Extremity of the Femur (Anterior View), to show the Relation of the Articular Capsule of the Hip-joint (in red) to the Epiphysial Lines.



should be noted that the **Y** is inverted. About the centre of its base, near the femoral attachment, is an aperture transmitting an articular twig from the ascending branch of the external circumflex artery.

The **ischio-capsular ligament** (fig. 308) is formed of very strong fibres attached all along the upper border of the groove for the external obturator, and to the ischial margin of the acetabulum above the groove. The highest of these incline a little upward as they pass laterally to be fixed to the greater trochanter in front of the insertion of the piriformis tendon, while the other fibres curve more and more upward as they pass laterally to their insertion at the inner side of the trochanteric fossa, blending with the insertion of the external rotator tendons. When the joint is in flexion, these fibres pass in nearly straight lines to their femoral attachment, and spread out uniformly over the head of the femur; but in extension they wind over the back of the femur in a zonular manner [zona orbicularis], embracing the posterior aspect of the neck of the femur.

The **pubo-capsular (pectineo-femoral) band** (fig. 306) is a distinct but narrow set of fibres which are individually less marked than the fibres of the other two bands; they are fixed above to the obturator crest and to the anterior border of the ilio-pectineal eminence, reaching as far down as the pubic end of the acetabular notch. Below, they reach the neck of the femur, and are fixed above and behind the lowermost fibres of the ilio-femoral band, with which they blend.

In **thickness** and strength the capsule varies greatly; thus, if two lines be drawn, one from the anterior inferior spine to the medial border of the femur near the lesser trochanter, and the other from the anterior part of the groove for the

Fig. 308.—Posterior View of the Articular Capsule of the Hip-joint.

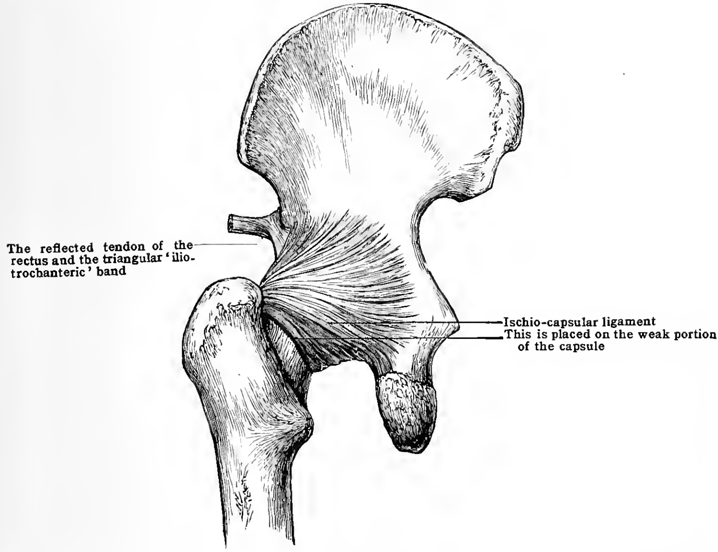


Fig. 309.—Section through the Hip-joint, showing the Glenoid Lip, Ligamentum Teres, and Retinacula.

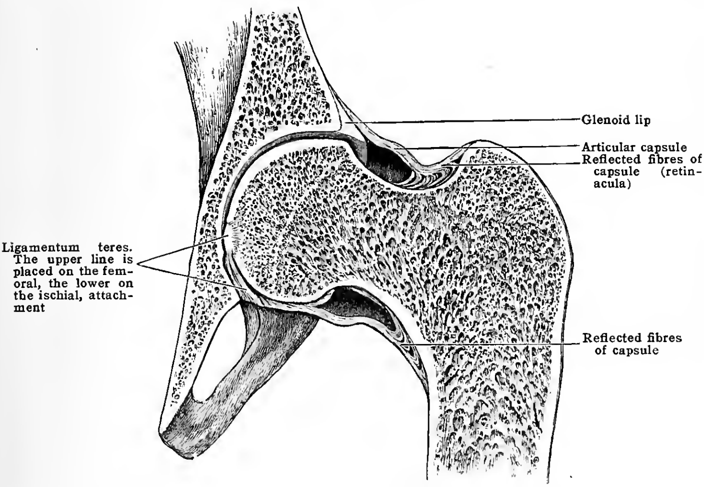
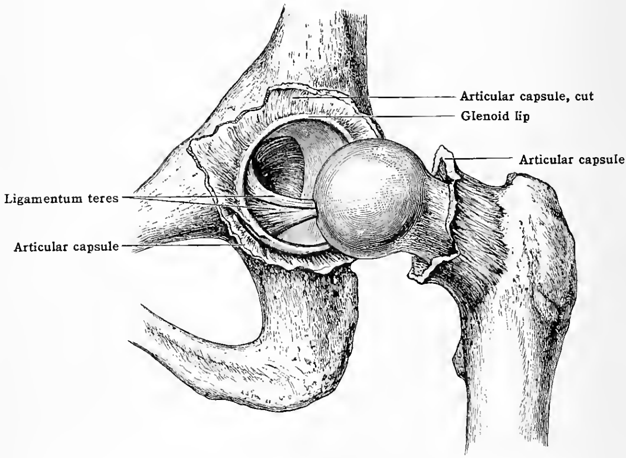


external obturator to the trochanteric fossa, all the ligament between these lines on the lateral and upper aspects of the joint is very thick and strong, while that below and to the medial side, except at the narrow pubo-capsular ligament, is thin and weak, so that the head of the bone can be seen through it. The capsule is thickest in the course of the ilio-femoral ligament, toward the lateral part of which it measures over 6 mm. ($\frac{1}{4}$ in.). Between the ilio-femoral and ischio-capsular ligaments the capsule is very strong, and with it here, near the acetabulum, is incorporated the reflected tendon of the rectus, and here also a triangular band of fibres runs downward and forward to be attached by a narrow insertion to the ridge on the front border of the greater trochanter near the gluteus minimus (the **ilio-trochanteric band**) (fig. 308).

The capsule is strengthened also at this point by a strong band from the under surface of the gluteus minimus, and by the **tendino-trochanteric band** which passes down from the reflected tendon of the rectus to the vastus lateralis (externus) (fig. 306). This is closely blended with the capsule near the lateral edge of the ilio-femoral ligament.

The thinnest part of the capsule is between the pubo-capsular and ilio-femoral ligaments; this is sometimes perforated, allowing the bursa under the psoas to communicate with the joint. The capsule is also very thin at its attachment to the back of the femoral neck, and again opposite the acetabular notch.

FIG. 310.—HIP-JOINT AFTER DIVIDING THE ARTICULAR CAPSULE AND DISARTICULATING THE FEMUR.



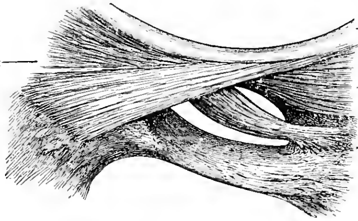
The **ligamentum teres** (figs. 309 and 310) is an interarticular flat band which extends from the acetabular fossa to the head of the femur, and is usually about 3.7 cm. ($1\frac{1}{2}$ in.) long. It has two bony attachments, one on either side of the acetabular notch immediately below the articular cartilage, while intermediate fibres spring from the lower surface of the transverse ligament. The ischial portion is the stronger, and has several of its fibres arising outside the cavity, below and in connection with the origin of the transverse ligament, where it is also continuous with the capsule and periosteum of the ischium. At the femur it is fixed to the front part of the depression on the head, and to the cartilage round the margin of the depression.

It is covered by a prolongation of synovial membrane, which also covers the cushion of fat in the recess of the acetabulum; the portion of the membrane reflected over the fatty tissue does not cling closely to the round ligament, but forms a triangular fold, the apex of which is at the femur.

The **transverse ligament** (fig. 311) passes across the acetabular notch and converts it into a foramen; it supports part of the glenoid fibro-cartilage, and is connected with the ligamentum teres and the capsule. It is composed of decussating fibres, which arise from the margin of the acetabulum on either side of the notch, those coming from the pubis being more superficial, and passing to form the deep part of the ligament at the ischium, while those superficial at the ischium are deep at the pubis. It thus completes the rim of the acetabulum.

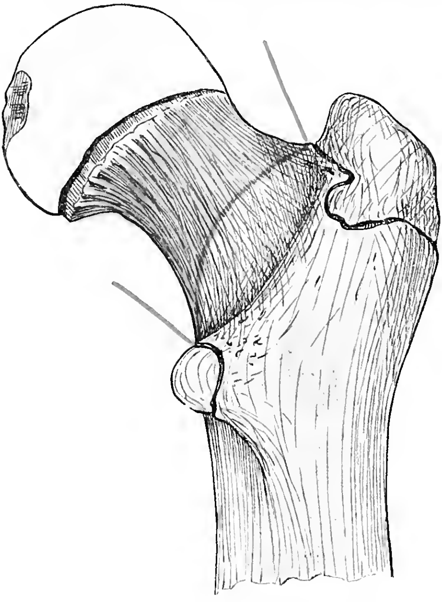
The **glenoid lip** (cotyloid fibro-cartilage) (figs. 309 and 310) is a yellowish-white structure, which deepens the acetabulum by surmounting its margin. It

Fig. 311.—Portions of Ischium and Pubis, showing the Acetabular Notch and the Ligamentum Teres attached outside the Acetabulum.



varies in strength and thickness, but is stronger at its iliac and ischial portions than elsewhere. Its base is broad and fixed to the bony rim as well as to the articular cartilage of the acetabulum on the inner, and the periosteum on the outer, side of it, and blends inseparably with the transverse ligament which supports it over the acetabular notch.

Fig. 312.—The Upper Extremity of the Femur (Posterior View), to show the Relation of the Articular Capsule of the Hip-joint (in red) to the Epiphysial Lines.



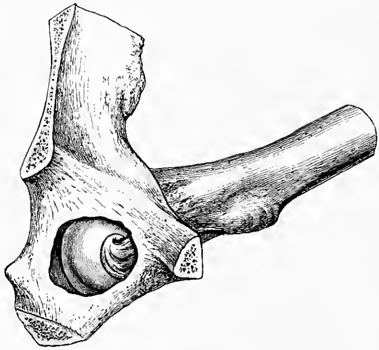
Its free margin is thin; on section it is somewhat lunated, having its outer surface convex and its articular face concave and very smooth in adaptation to the head of the bone, which it tightly embraces a little beyond its greatest circumference. It somewhat contracts the aperture of the acetabulum, and retains the head of the femur within its grasp after division of the muscles and capsular ligament. It is covered on both aspects by synovial membrane.

The **synovial membrane** lines the capsule and both surfaces of the glenoid lip, and passes over the border of the acetabulum to reach and cover the fatty cushion it contains. The part covering the fatty cushion is unusually thick, and is attached round the edges of the rough bony surface on which the cushion rests. The membrane is loosely reflected off this on to the ligamentum teres, along which it is prolonged to the head of the femur; thus the fibres of the round ligament are shut out from the joint cavity. From the capsule the synovial membrane is also reflected below on to the neck of the femur, whence it passes over the retinacula to the margin of the articular cartilage. A fold of synovial membrane on the under aspect of the neck often conveys to the head of the femur a branch of an artery—generally a branch of the medial circumflex.

The **arterial supply** comes from—(*a*) the transverse branches of the medial and lateral circumflex arteries; (*b*) the lateral branch of the obturator sends a branch through the acetabular notch beneath the transverse ligament, which ramifies in the fat at the bottom of the acetabulum, and travels down the round ligament to the head of the femur; (*c*) the inferior branch of the deep division of the superior gluteal; and (*d*) the inferior gluteal (sciatic) arteries. The branch from the obturator to the ligamentum teres is sometimes very large when the branch from the medial circumflex does not also supply the ligament.

The superior and inferior gluteal send several branches through the innominate attachment

Fig. 313.—Ligamentum Teres, lax in Flexion.



of the articular capsule: these anastomose freely beneath the capsule around the outer aspect of the acetabulum, and supply some branches to enter the bone, and others which enter the substance of the glenoid lip. There is quite an arterial crescent upon the posterior and postero-superior portions of the acetabulum; but no vessels are to be seen on the inner aspect of the glenoid lip.

The **nerve-supply** comes from—(*a*) femoral (anterior crural), (*b*) anterior division of the obturator, (*c*) the accessory obturator, and (*d*) the sacral plexus, by a twig from the nerve to the quadratus femoris, or from the upper part of the great sciatic, or from the lower part of the sacral plexus.

Relations.—In *front* and in contact with the capsule are the psoas bursa, the tendinous part of the psoas magnus, and the iliacus. Still more anteriorly and not in contact are the femoral artery, the femoral (anterior crural) nerve, the rectus femoris, the sartorius, and the tensor fasciæ latæ.

Above and in close relation with the capsule are the piriformis, the obturator internus and the gemelli, and the reflected head of the rectus femoris, whilst more superficially lie the gluteus minimus and medius.

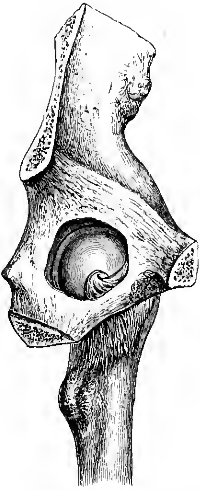
Behind and in close relation with the capsule are the obturator externus, the gemelli and obturator internus, and the piriformis. More superficially lie the quadratus femoris, the sciatic nerves, and the gluteus maximus.

Below the obturator externus, the pectineus, and the medial circumflex artery are in close relation with the capsule.

The movements.—The hip-joint, like the shoulder, is a ball-and-socket joint, but with a much more complete socket and a corresponding limitation of movement. Each variety of movement is permitted, viz., flexion, extension, abduction, adduction, circumduction, and rotation; and any two or more of these movements not being antagonistic can be combined, i. e., flexion or extension associated with abduction or adduction can be combined with rotation in or out.

It results from the obliquity of the neck of the femur that the movements of the head in the acetabulum are always more or less of a rotatory character. This is more especially the case during flexion and extension, and two results follow from it. First, the bearing surfaces of the femur and acetabulum preserve their apposition to each other, so that the amount of articular surface of the head in the acetabulum does not sensibly diminish *pari passu* with the transit of the joint from the extended to the flexed position, as would necessarily be the case if the movement of the femoral head, like that of the thigh itself, was simply angular, instead of rotatory and angular. Secondly, as rotation of the head can continue until the ligaments are tight without being checked by contact of the neck of the thigh bone with the rim of the acetabulum, flexion of the thigh so far as the joint is concerned is practically unlimited. Flexion is the most important, most frequent, and most extensive movement, and in the dissected limb, before the ligaments are disturbed, can be carried to 160°, and is then checked by the lower fibres of the ischio-capsular ligament. In the living subject simple flexion can continue until checked by the contact of the soft parts at the groin, if the knee be bent; if the knee be straight, flexion of the hip is checked in most persons by the hamstring muscles at nearly a right angle. This is very evident on trying to touch the ground with the fingers without bending the knees, the chief strain being felt at the popliteal space. This is due to the shortness of the hamstrings. Extension is limited by the ilio-femoral ligament.

Fig. 314.—Ligamentum Teres, very lax in Complete Extension.



Abduction and lateral rotation can be performed freely in every position of flexion and extension—abduction being limited by the pubo-capsular ligament; lateral rotation by the ilio-femoral ligament, especially its medial portion, during extension; but by the lateral portion, as well as by the ligamentum teres, during flexion.

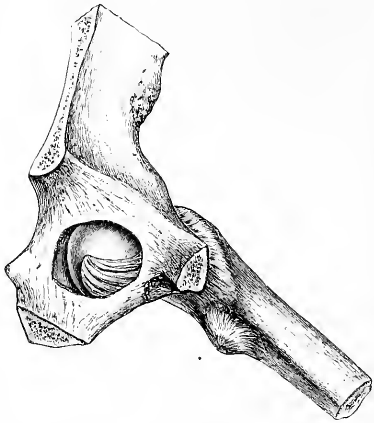
Adduction is very limited in the extended thigh on account of the contact with the opposite limb. In the slightly flexed position adduction is more free than in extension, and is then limited by the lateral fibres of the ilio-femoral band and the superior portion of the capsule. In flexion the range is still greater, and limited by the ischio-capsular ligament, the ligamentum teres being also rendered nearly tight. Medial rotation in the extended position is limited by the lower fibres of the ilio-femoral ligament; and in flexion by the ischio-capsular ligament and the portion of the capsule between it and the ilio-femoral band.

The ilio-femoral band also prevents the tendency of the trunk to roll backward on the thigh bones in the erect posture, and so does away with the necessity for muscular power for this purpose; it is put on stretch in the stand-at-ease position.

The ligamentum teres is of little use in resisting violence or in imparting strength to the joint. It assists in checking lateral rotation, and adduction during flexion. A ligament can only be of use when it is tight, and it was found by trephining the bottom of the acetabulum, removing the fat, and threading a piece of whipcord round the ligament, that the ligament was slack in simple flexion, and very loose in complete extension, but that its most slack condition was in abduction. It is tightest in flexion combined with adduction and lateral rotation and almost as tight in flexion with lateral rotation alone, and in flexion with adduction alone (figs. 313–315).

Muscles which act upon the hip-joint.—*Flexors.*—The psoas and iliacus, the rectus femoris, the pectineus, the adductors, the sartorius, the tensor fasciæ latæ, and the gluteus medius.

Fig. 315.—Ligamentum Teres, drawn Tight in Flexion Combined with Lateral Rotation and Adduction.



Extensors.—The gluteus maximus, the posterior fibres of the glutei medius and minimus, the biceps, the semitendinosus, the semimembranosus, and the ischial fibres of the adductor magnus; also (slightly) the piriformis, obturator internus and gemelli. *Abductors.*—Gluteus maximus (upper fibres), tensor fasciæ latæ, gluteus medius, gluteus minimus, and, when the joint is flexed, the piriformis, obturator internus, the gemelli, and the sartorius also become abductors. *Adductors.*—Adductores magnus, longus, brevis, and minimus, semitendinosus, biceps, the gracilis, the pectineus, the quadratus femoris, and the lower fibres of the gluteus maximus. *Medial rotators.*—Psoas (slightly), adductor magnus, semimembranosus, the anterior fibres of the gluteus medius and minimus, and the tensor fasciæ latæ. *Lateral rotators.*—Gluteus maximus, posterior fibres of gluteus medius and minimus, the adductors, obturator externus, quadratus femoris, obturator internus, the gemelli, and the piriformis when the joint is extended.

2. THE KNEE-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

The knee is the largest joint in the body. It is rightly described as a ginglymoid joint, but there is also an arthrodial element; for, in addition to flexion and extension, there is a sliding backward and forward of the tibia upon the femoral condyles, as well as slight rotation round a vertical axis. It is one of the most superficial, and, as far as adaptation of the bony surfaces goes, one of the weakest joints, for in no position are the bones in more than partial contact. Its strength lies in the number, size, and arrangement of the ligaments, and the powerful muscles and fascial expansions which pass over the articulation and enable it to withstand the leverage of the two longest bones in the body. It may be said to consist of two articulations with a common synovial membrane—the patello-femoral and the tibio-femoral, the latter being double. It is composed of the condyles and trochlear surface of the femur, the condyles of the tibia, and the patella, united by the following ligaments, which may be divided into an external and internal set:—

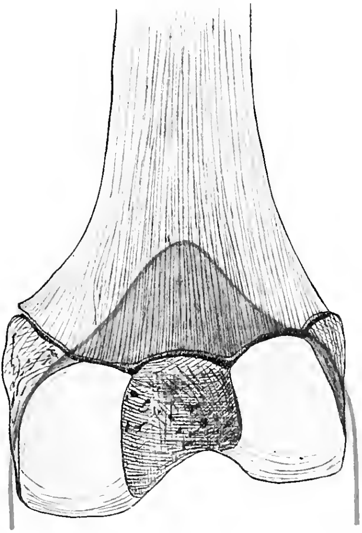
External	Internal
(1) Fibrous expansion of the extensors.	(1) Anterior crucial.
(2) Articular capsule.	(2) Posterior crucial.
(3) Oblique popliteal ligament.	(3) Medial meniscus.
(4) Fibular collateral.	(4) Lateral meniscus.
(5) Tibial collateral.	(5) Coronary.
(6) Ligamentum patellæ	(6) Transverse.

External Ligaments

Superficial to the fibrous expansion of the quadriceps extensor tendons the fascia lata of the thigh covers the front and sides of the knee-joint.

The deep fascia of the thigh, as it descends to its attachment to the tuberosity and oblique lines of the tibia, not only overlies but blends with the fibrous expansion of the extensor tendons. The oblique lines of the tibia curve upward and backward from the tuberosity on each side to the postero-lateral part of the condyles. The process of fascia attached to the lateral ridge of the tibia and to the head of the fibula descends from the tensor fasciæ latæ and is very thick and strong. It is firmly blended with the tendinous fibres of the vastus lateralis. The fascia lata, on the medial side of the patella, besides being attached to the medial oblique ridge of the tibia, sends some longitudinal fibres lower down to become blended with the fibrous expansion of the sartorius. The fascia is much thinner on the medial side of the patella than on the lateral, and blends much less with the tendon of the vastus medialis than the lateral part of the fascia does with the vastus lateralis. A thin layer of the fascia lata in the form of transverse or arciform fibres passes over the front of the joint. These fibres are specially well marked over the ligamentum patellæ, and blend here with the central portion of the quadriceps extensor fibres.

Fig. 316.—The Lower Extremity of the Femur (Posterior View), to show the Relation of the Articular Capsule of the Knee-joint (in red) to the Epiphysial Line.



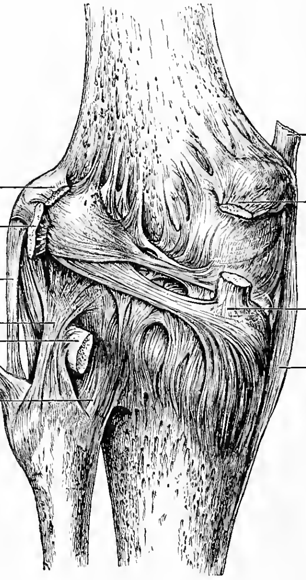
The **fibrous expansion of the extensor tendons** consists—(1) of a central portion, densely thick and strong, 3.7 cm. ($1\frac{1}{2}$ in.) broad, which is inserted into the anterior two-thirds of the upper border of the patella, many of its superficial fibres passing over the subcutaneous surface of the bone into the ligamentum patellæ; (2) of two side portions thinner, but strong.

The side portions are inserted into the patella along its upper border on either side of the central portion and also into its medial and lateral borders, nearer the anterior than the posterior surface, as low down as the attachment of the ligamentum patellæ; passing thence along the sides of the ligamentum patellæ to the tibia, they are attached to the oblique lines which extend from the tuberosity to the medial and lateral condyles, and reach as far as the tibial and fibular collateral ligaments. On the lateral side, the fibres blend with the ilio-tibial band of the fascia lata, and on the medial they extend below the oblique line to blend with the periosteum of the shaft. Thus there is a large hood spread over the whole of the front of the joint, investing the patella, and reaching from the sides of the ligamentum patellæ to the collateral ligaments, attached below to the tibia, and separated everywhere from the synovial membrane by a layer of fatty tissue.

The **ligamentum patellæ** (fig. 320) is the continuation in line of the central portion of the conjoined tendon, some fibres of which are prolonged over the front of the patella into the ligament. It is an extremely strong, flat band, attached above to the lower border of the patella; below, it is fixed to the lower part of the tuberosity and upper part of the crest of the tibia, somewhat obliquely, being prolonged downward further on the lateral side, so that this border is fully 2.5 cm. (1 in.) longer than the medial, which measures 6.7 cm. ($2\frac{1}{2}$ in.) in length. Behind, it is in contact with a mass of fat which separates it from the synovial membrane, and a small bursa intervenes between it and the head of the tibia. In front, a large bursa separates it from the subcutaneous tissue, and at the sides it is continuous with the fibrous expansion of the extensors.

The **tibial** (internal) **collateral ligament** (fig. 317) is a strong, flat band, which extends from the depression on the tubercle on the medial side of the medial

FIG. 317.—POSTERIOR VIEW OF THE KNEE-JOINT.



epicondyle of the femur, to the medial border and medial surface of the shaft of the tibia, 3.7 cm. ($1\frac{1}{2}$ in.) below the condyle. It is 8.7 cm. ($3\frac{1}{2}$ in.) long, well defined anteriorly, where it blends with the expansion of the conjoined extensor tendons; but not so well defined posteriorly, where it merges into the oblique popliteal ligament.

Some of the lower fibres blend with the descending portion of the *semimembranosus* tendon, Its deep surface is firmly adherent to the edge of the medial meniscus and coronary ligament. while part of the *semimembranosus tendon* and *inferior medial articular vessels* and *nerve* pass between it and the bone. Superficially, a bursa separates it from the tendons of the *gracilis* and *semitendinosus* muscles and from the aponeurosis of the *sartorius* muscle.

The **fibular** (external) **collateral ligament** (fig. 317) consists of two portions: the **anterior,** which is the longer and better marked, is a strong, rounded cord, about 5 cm. (2 in.) long, attached above to the tubercle on the lateral side of the lateral epicondyle of the femur, just below and in front of the origin of the lateral head of the *gastrocnemius*, whilst the *tendon* of the *popliteus* arises from the groove below and in front of it. Below, it is fixed to the middle of the lateral surface of the head of the fibula, 1.25 cm.($\frac{1}{2}$) in. or more anterior to the apex.

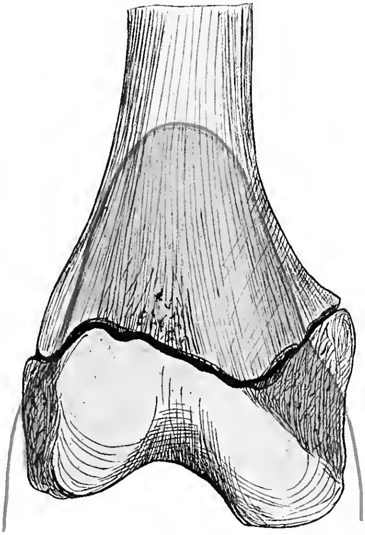
Superficially is the tendon of the *biceps,* which splits to embrace its lower extremity; while beneath it pass the *popliteus tendon* in its sheath, and the *inferior lateral articular vessels* and *nerve*.

Some fibres of the peroneus longus occasionally arise from the lower end of the ligament. The **posterior** portion is 8 mm. ($\frac{1}{3}$ in.) behind the anterior. It is broader and less defined; fixed below to the apex of the fibula, it inclines upward and somewhat backward, and ties down the *popliteus* against the lateral condyle of the tibia, blending beneath the lateral head of the *gastrocnemius* with the oblique popliteal ligament of the knee, of which it is really a portion.

The **oblique popliteal ligament** or ligamentum Winslowii (fig. 317) is a broad dense structure of interlacing fibres, with large orifices for vessels and nerves. It is attached above to the femur close to the articular margins of the condyles, stretching across the upper margin of the intercondyloid fossa, to which it is connected by fibro-fatty tissue; it thus reaches across from the tibial to the fibular collateral ligaments. Below, it is fixed to the border of the lateral condyle of the tibia, to the bone just below the posterior intercondyloid notch, and to the shaft of the tibia below the medial condyle, blending with the descending slip of the *semimembranosus* and tibial collateral ligament.

Superficially, an oblique fasciculus from the *semimembranosus* runs across the centre, passing upward and laterally from near the back part of the medial condyle of the tibia to the lateral

FIG. 318.—THE LOWER EXTREMITY OF THE FEMUR (ANTERIOR VIEW) TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE KNEE-JOINT (IN RED) TO THE EPIPHYSIAL LINE.



epicondyle of the femur, where it joins the lateral head of the gastrocnemius, a sesamoid plate being sometimes developed at the point of junction. This slip greatly strengthens the oblique popliteal ligament, of which, if not the chief constituent, it is at least a very important part.

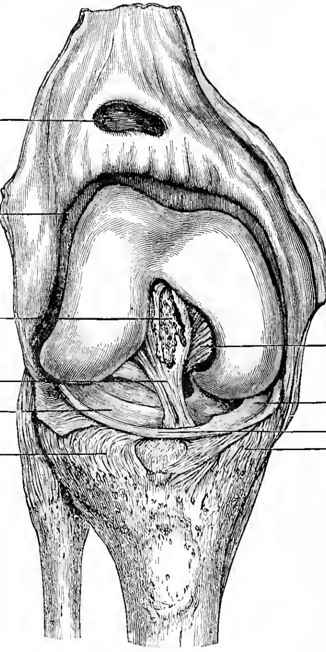
Its deep surface is closely connected with the semilunar menisci (especially the medial) and coronary ligaments, and in the interval between the cartilages with the posterior crucial ligament and fibro-fatty tissue within the joint. Superficially it forms part of the floor of the popliteal space. A special band, the arcuate ligament, is sometimes found extending from the lateral epicondyle to the oblique ligament.

The **articular capsule** (fig. 319) is thin but strong, covering the synovial membrane, and looking like a loose sac. It is attached to the femur near the articular margin on the medial side, but further away on the lateral; it passes beneath the fibular collateral ligament to join the sheath of the *popliteus*. Medially it joins the tibial collateral ligament. Below, it is fixed to the upper as well as the medial and lateral borders of the patella and the anterior border of the head of the tibia. It is strengthened superficially between the femur and patella by an expansion from the *articularis genu* (*sub-crureus*) and is separated from the fibrous expansion of the extensor tendon by a layer of fatty tissue. The synovial membrane lines its deep surface, and holds it against the borders of the semilunar menisci; it is also attached to the coronary ligaments.

Internal Ligaments

The **anterior crucial ligament** (figs. 319 and 320) is strong and cord-like. It is attached to the medial half of the fossa in front of the intercondyloid eminence of the tibia, and to the lateral border of the medial articular facet as far back as the medial intercondyloid tubercle. It passes upward, backward, and laterally to the back part of the medial surface of the lateral condyle of the femur. To

Fig. 319.—Anterior View of the Internal Ligaments of the Knee-joint.



the tibia, it is fixed behind the anterior extremity of the medial semilunar meniscus. Behind and to the lateral side it has the anterior extremity of the lateral meniscus, a few fibres of which blend with the lateral edge of the ligament.

Its anterior fibres at the tibial end are strongest and longest; being fixed highest on the femur; while the posterior, springing from the intercondyloid eminence, are shorter and more oblique. Near the spine, a slip is sometimes given off to the posterior crucial ligament.

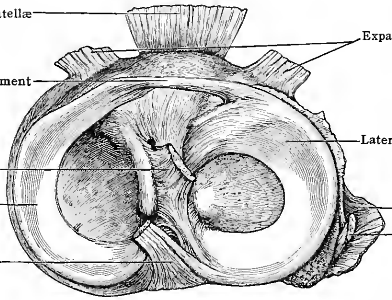
The **posterior crucial ligament** (fig. 319, 320, and 322) is stronger and less oblique than the anterior. It is fixed below to the greater portion of the fossa behind the intercondyloid eminence of the tibia, especially the lateral and posterior portion, and then medially along the posterior intercondyloid fossa; being joined by fibres which arise between the intercondyloid tubercles, it ascends to the anterior part of the lateral surface of the medial condyle of the femur, having a wide crescentic attachment 1.5 cm. ($\frac{3}{5}$ in.) in extent just above the articular surface.

Behind, it is connected at the tibia directly with the posterior ligament, and a little higher up by means of a quantity of interposed areolar tissue. In front it rests upon the posterior horn of the medial semilunar meniscus, and receives a large slip from the lateral meniscus, which ascends along it, either in front or behind, to the femur; higher up in front it is connected with the anterior crucial ligament.

Until they rise above the intercondyloid eminence of the tibia the two crucial ligaments are closely bound together, so that no interspace exists between their tibial attachments and the point of decussation; the only space between them is therefore a V-shaped one corresponding to the upper half of their X-shaped arrangement, and this is a mere chink in the undissected state, and can be seen from the front only, owing to the fatty tissue beneath the synovial membrane which surrounds their femoral attachment.

The interarticular menisci or semilunar fibro-cartilages (figs. 319 and 320) are two crescentic discs resting upon the circumferential portions of the articular facets of the tibia, and moving with the tibia upon the femur. They somewhat deepen the tibial articular surfaces, and are dense and compact in structure, becoming looser and more fibrous near their extremities, where they are firmly fixed in front of and behind the intercondyloid eminence of the tibia. The circumferential border of each is convex, thick, and somewhat loosely attached to the borders of the condyles of the tibia by the coronary ligaments and the reflexion of the synovial membrane. The inner border is concave, thin, and free. Half an inch (1.3 cm.) broad at the widest part, they taper somewhat toward their

FIG. 320.—STRUCTURES LYING ON THE HEAD OF THE TIBIA. (Right knee.)



extremities, and cover rather less than two-thirds of the articular facets of the tibia. Their upper surfaces are slightly concave, and fit on to the femoral condyles, while the lower are flat and rest on the head of the tibia; both surfaces are smooth and covered by synovial membrane.

The **lateral meniscus** (fig. 320) is nearly circular in form and less firmly fixed than the medial, and consequently slides more freely upon the tibia. Its anterior cornu is attached to a narrow depression along the lateral articular facet, just in front of the lateral intercondyloid tubercle of the tibia, close to, and on the lateral side of, the anterior crucial ligament; a small slip from the cornu is often fixed to the tibia in front of the crucial ligament. The posterior cornu is firmly attached to the tibia behind the lateral intercondyloid tubercle, blending with the posterior crucial ligament, and giving off a well-marked fasciculus, which runs up along the anterior border of the ligament to be attached to the femur (ligament of Wrisberg). It also sends a narrow slip into the back part of the anterior crucial ligament. Its outer border is grooved toward its posterior part by the *popliteus* tendon, which is held to it by fibrous tissue and synovial membrane, and separates it from the fibular collateral ligament. From its anterior border is given off the transverse ligament.

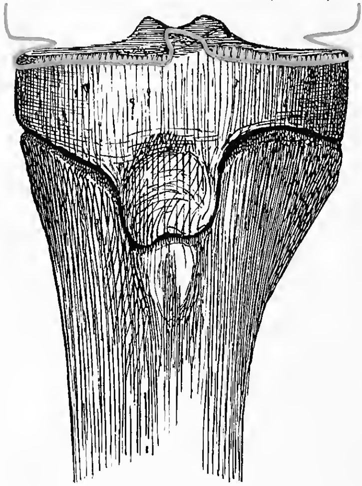
The **medial meniscus** (fig. 320) is a segment of a larger circle than the lateral, and has an outline more oval than circular. Its anterior cornu is wide, and has a broad and oblique attachment to the anterior margin of the head of the tibia. It reaches from the margin of the condyle toward the middle of the fossa in front of the intercondyloid eminence, being altogether in front of the anterior crucial ligament. The posterior cornu is firmly fixed by a broad insertion in an antero-posterior line along the medial side of the posterior intercondyloid fossa, from the medial tubercle to the posterior margin of the head of the tibia. Its convex border is connected with the tibial collateral ligament and the *semimembranosus* tendon.

The **transverse ligament** (figs. 319 and 320) is a rounded, slender, short cord, which extends from the convex border of the lateral meniscus to the concave border or anterior cornu of the medial, near which it is sometimes attached to the bone. It is an accessory band of the lateral meniscus, and is situated beneath the synovial membrane.

The **coronary ligaments** (fig. 319) connect the margins of the semilunar discs with the head of the tibia. The lateral is much more lax than the medial, permitting the lateral disc to change its position more freely than the medial. They are not in reality separate structures, but consist of fibres of the several surrounding ligaments of the knee-joint which become attached to the margins of the discs as they pass over them.

The **synovial membrane** (fig. 324) of the knee forms the largest synovial sac in the body. Bulging upward from the patella, it follows the capsule of the joint into a large *cul-de-sac* beneath the tendon of the extensor muscles on the front of the femur. It reaches some distance beyond the articular surface of the bone, and communicates very frequently with a large bursa interposed between the tendon and the femur above the line of attachment of the articular capsule. After investing the circumference of the lower end of the femur, it is reflected upon the

Fig. 321.—The Upper Extremity of the Tibia (Anterior View), to show the Relation of the Articular Capsule of the Knee-joint (in red) to the Epiphysial Line.



fibrous envelope of the joint formed by the capsular, posterior, and collateral ligaments.

The synovial membrane covers a great portion of the crucial ligaments, but leaves uncovered the back of the posterior crucial where the latter is connected with the posterior ligament, and the lower part of both crucial ligaments where they are united. Thus the ligaments are completely shut out of the synovial cavity. Along the fibrous envelope the synovial membrane is conducted down to the semilunar menisci, over both surfaces of which it passes, and is reflected off the under surface on to the coronary ligaments, and thence down to the head of the tibia, around the circumference of which it extends a short way. It dips down between the external meniscus and the head of the tibia as low as the superior tibio-fibular ligament, reaching inward nearly as far as the intercondyloid notch, and forming a bursa for the play of the popliteal tendon.

At the back of the joint two pouches are prolonged beneath the muscles, one on each side between the condyle of the femur and the origin of the gastrocnemius. Large processes of synovial membrane also project into the joint, and being occupied by fat serve as padding to fill up spaces. The chief of these processes, the **patellar synovial fold** (ligamentum mucosum) (figs. 322 and 324), springs from the infrapatellar fatty mass. This so-called ligament is the central portion of the large process of synovial membrane, of which the alar folds form the free margins. It extends from the fatty mass, below the patella, backward and upward to the intercondyloid notch of the femur, where it is attached in front of the anterior crucial, and lateral to the posterior crucial ligament. Near the femur it is thin and transparent, consisting of a double fold of synovial membrane, but near the patella it contains some fatty tissue. Its anterior or upper edge is free, and fully 2.5 cm. (an inch) long; the posterior or lower edge is half the length, and is attached to the crucial ligaments above, but is free below.

Passing backward from the capsule on each side of the patella is a prominent crescentic fold formed by reduplications of the synovial membrane—these are the **alar folds** (fig. 322). Their free margins are concave and thin, and are lost below in the patellar fold. There is a slight fossa above and another below each ligament.

Fig. 322.—Anterior View of the Knee-joint, showing the Synovial Ligaments. (Anterior portion of capsule with the extensor tendon thrown downward.)

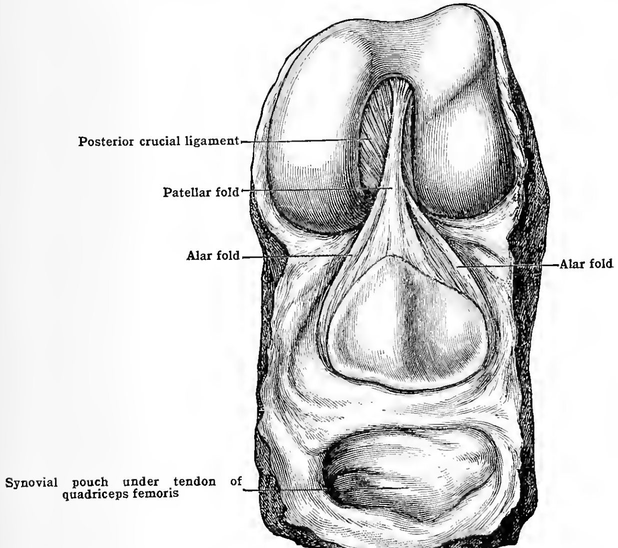


Fig. 323.—The Upper Extremity of the Tibia (Posterior View), to show the Relation of the Articular Capsule of the Knee-joint (in red) to the Epiphysial Line.

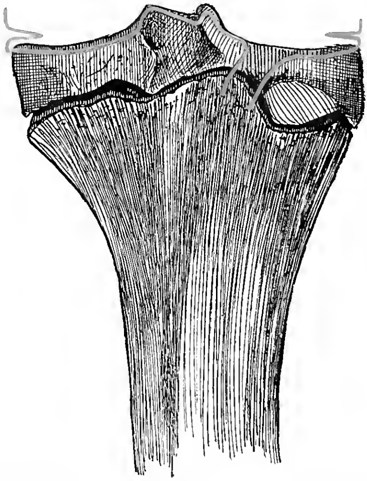
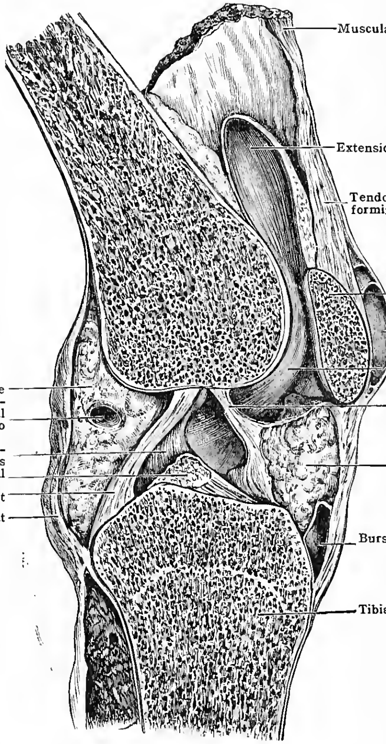


The **arterial supply** is derived from the art. genu suprema (anastomotica); the superior and inferior medial and lateral articular; the medial articular; the descending branch of the lateral circumflex; the anterior recurrent branch from the anterior tibial; and the posterior tibial recurrent.

The **nerve-supply** comes from the great sciatic, femoral, and obturator sources. The **great sciatic** gives off the tibial and common peroneal; the tibial sends two, sometimes three branches—one with the medial articular artery; one with the inferior medial, and sometimes one with the superior medial articular artery; the common peroneal gives a branch which accompanies the superior, and another which accompanies the inferior articular artery, and a recurrent branch which follows the course of the anterior recurrent branch of the anterior tibial artery. The **femoral** sends an articular branch from the nerve to the vastus lateralis; a second from the nerve to the vastus medialis; and sometimes a third from that to the vastus intermedius. Thus there are three articular twigs to the knee derived from the muscular branches of the femoral. The **obturator** by its deep division sends a branch through the adductor magnus on to the popliteal artery, which enters the joint posteriorly.

FIG. 324.—SAGITTAL SECTION OF THE KNEE-JOINT.
(The bones are somewhat drawn apart.)



Relations.—Anteriorly and at the sides the knee-joint is merely covered and protected by skin, fascia, and the tendinous expansions of the quadriceps extensor muscle. Laterally and posteriorly it is crossed by the biceps tendon. Medially and posteriorly lie the sartorius and the tendons of the gracilis and semitendinosus muscles. Posteriorly it is in relation with the popliteal vessels and nerves, the semimembranosus, the two heads of the gastrocnemius, and the plantaris. The tendon of the popliteus pierces the capsule behind and medial to the biceps tendon.

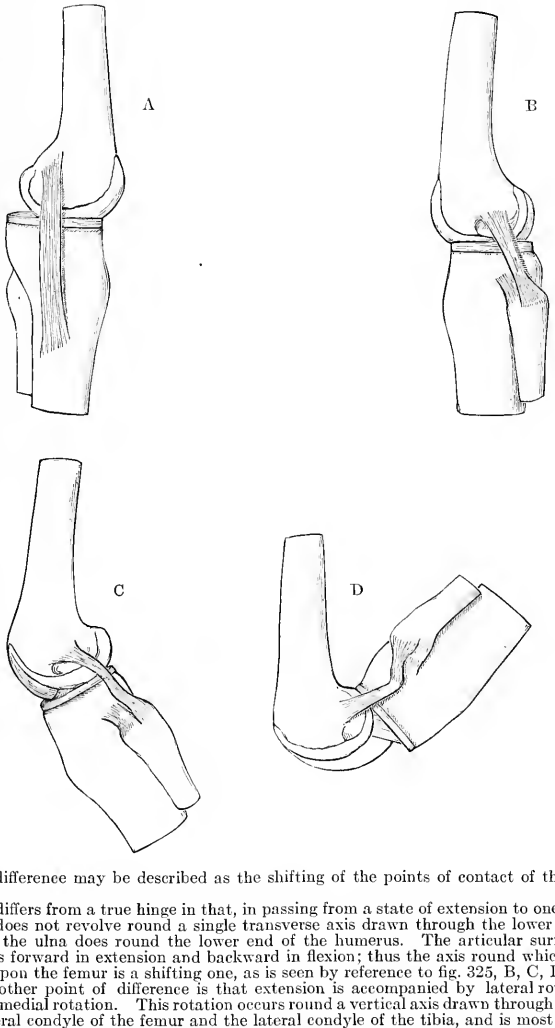
The **movements** which occur at the knee-joint are flexion and extension, with some slight amount of rotation in the bent position. These movements are not so simple as the corresponding ones at the elbow, for the knee is not a simple hinge joint. The movements of rotation instead of occurring between tibia and fibula, as between radius and ulna, are movements of the tibia with the fibula upon the condyles of the femur.

The knee differs from a true hinge joint, like the elbow or ankle, in the following particulars:—

1. The points of contact of the femur with the tibia are constantly changing. Thus, in

the flexed position, the posterior part of the articular surface of the tibia is in contact with the rounded back part of the femoral condyles; in the semiflexed position the middle parts of the tibial facets articulate with the anterior rounded part of the condyles; while in the fully extended position the anterior and middle parts of the tibial facets are in contact with the anterior flattened portion of the condyles. So with the patella: in extreme flexion the medial articular facet rests on the lateral part of the medial condyle of the femur; in flexion the upper pair of facets rests on the lower part of the trochlear surface of the femur; in mid-flexion the middle pair rests on the middle of the trochlear surface; while in extension the lower pair of facets on the patella rests on the upper portion of the trochlear surface of the femur.

Fig. 325.—The Collateral Ligaments of the Knee in Flexion and Extension.



This difference may be described as the shifting of the points of contact of the articular surface.

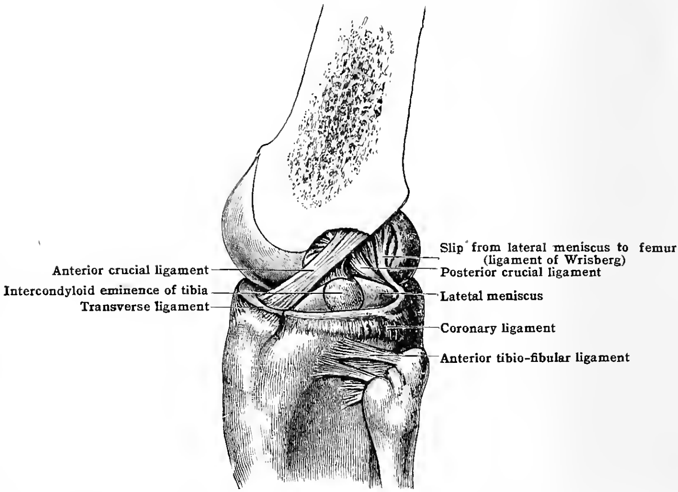
2. It differs from a true hinge in that, in passing from a state of extension to one of flexion, the tibia does not revolve round a single transverse axis drawn through the lower end of the femur, as the ulna does round the lower end of the humerus. The articular surface of the tibia slides forward in extension and backward in flexion; thus the axis round which the tibia revolves upon the femur is a shifting one, as is seen by reference to fig. 325, B, C, D.

3. Another point of difference is that extension is accompanied by lateral rotation, and flexion by medial rotation. This rotation occurs round a vertical axis drawn through the middle of the lateral condyle of the femur and the lateral condyle of the tibia, and is most marked at the termination of extension and at the commencement of flexion. This rotation of the leg at the knee is a true rotation about a vertical axis, and thus differs from the obliquity of the flexion

and extension movements at the elbow which is due to the oblique direction of the articular surfaces of the bones.

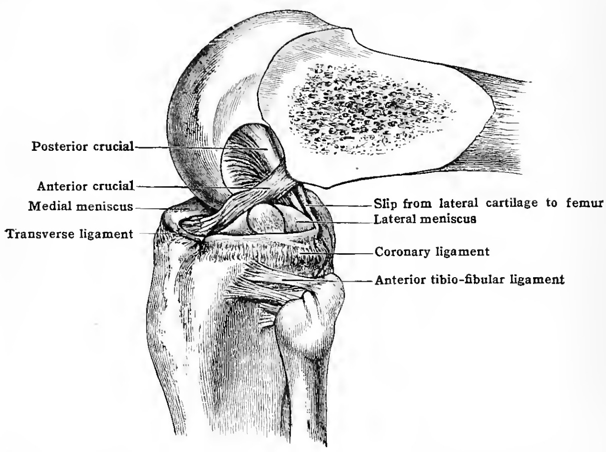
4. The antero-posterior spiral curve of the femoral condyles is such that the anterior part is an arc of a greater circle than the posterior; hence certain ligaments which are tightened during

FIG. 326.—SECTION OF KNEE, SHOWING CRUCIAL LIGAMENTS IN EXTENSION.



extension are relaxed during flexion, and thereby a considerable amount of rotatory movement is permitted in the flexed position. The axis of this rotation is vertical, and passes through the medial intercondyloid tubercle of the tibia, so that the lateral condyle moves in the arc of a larger circle than does the medial, and is therefore required to move more freely and easily;

FIG. 327.—CRUCIAL LIGAMENTS IN FLEXION.



hence the shape of the lateral articular facet and the loose connection of the lateral meniscus which is adapted to it.

In **extension,** all the ligaments are on the stretch with the exception of the ligamentum patellæ and front of the capsule. Extension is checked by both the crucial ligaments and the collateral ligaments (figs. 325, A, B, and 326).

In **flexion** the ligamentum patellæ and anterior portion of the capsule are on the stretch; so also is the posterior crucial in extreme flexion, though it is not quite tight in the semiflexed state of the joint. All the other ligaments are relaxed (fig. 325, C, D), although the relaxation of the anterior crucial ligament is slight in extreme flexion (fig. 327). Flexion is only checked during life by the contact of the soft parts, i. e., the calf with the back of the thigh.

Rotation medially is checked by the anterior crucial ligament; the collateral ligaments being loose.

Rotation laterally is checked by the collateral ligaments; the crucial ligaments have no controlling effect on it, as they are untwisted by it.

Sliding movements are checked by the crucial and collateral ligaments—sliding forward especially by the anterior, and sliding backward by the posterior crucial.

Muscles which act upon the knee-joint.—*Flexors.*—Biceps, semimembranosus, semitendinosus, sartorius, gastrocnemius, plantaris, and popliteus. *Extensor.*—Quadriceps extensor. **Medial** *Rotators.*—Sartorius, gracilis, semitendinosus, semimembranosus, popliteus. **Lateral** *Rotator.*—Biceps.

3. THE TIBIO-FIBULAR UNION

The fibula is connected with the tibia throughout its length by an interosseous membrane, and at the upper and lower extremities by means of two joints. Very little movement is permitted between the two bones.

(*a*) The **superior tibio-fibular joint.**
(*b*) The **middle tibio-fibular union.**
(*c*) The **inferior tibio-fibular joint.**

(*a*) The Superior Tibio-fibular Joint

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The superior tibio-fibular joint is about 6 mm.($\frac{1}{4}$ in.) below, and quite distinct from, the knee at its upper and anterior part; but at its posterior and superior aspect, where the border of the lateral condyle of the tibia is bevelled by the popliteus muscle, the joint is in the closest proximity to the bursa beneath the tendon of that muscle, and is only separated from the knee-joint by a thin septum of areolar tissue. There is often a communication between the synovial cavities of the two joints. The ligaments uniting the bones are:—

Articular capsule. Anterior tibio-fibular.

Posterior tibio-fibular.

The **articular capsule** is a well-marked fibro-areolar structure; it is attached close round the articular margins of the tibia and fibula. In front it is shut off completely from the knee-joint by the capsule of the knee and the coronary ligament; but behind, it is often very thin, and may communicate with the bursa under the popliteus tendon.

The **anterior tibio-fibular (capitular) ligament** (fig. 326) consists of a few fibres which pass upward and medially from the fibula to the tibia. It lies beneath the anterior portion of the tendon of the biceps.

The **posterior tibio-fibular (capitular) ligament** (fig. 317) consists of a few fibres which pass upward and medially between the adjacent bones, from the head of the fibula to the lateral condyle of the tibia.

The **superior interosseous ligament** consists of a mass of dense yellow fibroareolar tissue, binding the opposed surfaces of the bones together for 2 cm. ($\frac{3}{4}$ in.) below the articular facets. It is continuous with the interosseous membrane along the tibia.

The **biceps tendon** is divided by the fibular collateral ligament of the knee; of the two divisions the anterior is by far the stronger, and is inserted into the lateral condyle of the tibia as well as to the front of the head of the fibula, and thus the muscle, acting on both bones, tends to brace them more tightly together; indeed, it holds the bones strongly together after all other connections have been severed.

The **synovial membrane** which lines the joint sometimes communicates with the knee-joint through the bursa beneath the popliteus tendon.

The **arterial supply** is from the inferior lateral articular and recurrent tibial arteries.

The **nerve-supply** is from the inferior lateral articular, and also from the recurrent branch of the common peroneal.

Relations.—In front, the upper ends of the tibialis anterior, the extensor digitorum longus, and the peroneus longus. Behind, the tendon of the popliteus overlapped by the lateral head of the gastrocnemius. Laterally, the biceps tendon and the common peroneal nerve. Below and medially, the anterior tibial vessels.

The **movements** are but slight, and consist merely of a gliding of the two bones upon each other. The joint is so constructed that the fibula gives some support to the tibia in transmitting the weight to the foot. The articular facet of the tibia overhangs, and is received upon the articular facet of the head of the fibula in an oblique plane. This joint allows of slight yielding of the lateral malleolus during flexion and extension of the ankle-joint, the whole fibula gliding slightly upward in flexion, and downward in extension, of the ankle.

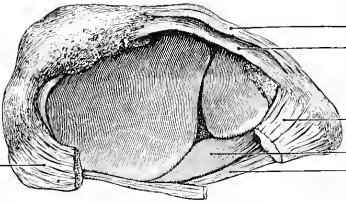
(*b*) The Middle Tibio-fibular Union

Class.—*Synarthrosis.* **Subdivision.**—*Syndesmosis.*

The **interosseous membrane** is attached along the lateral border of the tibia and the interosseous border of the fibula. It is deficient above for about 2.5 cm. (1 in.) or more, measured from the under aspect of the superior joint. Its upper border is concave, and over it pass the anterior tibial vessels.

The membrane consists of a thin aponeurotic and translucent lamina, formed of oblique fine fibres, some of which run from the tibia to the fibula, and some from the fibula to the tibia, but all are inclined downward. They are best marked at their attachment to the bones, and gradually grow denser and thicker as they approach the inferior interosseous ligament. The chief use of the membrane is to afford a surface for the origin of muscles. It is continuous below with the inferior interosseous ligament.

Fig. 328.—Lower Ends of Left Tibia and Fibula, showing the Ligaments. The synovial fold between these bones has been removed to show the transverse ligament forming part of the capsule of the joint, and the deeper fibres of the anterior lateral malleolar ligament which come into contact with the talus.
(From a dissection by Mr. W. Pearson, of the Royal College of Surgeons' Museum.)



In front of the interosseous membrane lie the tibialis anterior, the extensor digitorum longus, the extensor hallucis longus, and the anterior tibial vessels and nerves. Behind it is in relation with the tibialis posterior, the flexor hallucis longus, and the peroneal artery.

(*c*) The Inferior Tibio-fibular Articulation

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

This junction is formed by the lower ends of the tibia and fibula. The rough triangular surface on each of these bones formed by the bifurcation of their interosseous lines is closely and firmly united by the inferior interosseous ligament. The fibula is in actual contact with the tibia by an articular facet, which is small in size, crescentic in shape, and continuous with the articular facet of the malleolus.

The ligaments which unite the bones are:—

1. Anterior lateral malleolar ligament.
2. Posterior lateral malleolar ligament.
3. Transverse ligament.
4. Inferior interosseous ligament.

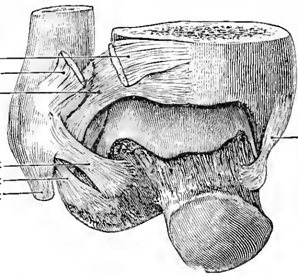
The **anterior lateral malleolar ligament** (anterior inferior tibio-fibular ligament) (figs. 328 and 334) is a strong triangular band about 2 cm. ($\frac{3}{4}$ in.) wide, and is attached to the lower extremity of the tibia at its anterior and lateral angle, close to the margin of the facet for the talus and passes downward and laterally to the anterior border and contiguous surface of the lower end of the fibula, some fibres passing along the edge nearly as far as the origin of the anterior talo-fibular ligament.

The fibres increase in length from above downward. In front it is in relation with the *peroneus tertius* and deep fascia of the leg, and gives origin to fibres of the anterior ligament of the ankle-joint. Behind, it lies in contact with the interosseous ligament, and comes into contact with the articular surface of the talus (see figs. 328 and 329).

The **posterior lateral malleolar ligament** (figs. 328 and 334) is very similar to the anterior, extending from the posterior and lateral angle of the lower end of the tibia downward and laterally to the lowest 1.5 cm. ($\frac{1}{2}$ in.) of the border separating the medial from the posterior surface of the shaft of the fibula, and to the upper part of the posterior border of the lateral malleolus. It is in relation in front with the interosseous ligament; below, it touches the transverse ligament.

The **inferior interosseous ligament** is a dense mass of short, felt-like fibres, passing transversely between and firmly uniting the opposed rough triangular surfaces at the lower ends of the tibia and fibula, except for 1 cm. ($\frac{3}{8}$ in.) at the extremity, where there is a synovial cavity. It extends from the anterior to the posterior lateral malleolar ligaments, reaching upward 4 cm. ($1\frac{1}{2}$ in.) in front, but only half this height behind.

Fig. 329.—Right Ankle-joint, showing the Ligaments.
(From dissection by Mr. W. Pearson, of the Royal College of Surgeons' Museum.)



The **transverse ligament** (fig. 331) is a strong rounded band, attached to nearly the whole length of the inferior border of the posterior surface of the tibia, just above the articular facet for the talus. It then inclines a little forward and downward, to be attached to the medial surface of the lateral malleolus, just above the fossa, and into the upper part of the fossa itself.

The **synovial membrane** is continuous with that of the ankle-joint; it projects upward between the bones beyond their articular facets as high as the inferior interosseous ligament.

The **nerve-supply** is the same as that of the ankle-joint; the **arterial supply** is from the peroneal and the anterior peroneal, and sometimes from the anterior tibial, or its lateral malleolar branch.

Relations.—In front of the inferior tibio-fibular joint are the anterior peroneal artery and the tendon of the peroneus tertius, and behind it are the posterior peroneal artery and the pad of fat which lies in front of the tendo Achillis.

The **movement** permitted at this joint is a mere gliding, chiefly in an upward and downward direction, of the fibula on the tibia. The bones are firmly braced together and yet form a slightly yielding arch, thus allowing a slight side to side expansion during extreme flexion, when the broad part of the talus is brought under the arch, by the upward gliding of the fibula on the tibia. To this end the direction of the fibres of the lateral malleolar ligaments is downward from tibia to fibula. This mechanical arrangement secures perfect contact of the articular surfaces of the ankle-joint in all positions of the foot.

4. THE ANKLE-JOINT

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

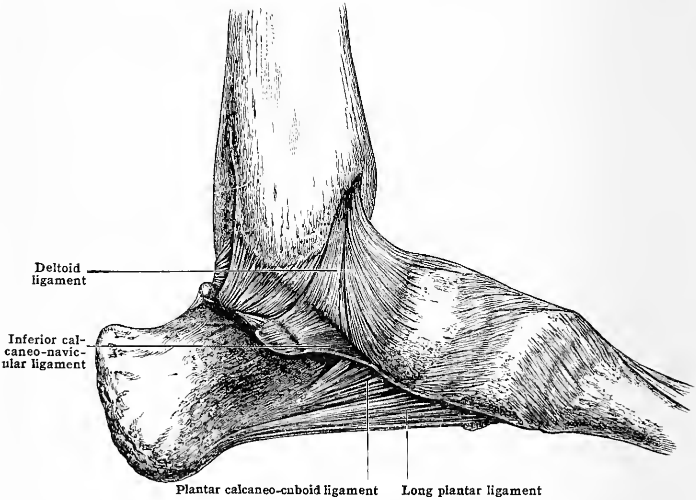
The ankle [articulatio talo-cruralis] is a perfect ginglymus or hinge joint. The bones which enter into its formation are: the lower extremity and medial malleolus of the tibia, and the lateral malleolus of the fibula, above; and the upper and lateral articular surfaces of the talus (astragalus) below. The ligaments (supplementing the articular capsule) uniting the bones are:—

Anterior.	Deltoid.
Posterior.	Lateral ligament.

The **anterior ligament** (fig. 334) is a thin, membranous structure, which completes the capsule in front of the joint. It is attached above to the anterior border of the medial malleolus, to a crest of bone just above the transverse groove at the lower end of the tibia, to the anterior lateral malleolar ligament, and to the anterior border of the lateral malleolus. Below, it is attached to the rough upper surface of the neck of the talus (astragalus). Medially it is thicker, and is fixed to the talus close to the facet for the medial malleolus, being continuous with the deltoid ligament, and passing forward to blend with the talo-navicular ligament. Laterally it is attached to the talus, just below and in front of the angle between the superior and lateral facets, close to their edges, and joins the anterior talo-fibular ligament.

It is in relation, in front with the *tibialis anterior* muscle, the anterior tibial vessels and nerve, the *extensor tendons of the toes*, and the *peroneus tertius;* and behind with a mass of fat and synovial membrane.

FIG. 330.—MEDIAL VIEW OF THE ANKLE AND THE TARSUS, SHOWING THE GROOVE FOR THE TENDON OF THE TIBIALIS POSTERIOR.

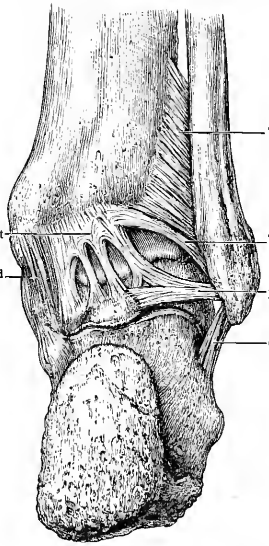


The **posterior ligament** (fig. 331) is a very thin and disconnected membranous structure, connected above with the lateral malleolus, medial to the peroneal groove; to the posterior margin of the lower end of the tibia lateral to the groove for the tibialis posterior; and to the posterior lateral malleolar ligament. Below, it is attached to the posterior surface of the talus from the deltoid to the lateral ligaments. The passage of the flexor hallucis longus tendon over the back of the joint serves the purpose of a much stronger posterior ligament.

The **deltoid ligament** (fig. 330) is attached superiorly to the medial malleolus along its lower border, and to its anterior surface superficial to the anterior ligament; some very strong fibres are fixed to the notch in the lower border of the malleolus, and, getting attachment below to the rough depression on the medial side of the talus, form a **deep** portion to the ligament. The ligament radiates; the posterior fibres are short, and incline a little backward to be fixed to the rough medial surface of the talus, close to the superior articular facet, and into the tubercle to the medial side of the flexor hallucis longus groove. The fibres next in front are numerous and form a thick and strong mass, filling up the rough depression on the medial surface of the talus, whilst some pass over the talo-calcaneal joint to the upper and medial border of the sustentaculum tali. The fibres which are connected above with the anterior surface of the malleolus pass downward and somewhat forward to be attached to the navicular and to the margin of the calcaneo-navicular ligament.

The **lateral ligament** (figs. 329 and 334) consists of three distinct slips (fasciculi). The **anterior talo-fibular ligament** (anterior fasciculus), is ribbon-like and passes from the anterior border of the lateral malleolus near the tip to the rough surface of the talus in front of the lateral facet, and overhanging the sinus pedis. The **calcaneo-fibular ligament** (middle fasciculus), is a strong roundish bundle, which extends downward and somewhat backward from the anterior border of the lateral malleolus close to the attachment of the anterior fasciculus, and from the lateral surface of the malleolus, just in front of the apex, to a tubercle on the middle of the lateral surface of the calcaneum. The **posterior talo-**

FIG. 331.—LIGAMENTS SEEN FROM THE BACK OF THE ANKLE-JOINT.



fibular ligament (posterior fasciculus), is almost horizontal; it is a strong, thick band attached at one end to the posterior border of the malleolus, and slightly to the fossa on the medial surface; and at the other end to the talus, behind the articular facet for the fibula, as well as to a tubercle on the lateral side of the groove for the *flexor hallucis longus.*

The middle fasciculus is covered by the tendons of the *peronei longus* and *brevis;* and in extension, the posterior fasciculus is received into the pit on the medial surface of the lateral malleolus.

The **synovial membrane** is very extensive. Besides lining the ligaments of the ankle, it extends upward between the tibia and fibula, forming a short *cul-de-sac* as far as the interosseous ligament. Upon the anterior and posterior ligaments it is very loose, and extends beyond the limits of the articulation. It is said to contain more synovia than any other joint.

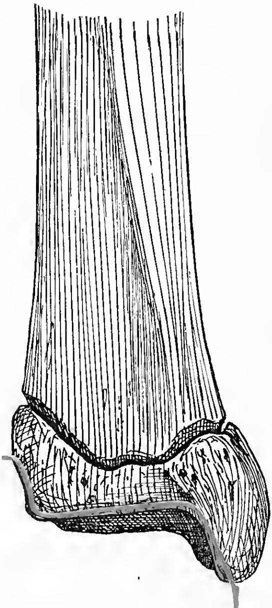
The **nerve-supply** is from the saphenous, posterior tibial, and the lateral division of the anterior tibial.

The **arterial supply** comes from the anterior tibial, the anterior peroneal, the lateral malleolar, the posterior tibial, and posterior peroneal.

Relations.—In front and in contact with the anterior ligament, from medial to lateral aspects, are the tendons of the tibialis anterior, the tendon of the extensor hallucis longus, the anterior tibial vessels, the anterior tibial nerve, the tendons of the extensor digitorum longus, and the tendon of the peroneus tertius. To the medial side of the tibialis anterior and to the lateral side of the peroneus tertius the joint is subcutaneous anteriorly. Behind and laterally are the tendons of the peroneus longus and brevis. Behind and medially, from medial to lateral side, are the tendon of the tibialis posterior, the tendon of the flexor digitorum longus, the posterior tibial vessels, the posterior tibial nerve, and the tendon of the flexor hallucis longus. Directly behind is a pad of fat which intervenes between the tendo Achillis and the joint. Below and on the lateral side, crossing the middle fasciculus of the lateral ligament, are the tendons of the peroneus longus and brevis. Below and on the medial side, crossing the deltoid ligament, are the tendons of the tibialis posterior and the flexor digitorum longus.

Movements.—This being a true hinge joint, flexion and extension are the only movements of which it is capable, there being no side to side motion, except in extreme extension, when the narrowest part of the talus is thrust forward into the widest part of the tibio-fibular arch.

FIG. 332.—THE LOWER EXTREMITY OF THE TIBIA (ANTERIOR VIEW), TO SHOW THE RELATION OF THE ARTICULAR CAPSULE OF THE ANKLE-JOINT (IN RED) TO THE EPIPHYSIAL LINE.



In flexion the talus is tightly embraced by the malleoli, and side to side movement is impossible. Flexion of the ankle-joint is limited by:—(i) nearly the whole of the fibres of the deltoid ligament, none but the most anterior being relaxed; (ii) the posterior and middle portions of the lateral ligament, especially the posterior; (iii) the posterior ligament of the ankle. It is also limited by the neck of the talus abutting on the edge of the tibia.

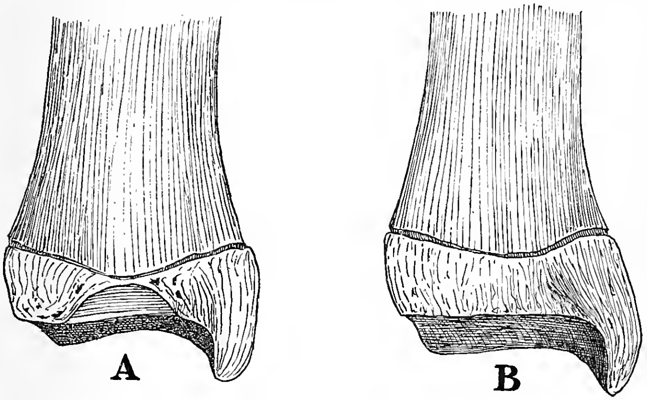
In most European ankle-joints the anterior edge of the lower end of the tibia is kept from actual contact with the neck of the talus in positions of extreme flexion by the intervention of a pad of fat situated beneath the anterior extension of the anterior ligament. In races which adopt a squatting posture, however, an actual articulation may be developed between these two bony surfaces, a facet being present both upon the anterior margin of the tibia and upon the neck of the talus. These facets are known as "squatting facets" (fig. 333, A) and are of common occurrence in ancient bones and in the bones of modern oriental people.

Extension of the ankle-joint is limited by:—(i) the anterior fibres of the deltoid ligament; (ii) the anterior and middle portions of the lateral ligament; (iii) the medial and stronger fibres of the anterior ligament. It is also limited by the posterior portion of the talus meeting with the tibia. Thus the middle portion of the lateral ligament is always on the stretch, owing to its obliquely backward direction, whereby it limits flexion; and its attachment to the fibula in front of the malleolar apex, whereby it prevents over-extension as soon as the foot begins to twist medialward. This medial twisting, or adduction of the foot, is partly due to the greater posterior length of the medial border of the superior articular surface of the talus, and to the less proportionate height posteriorly of the lateral border of that surface, but chiefly to the side to side movement in the talo-calcaneal joints. Flexion and extension take place round a transverse axis drawn through the body of the talus. The movement is not in a direct antero-posterior plane, but on a plane inclined forward and laterally from the middle of the astragalus to the intermetatarsal joint of the second and third toes.

Muscles which act on the ankle-joint.—*Flexors.*—Tibialis anterior, extensor hallucis longus, extensor digitorum longus, peroneus tertius. *Extensors.*—Tibialis posterior, flexor digitorum longus, flexor hallucis longus, peroneus longus, peroneus brevis, soleus, gastrocnemius, plantaris.

Fig. 333.—Anterior Aspect of the Lower Extremity of the Tibia.

In *A*, the articular surface is prolonged upward in front, forming a "squatting facet" which articulates with a corresponding facet on the neck of the talus. In *B* (the usual condition) the articular surface is confined to the lower aspect of the bone.



5. THE TARSAL JOINTS

These may be divided into the following sub-groups:—

(*a*) The **talo-calcaneal union.**
(*b*) The **articulations of the anterior portion of the tarsus.**
(*c*) The **medio-tarsal joint.**

(*a*) The Talo-calcaneal Union

There are two joints which enter into this union—viz., an anterior and a posterior.

(i) *The Posterior Talo-calcaneal Joint*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The calcaneus articulates with the talus by two joints, the anterior and posterior: the former communicates with the medio-tarsal; the posterior is separate and complete in itself. At the latter joint the two bones are united by an articular capsule with the following ligaments:—

Interosseous. Lateral talo-calcaneal.
Posterior talo-calcaneal. Medial talo-calcaneal.

The **interosseous ligament** (figs. 334 and 335) is a strong band connecting the apposed surfaces of the calcaneus and talus along their oblique grooves. It is composed of several vertical laminæ of fibres, with some fatty tissue in between.

It is better marked, deeper, and broader laterally. Strong laminæ extend from the rough inferior and lateral surfaces of the neck of the talus to the rough superior surface of the calcaneus anteriorly, forming the posterior boundary of the anterior talo-calcaneal joint; these have been described as the **anterior (interosseous) ligament.** The posterior laminæ extend from the roof of the sinus pedis to the calcaneus immediately in front of the lateral facet, thus forming the anterior part of the capsule of the posterior joint.

The **lateral talo-calcaneal ligament** (fig. 334) extends from the groove just below and in front of the lateral articular facet of the talus, to the calcaneus some little distance from the articular margin. Its fibres are nearly parallel with those of the calcaneo-fibular ligament of the ankle, which passes over it and adds to its strength. It fills up the interval between the calcaneo-fibular and anterior talo-fibular ligaments, a considerable bundle of its fibres blending with the anterior border of the calcaneo-fibular.

The **posterior talo-calcaneal ligament** passes from the lateral tubercle of the talus and lower edge of the groove for the flexor hallucis longus to the calcaneus, a variable distance from the articular margin.

The **medial talo-calcaneal ligament** includes two portions. The first is a narrow band of well-marked fibres passing obliquely downward and forward from the medial tubercle of the talus, just behind the medial end of the sinus tarsi, to the calcaneus behind the sustentaculum tali, thus completing the floor of the groove for the flexor hallucis longus tendon. The second portion, which is often considered a separate ligament, is described below with the anterior talo-calcaneal joint.

The **synovial sac** is distinct from any other.

The **nerve-supply** is from the posterior tibial or one of its plantar branches.

The **arteries** are, a branch from the posterior tibial, which enters at the medial end of the sinus pedis; and twigs from the tarsal, lateral malleolar, and the peroneal, which enter at the lateral end of the sinus.

(ii) *The Anterior Talo-calcaneal Joint*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

This joint is formed by the anterior facet on the upper surface of the calcaneus and the facets on the lower surface of the neck and head of the talus; it is bounded on the sides and behind by ligaments, and communicates anteriorly with the talo-navicular joint. The ligaments are:—

Interosseous.	Medial talo-calcaneal.
	Lateral calcaneo-navicular.

The **interosseous ligament** by its anterior laminæ limits this joint posteriorly. It has been already described.

The **medial talo-calcaneal** ligament (second portion; see above) consists of short fibres attached above to the medial surface of the neck of the talus, and below to the upper edge of the free border of the sustentaculum tali, blending posteriorly with the medial extremityof the interosseous ligament, and anteriorly with the upper border of the plantar calcaneo-navicular ligament. It is strengthened by the deltoid ligament, the anterior fibres of which are also attached to the plantar calcaneo-navicular ligament.

The **lateral calcaneo-navicular** (figs. 334 and 335) limits this, as well as the talo-navicular joint, on the lateral side. It is a strong, well-marked band, extending from the rough upper surface of the calcaneus, lateral to the anterior facet, to a slight groove on the lateral surface of the navicular near the posterior margin. It blends below with the plantar calcaneo-navicular, and above with the talo-navicular ligament. Its fibres run obliquely forward and medially. The deltoid ligament and middle fasciculus of the lateral ligament of the ankle-joint also add to the security of these two joints, and assist in limiting movements between the bones by passing over the talus to the calcaneus.

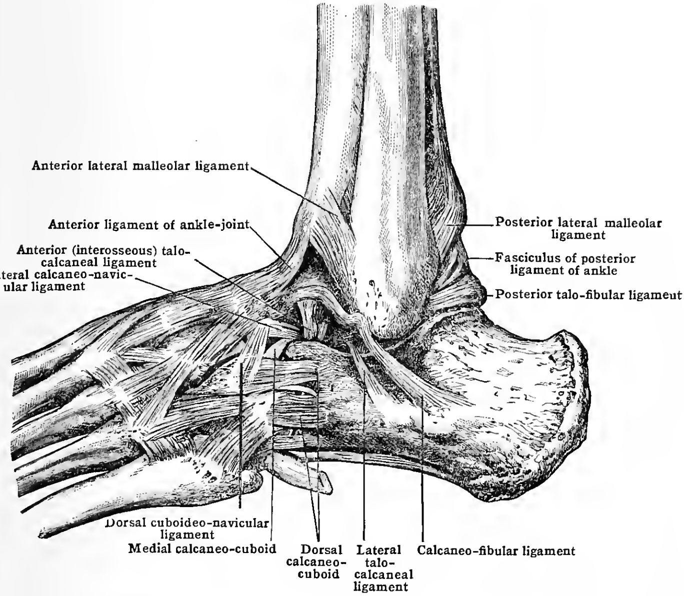
The **synovial membrane** is the same as that of the talo-navicular joint. The **arteries** and **nerves** are derived from the same sources as those of the medio-tarsal joints.

The **movements** of which these two joints are capable are adduction and abduction, with some amount of rotation. Adduction, or inclination of the sole medialward, is combined with some medial rotation of the toes, and some lateral rotation of the heel; while abduction, or inclination of the foot lateralward, is associated with turning of the toes laterally and the heel medially. Thus the variety and the range of movements of the foot on the leg, which at the ankle are almost limited to flexion and extension, are increased. The cuboid moves with the calcaneus, while the navicular revolves on the head of the talus.

In walking, the heel is first placed on the ground; the foot is slightly adducted; but as the body swings forward, first the lateral then the medial toes touch the ground, the talus presses against the navicular and sinks upon the plantar calcaneo-navicular ligament; the foot then becomes slightly abducted. When the foot is firmly placed on the ground, the weight is transmitted to it obliquely downward and medially, so that if the ligaments between the calcaneus and talus did not check abduction, medial displacement of the talus from the tibio-fibular arch would only be prevented by the tendons passing round the medial ankle (especially the *tibialis posterior*). If the ligaments be too weak to limit abduction, the weight of the body increases it, and forces the medial malleolus and talus downward and medially, giving rise to flat foot.

The advantages of the obliquity and peculiar arrangement of the posterior talo-calcaneal articulation are seen in walking:—(i) for the posterior facet of the calcaneus receives the whole weight of the body when the heel is first placed on the ground; (ii) by the upward pressure of this facet against the talus it transfers the weight to the ball of the toes as the heel is raised, the posterior edge of the sustentaculum tali and the anterior and lateral part of the upper surface of the calcaneus preventing the talus from being displaced too far forward by the superincumbent weight; and (iii) the calcaneus serves to suspend the talus when, with the heel raised by muscular action, the other foot is being swung forward.

Fig. 334.—Lateral View of the Ligaments of the Foot and Ankle.



(b) The Articulations of the Anterior Part of the Tarsus

These include (i) the cuboideo-navicular; (ii) cuneo-navicular; (iii) inter-cuneiform; and (iv) cuneo-cuboid joints.

(i) *The Cuboideo-navicular Union*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The joint cavity is only occasionally present and this joint is often included in the transverse tarsal.

The ligaments which unite the cuboid and navicular are:—

Dorsal. Plantar. Interosseous.

The **dorsal cuboideo-navicular ligament** (fig. 334) runs forward and laterally from the lateral end of the dorsal surface of the navicular to the middle third of the medial border of the cuboid on its dorsal aspect, passing over the posterior lateral angle of the third cuneiform bone. It is wider laterally.

The **plantar cuboideo-navicular ligament** is a well-marked strong band, which runs forward and laterally, from the plantar surface of the navicular to the depression on the medial surface of the cuboid, and slightly into the plantar surface just below it.

The **interosseous cuboideo-navicular ligament** is a strong band which passes between the apposed surfaces of these bones from the dorsal to the plantar ligaments. Some of its posterior fibres reach the plantar surface of the foot behind the cuboideo-navicular ligament, and radiate laterally and backward over the medial border of the cuboid to blend with the anterior extremity of the plantar calcaneo-cuboid ligament.

(ii) *The Cuneo-navicular Articulation*

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The ligaments uniting the navicular with the three cuneiform bones are:—

Dorsal. Plantar.
Medial.

The **dorsal cuneo-navicular ligament** is very strong, and stretches as a continuous structure on the dorsal surface of the navicular, between the tubercle of the navicular on the medial side, and the dorsal cuboideo-navicular ligament laterally, passing forward and a little laterally to the dorsal surfaces of the three cuneiform bones.

The **medial cuneo-navicular ligament** is a very strong thick band which connects the tubercle of the navicular with the medial surface of the first cuneiform bone. It is continuous with the dorsal and plantar ligaments. Its lower border touches the tendon of the *tibialis posterior*.

The **plantar cuneo-navicular ligament** forms, like the dorsal, a continuous structure extending between the plantar surfaces of the bones. Its fibres pass forward and laterally. It is in relation below with the tendon of the *tibialis posterior*.

It must be noticed that the expanded tendon of insertion of the *tibialis posterior*, and the ligaments uniting the navicular with the cuboid and cuneiform bones, pass forward and laterally, while the *peroneus longus* tendon and the ligaments uniting the first and second rows of bones, except the medial half of the dorsal talo-navicular ligaments, pass forward and medially. This arrangement is admirably adapted to preserve the arches of the foot, and especially the transverse arch. Had these tendons and ligaments run directly forward, all the strain on the transverse arch would have fallen on the interosseous ligaments, but as it is, the arch is braced up by the above-mentioned structures.

(iii) *The Intercuneiform and* (iv) *The Cuneo-cuboid Articulations*

Class.—*Diarthrosis.* **Subdivision**—*Arthrodia.*

The uniting ligaments of these bones are divided into three sets:—

Dorsal. Plantar.
Interosseous.

The **dorsal ligaments** are three in number, two, the dorsal **intercuneiform**, connecting the three cuneiform bones, and a third, the dorsal **cuneo-cuboid**, uniting the third cuneiform with the cuboid. They pass between the contiguous margins of the bones, and are blended behind with the dorsal ligaments of the cuboideo-navicular and cuneo-navicular joints.

The **plantar ligaments** are two in number: a very strong one, the **plantar intercuneiform,** passes laterally and forward from the lateral side of the base of the first cuneiform to the apex of the second cuneiform, winding somewhat to its lateral side. The second, the **plantar cuneo-cuboid,** connects the apex of the third cuneiform with the anterior half of the medial surface of the cuboid along its plantar border, joining with the plantar cuboideo-navicular ligament behind.

The **interosseous ligaments** are three in number. They are strong and deep masses of ligamentous tissue which connect the second cuneiform with the first and third cuneiform bones, and the third cuneiform with the cuboid; occupying all the non-articular portions of the apposed surfaces of the bones. The ligaments extend the whole vertical depth between the second cuneiform and the third, and the third cuneiform and the cuboid, and blend with the dorsal and plantar ligaments; they are situated in front of the articular facets, and completely shut off the synovial cavity behind from that in front. The ligament between the first and second cuneiform bones occupies the inferior and anterior two-thirds of the apposed surfaces, and does not generally extend high enough to separate the synovial cavity of the anterior tarsal joint from that of the second and third metatarsal and cuneiform bones. If it does extend to the dorsal surface, it divides the facets completely from one another, making a seventh synovial sac in the foot.

The **synovial cavity** will be described later on.

The **arterial supply** is from the metatarsal and plantar arteries.

The **nerves** are derived from the deep peroneal and medial and lateral plantar.

The **movement** permitted in these joints is very limited, and exists only for the purpose of adding to the general pliancy and elasticity of the tarsus without allowing any sensible alteration in the position of the different parts of the foot, as the medio-tarsal and talo-calcaneal joints do. It is simply a gliding motion, and either deepens or widens the transverse arch. The third cuneiform being wedged in between the others is less movable, and so forms a pivot upon which the rest can move. The movement is more produced by the weight of the body than by direct muscular action; and of the muscles attached to this part of the tarsus, all deepen the arch save the tibialis anterior, which pulls the first cuneiform up, and so tends to widen it.

(c) The Transverse Tarsal Joints

The articulations of the anterior and posterior portions of the tarsus, although in the same transverse line, consist of two separate joints, viz., (i) a medial, the talo-navicular, which communicates with the anterior talo-calcaneal articulation; and (ii) a lateral, the calcaneo-cuboid, which is complete in itself. The movements of the anterior upon the posterior portions of the foot take place at these joints simultaneously. It will be most convenient to deal with the joints separately as regards the ligaments; while the arteries, nerves, and movements will be considered together.

(i) *The Talo-navicular Articulation*

Class.—*Diarthrosis.* **Subdivision.**—*Enarthrodia.*

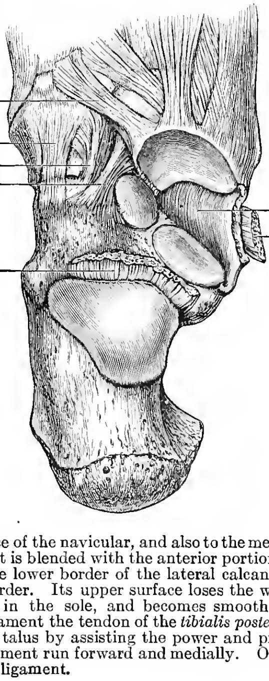
This is the only ball-and-socket joint in the tarsus. It communicates with the anterior talo-calcaneal articulation, and two of the ligaments which close it in do not touch the talus, but pass from the calcaneus to the navicular. The uniting ligaments include, in addition to the articular capsule, the following:—

Lateral calcaneo-navicular. Plantar calcaneo-navicular
Talo-navicular.

The **lateral calcaneo-navicular** has been already described (p. 302).

The **plantar calcaneo-navicular ligament** (figs. 335 and 336) is an exceedingly dense, thick plate of fibro-elastic tissue. It extends from the sustentaculum tali and the under surface of the calcaneus in front of a ridge curving laterally to the anterior tubercle of that bone, to the

Fig. 335.—View of the Foot from above, with the Talus removed to show the Plantar and Lateral Calcaneo-navicular Ligaments



whole width of the inferior surface of the navicular, and also to the medial surface of the navicular behind the tubercle. Medially it is blended with the anterior portion of the deltoid ligament of the ankle, and laterally with the lower border of the lateral calcaneo-navicular ligament. It is thickest along the medial border. Its upper surface loses the well-marked fibrous appearance which the ligament has in the sole, and becomes smooth and faceted. In contact with the under surface of the ligament the tendon of the *tibialis posterior* passes, giving considerable support to the head of the talus by assisting the power and protecting the spring of the ligament. The fibres of the ligament run forward and medially. On account of its elasticity it is sometimes termed the spring ligament.

20

The **talo-navicular ligament** is a broad, thin, but well-marked layer of fibres which passes from the dorsal and lateral surfaces of the neck of the talus to the whole length of the dorsal surface of the navicular. Many of the fibres converge to their insertion on the navicular. The fibres low down on the lateral side blend a little way from their origin with the upper edge of the lateral calcaneo-navicular ligament, and then pass forward and medially to the navicular; those next above pass obliquely and with a distinct twist over the upper and lateral side of the head of the talus to the centre of the dorsum of the navicular, overlapping fibres from the medial side of the talus as well as some from the anterior ligament of the ankle-joint.

Synovial membrane.—The talo-navicular is lined by the same synovial membrane as the anterior talo-calcaneal joint.

(ii) *The Calcaneo-cuboid Articulation*

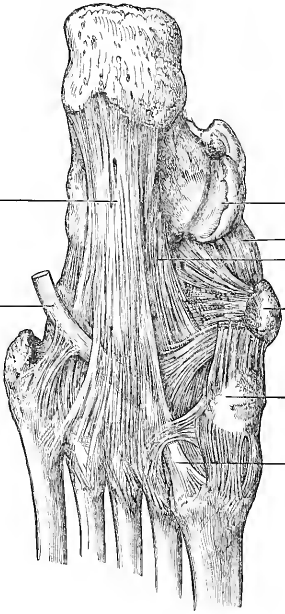
Class.—*Diarthrosis.* **Subdivision.**—*Saddle-shaped Arthrodia.*

The ligaments which are supplementary to the articular capsule and unite the bones forming the outer part of the medio-tarsal joint are:—

Medial calcaneo-cuboid.	Dorsal calcaneo-cuboid.
Long plantar.	Plantar calcaneo-cuboid.

The **medial calcaneo-cuboid ligament** (fig. 335) is a strong band of fibres attached to the calcaneus along the medial part of the non-articular ridge above the articular facet for the cuboid, and also to the upper part of the medial surface close to the articular margin, and passes forward to be attached to the depression on the medial surface of the cuboid, and also to the rough angle

Fig. 336.—Ligaments of the Sole of the Left Foot.



between the medial and inferior surfaces. At the calcaneus this ligament is closely connected with the lateral calcaneo-navicular ligament. Toward the sole it is connected with the plantar calcaneo-cuboid ligament, and superiorly with the dorsal calcaneo-cuboid.

The **dorsal calcaneo-cuboid** (fig. 335) is attached to the dorsal surfaces of the two bones, extending low down laterally to blend with the lateral part of the plantar calcaneo-cuboid ligament. Over the medial half, or more, the ligament stretches some distance beyond the margins of the articular surfaces, reaching well forward upon the cuboid to be attached about midway between its anterior and posterior borders; but toward the lateral side, the ligament is much shorter, and is attached to the cuboid behind its tubercle.

The **long plantar ligament** (fig. 336) is a strong, dense band of fibres which is attached posteriorly to the whole of the inferior surface of the calcaneus between the posterior tubercles and the rounded eminence (the anterior tubercle) at the anterior end of the bone. Most of its fibres pass directly forward, and are fixed to the lateral two-thirds or more of the oblique ridge behind the peroneal groove on the cuboid, while some pass further forward and medially, expanding into a broad layer, and are inserted into the bases of the second, third, fourth, and medial half of the fifth metatarsal bones. This anterior expanded portion completes the canal for the *peroneus longus tendon*, and from its under surface arise the *oblique adductor hallucis* and the *flexor quinti digiti brevis* muscles.

The **plantar calcaneo-cuboid** (short plantar) (fig. 336) is attached to the rounded eminence (anterior tubercle) at the anterior end of the under surface of the calcaneus, and to the bone in front of it, and then takes an oblique course forward and medially, and is attached to the whole of the depressed inferior surface of the cuboid behind the oblique ridge, except its lateral angle. It is strongest near its lateral edge, and is formed by dense strong fibres.

The **synovial membrane** is distinct from that of any other tarsal joint.

The **arterial supply** of the medio-tarsal joints is from the anterior tibial, from the tarsal and metatarsal branches of the dorsalis pedis, and from the plantar arteries.

The **nerve-supply** of the medio-tarsal joints is from the lateral division of the deep peroneal, and occasionally from the superficial peroneal or lateral plantar.

Relations.—On the *dorsal aspect* of the mid-tarsal joint lie the tendons of the tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneus tertius, the muscular part of the extensor digitorum brevis, the dorsalis pedis artery, and the anterior tibial nerve. On its *plantar aspect* are the tendons of the flexor digitorum longus and hallucis longus, quadratus plantæ (accessorius), and the medial and lateral plantar vessels and nerves. It is crossed laterally by the tendons of the peroneus longus and brevis and medially by the tendon of the tibialis posterior.

The **movements** which take place at the medio-tarsal joints are mainly flexion and extension, with superadded side-to-side and rotatory movements. Flexion at these joints is simultaneous with extension of the ankle, and *vice versa.* Flexion and extension do not take place upon a transverse, but round an oblique, axis which passes from the medial to the lateral side, and somewhat backward and downward through the talus and calcaneus.

Combined with flexion and extension is also some rotatory motion round an antero-posterior axis which turns the medial or lateral border of the foot upward. There is also a fair amount of side-to-side motion whereby the foot can be inclined medially (i. e., adducted) or laterally (i. e., abducted).

These movements of the medio-tarsal joint occur in conjunction with those of the ankle and talo-calcaneal joints. Rotation at the talo-calcaneal joint is, however, round a vertical axis in a horizontal plane, and so turns the toes medially or laterally; whereas at the medio-tarsal union the axis is antero-posterior and the medial or lateral edge of the foot is turned upward. Gliding at the talo-calcaneal joint elevates or depresses the edge of the foot, while at the medio-tarsal it adducts or abducts the toes without altering the relative position of the calcaneus to the talus.

Thus flexion at the medio-tarsal joint is associated with adduction and medial rotation of the foot, occurring simultaneously with extension of the ankle; and extension at the medio-tarsal joint is associated with abduction and lateral rotation, occurring simultaneously with flexion of the ankle.

Flexion and medial rotation are far more free than extension and lateral rotation, which latter movements are arrested by the ligaments of the sole as soon as the foot is brought into the position in which it rests on the ground.

Although the talo-navicular is a ball-and-socket joint, yet, owing to the union of the navicular with the cuboid, its movements are limited by the shape of the calcaneo-cuboid joint; this latter being concavo-convex from above downward, prevents rotation round a vertical axis, and also any side-to-side motion except in a direction obliquely downward and medially, and upward and laterally. This is also the direction of freest movement at the talo-navicular joint. Movement is also limited by the ligamentous union of the calcaneus with the navicular. The twisting movement of the foot, such as turning it upon its medial or lateral edge, and the increase or diminution of the arch, take place at the tarsal joints, especially the medio-tarsal and talo-calcaneal articulations. Here too those changes occur which, owing to paralysis of some muscles or contraction of others, result in talipes equino-varus, or valgus.

Muscles which act on the mid-tarsal joint.—*Medial rotators.*—Tibialis anterior and posterior acting simultaneously; they are aided by the flexor digitorum longus and flexor hallucis longus. *Lateral rotators.*—The peronei longus, brevis, and tertius, acting simultaneously. They are aided by the extensor digitorum longus.

6. THE TARSO-METATARSAL ARTICULATIONS

There may be said to be three articulations between the tarsus and metatarsus, viz.:—

(*a*) The medial, between the first cuneiform and first metatarsal bones.

(*b*) The intermediate, between the three cuneiform and second and third metatarsal bones.

(*c*) The lateral, or cubo-metatarsal, between the cuboid and fourth and fifth metatarsal bones.

(a) The Medial Tarso-metatarsal Joint

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

A complete **articular capsule** unites the first metatarsal with the first cuneiform, the fibres of which are very thick on the inferior and medial aspects; those on the lateral side pass from behind forward in the interval between the interosseous ligaments which connect the two bones forming this joint with the second metatarsal. The ligament on the plantar aspect is by far the strongest, and blends at the cuneiform bone with the cuneo-navicular ligament.

(b) The Intermediate Tarso-metatarsal Joint

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

Into this union there enter the three cuneiform and second and third metatarsal bones, which are bound together by the following ligaments (supplementary to the articular capsule): dorsal, plantar, interosseous.

The dorsal ligaments.—1. Some short fibres cross obliquely from the lateral edge of the first cuneiform bone to the medial border of the base of the second metatarsal bone; they take the place of a dorsal metatarsal ligament, which is wanting between the first and second metatarsal bones.

2. Between the second cuneiform and the base of the second metatarsal bone some fibres run directly forward.

3. The third cuneiform is connected with (1) the lateral corner of the second metatarsal bone by a narrow band passing obliquely medially; (2) with the third metatarsal by fibres passing directly forward; and (3) with the fourth metatarsal by a short band passing obliquely laterally to the medial edge of its base.

The plantar ligaments.—A strong ligament unites the first cuneiform and the bases of the second and third metatarsal bones. The *tibialis posterior* is inserted into these bones close beside it. Other slender ligaments connect the second cuneiform with the second, and the third cuneiform with the third metatarsal bones.

The interosseous ligaments.—(1) A strong broad interosseous ligament extends between the lateral surface of the first cuneiform and the medial surface of the base of the second metatarsal bone. It is attached to both bones below and in front of the articular facets, and separates the intermediate from the medial tarso-metatarsal joint. (2) A second band is attached behind to a fossa on the anterior and lateral edge of the third cuneiform and to the interosseous ligament between it and the cuboid, and passes horizontally forward to be attached to the whole depth of the fourth metatarsal bone behind its medial facet, and to the opposed surfaces of the third and fourth below the articular facets upon their sides. It separates the middle tarso-metatarsal, and intermetatarsal between the third and fourth bones, from the cubo-metatarsal joint. It is more firmly connected with the third bone than with the fourth. (3) A slender ligament composed only of a few fibres often passes from a small tubercle on the medial and anterior edge of the third cuneiform to a groove on the lateral edge of the second metatarsal bone between the two facets upon their sides.

The **synovial membrane** is prolonged forward from that of the naviculari-cuneiform and inter-cuneiform articulations.

The **arteries for the tarso-metatarsal joints** are derived:—(1) for the medial, from the dorsalis pedis and medial plantar; (2) for the rest, twigs from the arcuate and deep plantar arch.

The **nerve-supply** comes from the deep peroneal and plantar nerves.

The **movements** permitted at these joints are flexion and extension of the metatarsus on the tarsus; and at the medial and lateral divisions, slight adduction and abduction. In the lateral, the side-to-side motion is freer than in the medial joint, and freest between the fifth metatarsal bone and the cuboid. In the medial joint, flexion is combined with slight abduction and extension with abduction.

There is also a little gliding, which allows the transverse arch to be increased or diminished in depth; the medial and lateral two bones sliding downward, and the two middle a little upward, when the arch is increased; and *vice versa* when the arch is flattened.

(c) The Lateral or Cubo-metatarsal Joint

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The bones comprising this joint are the fourth and fifth metatarsal and the anterior surface of the cuboid, firmly connected on all sides by the articular capsule, strengthened by the following ligaments:—

Dorsal. Plantar. Interosseous.

The **plantar cubo-metatarsal ligament** is a broad, well-marked ligament, which extends from the cuboid behind to the bases of the fourth and fifth metatarsal bones in front. It is continuous along the groove at the base of the fifth metatarsal bone with the dorsal ligament, and as it passes round the lateral border of the foot it is somewhat thickened, and may be described as the **lateral cubo-metatarsal ligament.** On its medial side it joins the interosseous ligaments, thus completing the capsule below. It is not a thick structure, and to see it the long plantar ligament, the peroneus longus, and lateral slip of the tibialis posterior must be removed; the attachment of these structures to the fourth and fifth metatarsal bones considerably assists to unite them with the tarsus.

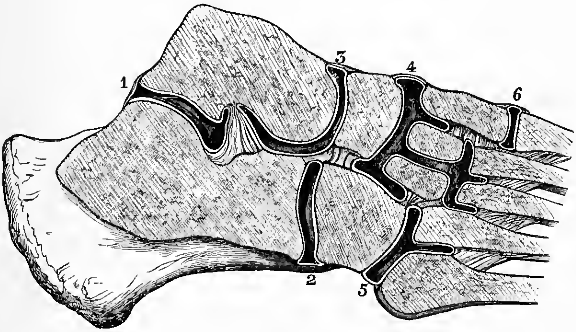
The **dorsal cubo-metatarsal ligament** is composed of fibres which pass obliquely outward and forward from the cuboid to the bases of the fourth and fifth metatarsal bones. They complete the capsule above, and are continuous laterally with the lateral cubo-metatarsal ligament.

The **interosseous ligament** shuts off the cubo-metatarsal from the middle tarso-metatarsal joint. It is attached to the third cuneiform behind, and to the whole depth of the fourth metatarsal behind its medial facet, and to the apposed surfaces of the third and fourth bones below their articular facets. It is continuous below with the plantar ligament.

The **synovial membrane** is separate from the other synovial sacs of the tarsus, and is continued between the fourth and fifth metatarsal bones.

Relations.—The line of the tarso-metatarsal joints is crossed dorsally by the tendons of the long and short extensor muscles of the toes and the tendon of the peroneus tertius. On the plantar aspect it is in relation with the oblique adductor of the great toe, the short flexor of the great toe, the lateral plantar artery, and the tendon of the peroneus longus. Its medial end is subcutaneous except that it is crossed, near the plantar surface, by a slip of the tendon of the tibialis anterior, and its lateral end is crossed by the tendon of the peroneus brevis.

Fig. 337.—Section to show the Synovial Cavities of the Foot.



1. Posterior talo-calcaneal. 2. Calcaneo-cuboid. 3. Anterior talo-calcaneo-navicular. 4. Tarsal. 5. Cubo-metatarsal. 6. First metatarso-cuneiform.

7. THE INTERMETATARSAL ARTICULATIONS

Class.—*Diarthrosis.* **Subdivision.**—*Arthrodia.*

The bases of the metatarsal bones are firmly held in position by dorsal, plantar, and interosseous ligaments, supplementing the articular capsules. The first occasionally articulates by means of a distinct facet with the second metatarsal (figs. 245 and 246).

The **dorsal ligaments** are broad, membranous bands passing between the four lateral toes on their dorsal aspect; but in place of one between the first and second metatarsal bones, a ligament extends from the first cuneiform to the base of the second metatarsal bone.

The **plantar ligaments** are strong, thick, well-marked ligaments which connect the bones on their plantar aspect.

The **interosseous ligaments** are three in number, very strong, and are situated at the points of union of the shaft with the bases of the bones, and fill up the sulci on their sides. They limit the synovial cavities in front of the synovial facets.

The common **synovial membrane** of the tarsus extends between the second and third, and third and fourth bones; that of the cubo-metatarsal joint extending between the fourth and fifth.

The **arterial** and **nerve-supply** is the same as for the tarso-metatarsal joints.

The **movements** consist merely of gliding, so as to allow the raising or widening of the transverse arch. Considerable flexibility and elasticity are thus given to the anterior part of the foot, enabling it to become moulded to the irregularities of the ground.

The Union of the Heads of the Metatarsal Bones

The **heads of the metatarsal bones** are connected on their plantar aspect by the **transverse ligament** [Ligg. capitulorum transversa], consisting of four bands of fibres passing transversely from bone to bone, blending with the fibro-cartilaginous or sesamoid plates of the metatarso-phalangeal joints, and the sheaths of the flexor tendons where they are connected with the fibro-cartilages. It differs from the corresponding ligament in the hand by having a band from the first to the second metatarsal bone.

8. THE METATARSO-PHALANGEAL ARTICULATIONS

(*a*) The Metatarso-phalangeal Joints of the Four Lateral Toes

Class.—*Diarthrosis.* **Subdivision.**—*Condylarthrosis.*

These joints are formed by the concave proximal ends of the first phalanges articulating with the rounded heads of the metatarsal bones, and united by articular capsules strengthened by the following ligaments:—

Collateral. Dorsal. Plantar accessory.

The two **collateral ligaments** are strong bands passing from a ridge on each side of the head of the metatarsal bone to the sides of the proximal end of the first phalanx, and also to the sides of the sesamoid plate which unites the two bones on their plantar surfaces. On the dorsal aspect they are united by the dorsal ligament.

The **dorsal ligament** consists of loose fine fibres of areolo-fibrous tissue, extending between the collateral ligaments, thus completing a capsule. It is connected by fine fibres to the under surface of the extensor tendons, which pass over and considerably strengthen this portion of the capsule.

The **plantar accessory ligament** or sesamoid plate helps to deepen the shallow facet of the phalanx for the head of the metatarsal bone, and corresponds to the accessory volar ligament of the fingers. It is firmly connected to the collateral ligaments and the transverse ligament, and is grooved inferiorly where the flexor tendons pass over it. It serves to prevent dorsal dislocation of the phalanx.

The second metatarso-phalangeal joint is 6 mm. ($\frac{1}{4}$ in.) in front of both the first and third metatarso-phalangeal joints.

The third metatarso-phalangeal joint is 6 mm. ($\frac{1}{4}$ in.) in front of the fourth, and the fourth 9 mm. ($\frac{3}{8}$ in.) in front of the fifth.

The head of the fifth metatarsal is in line with the neck of the fourth.

Thus the lateral side of the longitudinal arch of the foot is shorter than the medial, it is also distinctly shallower.

(*b*) The Metatarso-phalangeal Joint of the Great Toe

The metatarso-phalangeal joint of the great toe differs from the rest in the following particulars:—

(1) The bones are on a larger scale, and the articular surfaces are more extensive.

(2) There are two grooves on the plantar surface of the metatarsal bone, one on each side of the median line, for the sesamoid bones.

(3) The sesamoid bones replace the accessory plantar ligament (sesamoid plate). They are two small hemispherical bones developed in the tendons of the flexor hallucis brevis, convex below, but flat above where they play in grooves on the head of the metatarsal bone; they are united by a strong transverse ligamentous band, which is smooth below and forms part of the channel along which the long flexor tendon plays. They are firmly united to the base of the phalanx by strong short fibres, but to the metatarsal bone they are joined by somewhat looser fibres. At the sides they are connected with the collateral ligaments and the sheath of the flexor tendon. They provide shifting leverage for the *flexor hallucis brevis* as well as for the *flexor hallucis longus*.

The **arteries** come from the digital and metatarsal branches; and the **nerves** from the cutaneous digital, or from small twigs of the nerves to the interossei muscles.

The **movements** permitted are: flexion, extension, abduction, adduction, and circumduction. Flexion is more free than extension, and is limited by the extensor tendons and dorsal ligaments; extension is limited by the flexor tendons, the plantar fibres of the collateral ligaments, and the sesamoid plates. The side-to-side motion is possible from the shape of the bony surfaces, but is very limited, being most marked in the great toe. It is limited by the collateral ligaments and sesamoid plates.

9. THE INTERPHALANGEAL JOINTS

Class.—*Diarthrosis.* **Subdivision.**—*Ginglymus.*

The articulations between the first and second and second and third phalanges of the toes are similar to those of the fingers, with this important difference, that the bones are smaller and the joints, especially between the second and third phalanges, are often ankylosed. The ligaments which unite them include, in addition to the articular capsule:—

Collateral. Dorsal. Accessory plantar.

The **two collateral ligaments** are well marked, and pass on each side of the joints from a little rough depression on the head of the proximal, to a rough border on the side of the base of the distal phalanx of the joint.

The **dorsal ligament** is thin and membranous, and extends across the joint from one collateral ligament to the other beneath the extensor tendon, with the deep surface of which it is connected and by which it is strengthened.

The **accessory plantar ligament** covers in the joint on the plantar surface. It is a fibrocartilaginous plate, connected at the sides with the collateral ligaments, and with the bones by short ligamentous fibres; the plantar surface is smooth, and grooved for the flexor tendons.

The **arteries and nerves** are derived from the corresponding digital branches.

The only **movements** permitted at these joints are flexion and extension.

At the interphalangeal joint of the great toe there is very frequently a small sesamoid bone which plays on the plantar surface of the first phalanx, in the same way as the sesamoid bones of the metatarso-phalangeal joint play upon the plantar surface of the head of the metatarsal bone.

Relations of the muscles acting on the metatarso-phalangeal and interphalangeal joints of the foot.—If the student will refer to the accounts given of the relations of the corresponding joints in the hand and of the actions of the muscles upon those joints, and if he contrasts and compares the muscles of the hand with those of the foot, he will readily be able to construct tables of the relations of the metatarso-phalangeal and interphalangeal joints of the foot, and tables of the muscles acting upon the joints.

References.—A complete bibliography for the joints is given in the "Handbuch der Anatomie und Mechanik der Gelenke," by Professor Rudolf Fick (in von Bardeleben's Handbuch der Anatomie). References are also given in the larger works on human anatomy by Quain, Rauber-Kopsch, Poirier-Charpy, etc. References to the most recent literature may be found in Schwalbe's Jahresbericht, the Index Medicus and the various anatomical journals.

SECTION IV

THE MUSCULATURE

REVISED FOR THE FIFTH EDITION

By C. R. BARDEEN, A.B., M.D.

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF WISCONSIN

MUSCLES, the movements of which are under the control of the will, almost completely envelope the skeletal framework of the body; close in the oral, abdominal, and pelvic cavities; separate the thoracic from the abdominal cavity; surround the pharynx and the upper portion of the œsophagus; and are found connected with the eye, ear, larynx, and other organs. They constitute about two-fifths to three-sevenths of the weight of the body.

In this section an account is given of the gross anatomy of the musculature attached to the skeleton and the skin, with the exception of certain of the muscles which are more conveniently treated in connection with the organs to which they are appended. Thus, the muscles of the eye, the ear, the pharynx, the larynx, and the intrinsic muscles of the tongue are described in the sections devoted to those structures.

Relations to the skin.—Beneath the skin is a sheet of connective tissue, the **tela subcutanea.** In this, in some regions of the body (the head, neck, and palm), thin, flat, **subcutaneous muscles** are embedded. Superficial muscles of this kind constitute a **panniculus carnosus,** much more extensive in the lower mammals than in man. The tela subcutanea is separated from the more deeply seated musculature by areolar tissue, which, in most places, is loose in texture over the muscles. In some regions, as over the upper part of the back, the tela subcutanea is firmly united to the underlying musculature and is less freely movable. In the tela subcutanea more or less fat is usually embedded. This constitutes the **panniculus adiposus,** which varies greatly in thickness in different parts of the body. As a rule, it is much more developed over muscles than over those regions where bone and joints lie beneath the skin. From the tela subcutanea of the eyelids, penis, and scrotum fat is absent. The deeper layer of the tela subcutanea is more or less free from fat, and in it run the main trunks of the cutaneous nerves and vessels. In some regions, as over the lower part of the abdomen, one or more fibrous membranes are differentiated in this deeper layer.

To the tela subcutanea the term **superficial fascia** has been commonly applied, but since this leads to a confusion with the superficial fasciæ which immediately invest the muscles, it seems better to restrict the term fascia to the membranes connected with the muscular system, and to use the term **tela subcutanea** for the layer of connective tissue which underlies the skin and is continuous over the whole surface of the body.

In several places where the skin overlies bony prominences well-marked **synovial bursæ,** or sacs (**bursæ mucosæ**), are developed in the tela subcutanea.

Since the skin and the subcutaneous tissue must be removed in order to study the muscles of various regions, the tela subcutanea and subcutaneous bursæ may be conveniently described in connection with the muscles, and brief references will, therefore, be made to them in connection with the musculature of various regions.

Muscle fasciæ.—The musculature of the body, with the exception of some of the subcutaneous muscles, is ensheathed by fibrous tissue, which, in certain regions forms distinct membranes, while in other regions it is delicate and not clearly to be distinguished from the superficial connective tissue of the muscles, the perimysium externum. The membranes, or **muscle fasciæ,** are united to various parts of the skeleton, either directly or by means of intermuscular septa, and, where strong, keep the underlying musculature in place. In some regions they are united to the muscles; in others they are separated from the underlying musculature by loose areolar tissue, which allows free movement between the surface of the muscles and the overlying fascia. The best example of a strong fascia of this nature is that which envelopes the extensor muscles of the thigh. Where the fasciæ are well developed, the main bundles of constituent fibres take a course directly or obliquely transverse to the direction of the underlying muscles. They may be composed of several successive layers of fibrous tissue, the fibres of one layer taking a different direction from those of the next layer.

The **function** of the fasciæ is the mechanical one of restraining or modifying muscle action. The direction of the main component fibre-bundles indicates the direction of the greatest stress to which the fasciæ are subjected. Indirectly the fasciæ promote the circulation of the blood and lymph in places where the vessels lie between the contracting muscles and the overlying fascia.

Intermuscular septa.—Muscle fasciæ enclose not only the external layer of the musculature of the body, but also the various groups of more deeply seated muscles. In addition, between the individual muscles, and between the different layers and groups of muscles, there intervenes a greater or less amount of connective tissue, sometimes loose in texture, sometimes dense in structure. In these intermuscular septa run the chief nerves and blood-vessels of the region in which the musculature lies.

Gross structure of the muscles.—The muscles are composed of bundles of reddish fibres surrounded by a greater or less extent of white and glistening connective tissue. They are attached by prolongations of this tissue in the form of **tendons** or **aponeuroses** usually to the bony skeleton, but also in places to cartilages, as in the thorax and larynx; to the skin, as in the face; to mucous membranes, as in the tongue and cheeks; to the tendons of other muscles, as in the case of the lumbrical muscles; to muscle fasciæ, as in the case of the oblique and transverse muscles of the abdomen; and to other structures, as, for instance, to the eyeball.

The fleshy portion of the muscle is called the **belly.** The belly is usually attached at one extremity to a portion of the skeleton or to some other structure which serves as a support for its action on the structures to which its other extremity is attached. The attachment to the more fixed part is called the **origin** of the muscle; the attachment to the structure chiefly acted on is called the **insertion.** Thus the origin of the biceps muscle, the chief flexor of the forearm at the elbow, is from the scapula; the insertion is into the radius and into the fascia of the forearm. The part of the muscle attached to the origin is called the **head** of the muscle. The part attached to the insertion is sometimes called the **tail,** but this term is much less frequently used than the former.

The muscles vary greatly in **size** and **form.** Thus the stapedius muscle of the middle ear is a slender little structure, only a few millimetres long, while the gluteus maximus muscle of the hip is a large, rhomboid structure often several centimetres thick and with a surface area of over 500 square centimetres. The length of a muscle from origin to insertion may be much less than the width of the muscle, as in the intercostal muscles; or much greater than the width, as in most of the long muscles of the limbs. The thickness of a muscle is usually less than the width—so much so in some instances that the muscle is described as flat, sheet-like, or ribbon-like; while in other instances the belly is cylindrical. In flat muscles the general outline is usually quadrilateral or triangular. In triangular muscles in most instances one angle of the triangle marks the insertion of the muscle, while the opposite side marks the origin. In cylindrical muscles the belly usually has a somewhat fusiform shape, and grows smaller both toward the origin and the insertion of the muscle.

Some muscles are divided by tendons transverse to the long axis of the muscle. When one such tendon exists, the muscle is called **digastric** (fig. 348); when several, **polygastric,** e. g., rectus abdominis (fig. 388).

Two muscle masses with separate origins may have a common insertion. Such muscles are usually designated **bicipital** muscles (biceps muscles of the arm and thigh). Other muscles have three heads (the triceps muscle of the arm) or four (the quadriceps muscle of the thigh). In the latter case special names are given to the four parts or muscles which constitute the quadriceps as a whole. In addition to these comparatively simple compound muscles there are others in which the various component fasciculi and the tendons of origin and insertion are numerous and complexly interrelated. The intrinsic muscles of the back offer good illustrations of muscles of this nature.

In addition to muscles with distinct regions of origin and insertion, there are a few voluntary muscles which surround hollow viscera or their orifices and have a circular or tube-like form (sphincter muscles, voluntary muscles of the œsophagus, etc.).

Number of muscles.—A logical constancy does not appear always to have been followed in the commonly accepted division of the musculature into muscles individually designated. Most of the muscles are symmetrically placed in pairs, one on each side of the body. Authors not only vary in the extent to which they carry the subdivisions of the musculature on each side of the body into individual muscles, but also in describing muscles placed near the median line either as single muscles with bilateral halves or as paired muscles. In addition some muscles are not constantly present, and there are differences of opinion as to which of these less constant muscles should be classed with the normal musculature. The BNA recognises 347 paired and two unpaired skeletal muscles, and 47 paired and two unpaired muscles belonging to the visceral system and organs of special sense. Of the skeletal muscles the head has 25 paired and one unpaired; the neck 16 paired; the back 112 paired; the thorax 52 paired, one unpaired; the abdomen and pelvis 8 paired; the upper extremity, 52 paired; the lower extremity, 62 paired (Eisler).

Finer structure of muscles.—While no attempt can be made here to describe in detail the finer microscopic features of muscle structure, some of the more general features of muscle architecture may be briefly mentioned.

The contractile cells of voluntary muscle are long, slender, multinucleated **'fibres,'** the protoplasm of which exhibits both cross and longitudinal striation. The longitudinal striation is due to the presence of fibrils situated in the sarcoplasma. The cross striation is due to alternate segments of singly and doubly refracting substance in these fibrils. The length of these fibres in the human body varies from a few millimetres to sixteen centimetres or more, and the thickness from ten to eighty microns. Each muscle-fibre is surrounded by an especially differentiated sheath, the **sarcolemma.** Outside of this is a layer of delicate connective tissue, the **perimysium internum** or **endomysium,** the fibres of which are in part inserted into the sarcolemma. This connective tissue, which is especially developed at the ends of the fibres, serves to attach them either directly to the structures on which the muscle acts or to the skeletal framework of the muscle.

In the simplest mammalian muscles the muscle-fibres take a parallel course from tendon to tendon, and are not definitely bound into secondary groups. An example may be seen in fig. 338, a, which represents two segments of the rectus abdominis muscle of a mouse. More often, however, the individual fibres do not run the entire distance from tendon to tendon, but instead they interdigitate, and the interdigitating fibres are bound up into secondary and tertiary anastomosing fibre-bundles by connective tissue, in which there is usually a considerable amount of elastic tissue. Fig. 338, b, represents diagrammatically this interdigitation of fibre-bundles as seen in the abdominal musculature of one of the larger mammals.

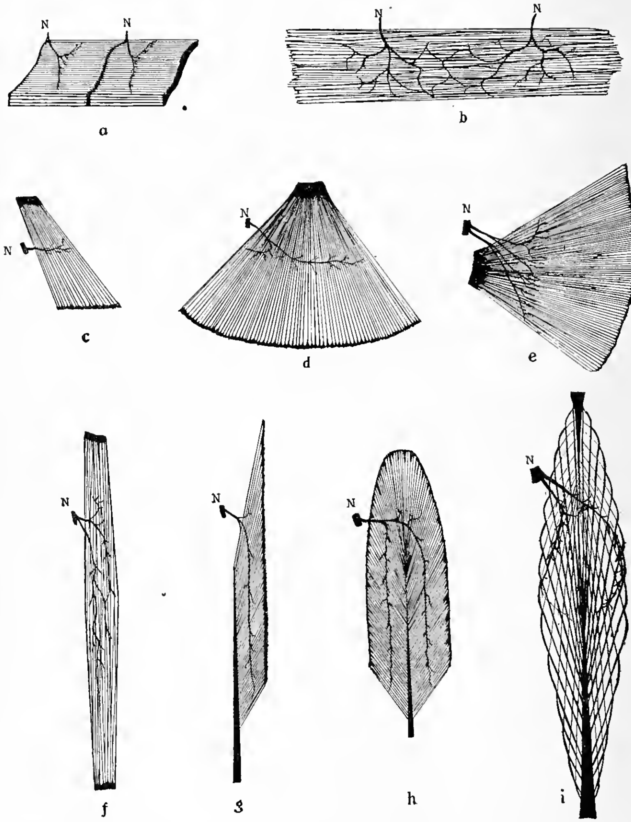
In most of the flat muscles of the body the fibre-bundles either take a nearly parallel course from tendon to tendon or they converge from the tendon of origin toward the tendon of insertion (see fig. 338, c–e). The greater the distance from tendon to tendon, the more marked is the interdigitation of the constituent fibre-bundles.

In elongated muscles the tendons of origin and insertion may either arise near the extremities of the muscle or may extend for a considerable distance on the surface or within the substance of the muscle. In the former case the belly of the muscle is composed of bundles of interdigitating fibres which take a course parallel with the long axis of the muscle. This is shown diagrammatically in fig. 338, f. An example may be seen in the sartorius muscle of the thigh (fig. 411). When the tendons extend far on the surface or within the substance of the muscle, the constituent fibre-bundles take a course oblique to the long axis of the muscle. When they take a course from a tendon of origin on one side toward a tendon of insertion on the other, the muscle is called **unipenniform** (see fig. 338, g, and the extensor digitorum longus, fig. 415). In other instances the fibre-bundles converge from two sides toward a central tendon. Such a muscle is called **bipenniform** (see fig. 338, h, and the flexor hallucis longus, fig. 416). When there are several tendons in the muscle between which the fibre-bundles run obliquely, the muscle is called **multipenniform.** In **fusiform** muscles the tendons usually either embrace the extremity of the muscle like a hollow cone, or they extend far on the surface or within the substance of the muscle. In such muscles the fibre-bundles take a curved course from one tendon to the other. The bundles which arise highest on one tendon are inserted highest on the other, and the fibre-bundles of lowest origin have the lowest insertion. This structure is diagrammatically shown in fig. 338, i. A good example may be found in the rectus femoris muscle (fig. 411).

Many other arrangements of the fibre-bundles are found, and the arrangements here shown may be variously combined. In most muscles the architecture is decidedly complex. In the more complex muscles dense connective-tissue septa, or intramuscular fasciæ, serve to separate different regions of the muscle from one another. In general there are groups of muscle fibre-bundles surrounded by a greater amount of connective tissue, or perimysium internum, than that surrounding the individual fibre-bundles, and the latter are surrounded by a denser connective

Fig. 338.—Diagrammatic Outlines to Illustrate Various Types of Muscle Architecture and the Relations of the Main Nerve Branches to the Fibre-bundles of the Muscle.

a. Two segments of the rectus abdominis muscle of a small mammal. b. Portion of sheet-like muscle with two nerve-branches and intramuscular nerve plexus. c. Typical quadrilateral muscle with nerve passing across the muscle about midway between the tendons. d and e. Two triangular muscles with different types of innervation. f. Long ribbon-like muscle with interdigitating fibre-bundles. g. Unipenniform muscle. h. Bipenniform muscle. i. Typical fusiform muscle. The main intramuscular nerve-branches are distributed to the fibre-bundles about midway between their origins and insertions. N. nerve.



tissue than that surrounding the component muscle-fibres. The muscles are surrounded externally by a more or less dense sheet of connective tissue called the **perimysium externum**, or epimysium, which is continuous with the connective tissue within the muscle, the perimysium internum. In the following pages 'muscle fibre-bundle' is used to denote small groups of muscle-fibres, 'fasciculus' to denote large, more or less isolated, groups of fibre-bundles.

Embryonic development of muscles.—The voluntary muscles are of mesodermal origin. The muscles of the trunk arise chiefly from the myotomes, those of the head and limbs chiefly from the mesenchyme in these regions. New muscle fibres are formed mainly before birth. After birth, growth of muscles depends on growth of individual muscle fibres.

Tendons.—Muscles vary not only in general form and in the relations of the constituent fibre-bundles to the intrinsic skeletal framework, but also in the mode of attachment to the parts on which they act. In many instances the fibre-bundles impinge, perpendicularly or obliquely, directly upon a bone or cartilage. The tendinous tissue arising from the fibre-bundles of the muscle here is attached to the periosteum or perichondrium or to the bone directly. A broad attachment is thus offered the muscle. Instances of this mode of attachment may be seen in the attachment of the intercostal muscles and of many of the muscles attached to the shoulder and hip girdles.

In the case of most thin, flat muscles the muscle is continued at one or both extremities into thin, tendinous sheets called **aponeuroses,** composed of connective tissue. Well-marked instances may be seen in the transverse muscle of the abdomen (fig. 390), and the trapezius and latissimus dorsi muscles of the back (fig. 355). The extent of development of these aponeuroses is generally inversely proportional to the development of the muscle—the more extensively developed the muscle is in a given individual, the less extensive the aponeurotic sheet.*

Most muscles are continued at one or both extremities into dense, tendinous bands which may be comparatively short and thick, like the tendon of Achilles (fig. 413), or very long and narrow, like the tendon of the palmaris longus (fig. 370). In this latter case the tendon represents in part the remnants of musculature more highly developed in the lower vertebrates. In most instances, however, the tendons are structures specifically differentiated for definite functions and are composed of bundles of parallel connective-tissue fibrils held together by an interlacing fibrous-tissue framework. The tendons usually contain a relatively small amount of elastic tissue.

The tendons are attached to the skeleton early in embryonic development. As the bones enlarge the tendons become in part incorporated in the substance of the bone and ossified.

In some tendons **sesamoid bones** are developed in the neighbourhood of joints over which the tendons pass. Examples of these are the patella at the knee-joint (fig. 412) and the sesamoid bones of the thumb and great toe.

Where muscles or tendons closely envelope a joint, there is usually formed a close union between the connective tissue of the capsule of the joint and that of the muscle or the tendon. Special bands may develop in the direction of the pull of the muscle (lig. popliteum obliquum).

Where tendons run for some distance across or beneath a fascia, they are usually either bound to the fascia by a special investment, as near the wrist and knee (fig. 366 and fig. 414), or are fused with the fascia, as in the case of the iliotibial band. Fibrous tracts in the fascia may indicate stress under muscle contraction (the lacertus fibrosus of the fascia of the forearm).

Often in broad aponeurotic attachments of muscles there is formed in the tendon near the attachment a fibrous archway [**arcus tendineus**] for the passage of blood-vessels, nerves, muscles, or tendons. The tendinous arch is either fastened at both ends to the bone, or at one end it is connected with a joint capsule or other membrane. The dorsal attachment of the diaphragm (fig. 391) and that of the adductor magnus to the femur (fig. 409) offer good examples of tendon arches.

In digastric and polygastric muscles the transverse tendons which separate the bellies are often composed of narrow, incomplete bands of fibrous tissue. Such a transverse band is called an **inscriptio tendinea** (see Rectus Abdominis Muscle, fig. 388).

Tendon sheaths.—The tendons are held in place by sheaths composed of dense connective tissue. These sheaths vary in different regions. In the most complete form they confine tendons in osseous grooves which they convert into osteofibrous canals on the flexor surface of the digits. The sheath is here called a **vagina fibrosa tendinis.** It is strengthened by tendinous bands (**vaginal ligaments**). In other regions special dense bands or ligaments, **retinacula tendinum,** confine a series of tendons in place, as at the ankle (fig. 417), or fasciæ may be modified for this purpose, as at the back of the wrist (fig. 366). A tendinous loop,

* The terms fascia and aponeurosis are often loosely and interchangeably used. It seems best to make a distinction by restricting the term fascia to membranous sheets of investment, and aponeurosis to broad tendons. The latter may, however, be inserted into and form a part of the former.

annulus fibrosus, may hold a tendon in place, as, for instance, the trochlea of the tendon of the superior oblique muscle of the eye.

Synovial bursæ [bursæ mucosæ].—Where there is freedom of action between muscles and tendons and the surrounding parts, there intervenes a loose connective tissue. In regions where the pressure is great or considerable friction would result were these conditions retained, there are developed special cavities with smooth surfaces and containing fluid. Most of these bursæ are developed from the intervening connective tissue at a period in embryonic life preceding muscular activity, but special bursæ may later be developed as the result of unusual pressure or muscular activity after birth. An instance of a bursa lying in a region of friction may be seen in the bursa intervening between the tendinous posterior surface of the ilio-psoas muscle and the ilio-femoral ligament. As an instance of a bursa lying in a region of intermittent pressure may be cited that between the tendon of Achilles and the calcaneus.

Most synovial bursæ intervene between a tendon and a bone, a tendon and a ligament, or between two tendons (**subtendinous bursæ mucosæ**). Others lie between two muscles, a muscle and some skeletal part, or between a muscle and a tendon (**submuscular bursæ mucosæ**); or below a fascia (**subfascial bursæ mucosæ**). Subcutaneous bursæ have been referred to in connection with the tela subcutanea (see p. 313). Most bursæ are developed near joints. The bursæ may so expand during active life that they come to communicate with other bursæ or with a neighbouring joint cavity.

Synovial sheaths [vaginæ mucosæ tendinum].—Synovial sheaths are developed about tendons where the latter are confined in osteo-fibrous canals, as in the fingers. The wall of the canal and the enclosed tendon, or tendons, are each covered by a smooth membrane which at the extremities of the canal is reflected from the wall to the tendon. Between the membrane covering the tendon and that lining the canal is a synovial cavity. An interesting feature of these tendon-sheaths is the presence of **mesotendons,** delicate bands of vascular connective tissue which run in places from the osseous groove to the tendon and carry blood-vessels and nerves.

Trochleæ.—Where a tendon passes at an angle about a bone, the tissue in the groove in which the tendon runs frequently is composed of hyaline cartilage instead of bone. An example may be seen in the trochlear process of the calcaneus.

Nerves.—To each muscle of the body a nerve containing motor and sensory fibres is distributed. A few muscles receive two or more nerves. Sherrington has estimated that in the muscle-nerves of the cat two-fifths of the fibres are sensory and three-fifths motor.

The muscles of the head and in part those of the neck are supplied by branches of the cranial nerves. The intrinsic muscles of the neck, back, thorax, and abdomen are supplied by branches which arise fairly directly from the spinal nerves. The muscles of the limbs are supplied by branches from nerve-trunks which arise from plexuses formed by the spinal nerves in the regions near which the limbs are attached.

The main nerve-trunks lie beneath the superficial muscles. They usually run in the intermuscular septa which separate the deeper groups of muscles from one another and from the superficial muscles. The nerve-branches which enter a given muscle usually pass in where the larger intramuscular septa approach the surface of the muscle, and then ramify through the perimysium internum, the smaller branches being distributed in the finer layers of connective tissue which surround and separate the primary muscle fibre-bundles, to the constituent muscle-fibres of which terminal branches are given. Special sensory end organs are distributed chiefly in the large intramuscular septa, in the tendons and in the muscles near the tendons. Simple sensory endings are found on the muscle fibres.

The size of a nerve supplying a muscle is not proportional to the size of the latter, but rather to the complexity of movements in which the muscle plays a part.

Muscles receive their nerve supply early in development. During later development the muscle may wander a considerable distance from its place of origin and carry its nerve with it. The diaphragm, innervated by cervical nerves, is a good example.

The distribution of the motor nerves varies according to the architecture of the muscle, but in general it appears that the nerves are so distributed as to carry the main branches of distribution most directly to the middle of the constituent fibre-bundles. This is seen most clearly in muscles with comparatively short fibre-bundles, where the individual muscle-fibres run nearly or quite the entire distance from tendon to tendon (fig. 338 a, c, d, e, g, h, and i). When the distance is long, a marked plexiform arrangement is found (fig. 338, b and f). To each muscle fibre there is distributed a terminal nerve-fibre which passes through the sarcolemma and ends in a motor end organ (muscle plate). Occasionally there are two such nerve-fibres to one muscle-fibre.

Vessels.—The muscles are richly supplied with blood. In many instances the larger blood-vessels accompany the larger nerve-trunks as they enter the muscle, and their primary branches are distributed in the larger intramuscular septa. Often, however, the main blood-vessels approach a muscle from a direction different from that taken by the nerves. Each muscle has, however, its own blood supply. There is little anastomosis between the blood-vessels of a muscle and those of a neighbouring structure, but the anastomosis between the vessels within the muscle is exceedingly rich. Veins, as a rule, accompany all but the smallest arteries within the muscle. The veins are richly supplied with valves, so that muscle contraction promotes the flow of blood through the muscle. Rich capillary plexuses surround the muscle-fibres. The capillaries are of unusually small diameter.

During contraction, the blood is forced from the muscles; during expansion it rushes in through dilated arteries which furnish five or six times as much blood to muscles during exercise as that supplied to them during rest.

The connective-tissue sheaths, the larger intramuscular septa, and the tendons of muscles are richly supplied with lymphatics. There are no lymphatics within the muscle bundles or in small muscles.

Nomenclature.—The names of the various muscles and their classification are less satisfactory than is desirable. The muscular system was first carefully studied in the human body, and names based sometimes upon the shape, structure, size, or position, at other times upon the supposed function or other associated facts, were applied to the muscles found in various regions. Sometimes two or more names were applied to a muscle to indicate several of these factors. Thus *trapezius* and *triangularis* indicate the shape of the corresponding muscles; *biceps* or *triceps* indicates the origin by two or three heads; *rectus*, *obliquus*, and *transversus* represent the direction taken by a muscle or its constituent fibre-bundles; *magnus* and *minimus* indicate size; *sublimis* (superficial) and *profundus* (deep) represent the relative positions occupied; *sterno-cleido-mastoid* indicates structures to which the muscle is attached; *flexor* and *extensor* indicate function; and *sartorius* indicates that the corresponding muscle was supposed to be of use to tailors.

Since careful study has been devoted to the comparative anatomy of the muscles in various vertebrates, it has become apparent that a simple and more consistent nomenclature applicable to corresponding muscles found in various animals would be of great value. A satisfactory nomenclature of this sort has not, however, as yet been devised and adopted in comparative anatomy, and the established usage of the terms now familiarly applied to the muscles of the human body makes it seem improbable that even if such a system were devised for comparative anatomy it could be brought into extensive use in human anatomy. For many of the muscles in the human body various synonyms have been in use in different countries. The Anatomical Congress assembled at Basel in 1895, to simplify the nomenclature of human anatomy, adopted in large part the terms in familiar use in England and America. In the following pages the terms approved by the Congress will be employed, but where they differ materially from those previously in use, the synonym will be given in parentheses.

Classification.—The muscles are usually treated strictly according to the region of the body in which they are found. This method of consideration is still of value in a dissector's guide and in text-books of topographical anatomy. But in studying the muscles scientifically it is of importance also to consider them in their more fundamental genetic relationships to one another and to the nervous system. Embryology and comparative anatomy have proved of the greatest value in revealing these relationships. Studies of this nature have revealed well-marked relationships in the adult human musculature which are of practical as well as scientific importance. The voluntary musculature may be broadly divided into that of the skeletal axis, the limbs, and the visceral orifices. The musculature of each of these divisions has a different and in general simpler form in the lower than in the higher vertebrates, and in the embryos of the higher vertebrates than in the adult. The musculature of the spinal region of the body axis of fishes, the tailed amphibia, and all vertebrate embryos is metamerically segmented; that is, it is divided along the axis of the body into a series of components corresponding with the segmentation of the vertebral column. Although marked alterations take place in the subsequent ontogenetic differentiation in higher vertebrates, traces of this primitive segmentation are still to be found in the adult; in man, for instance, in the intercostal muscles and the segments of the rectus abdominis. In the region of the head conditions are complex, owing to the concurrent presence of muscles which primitively correspond in nature with the segmental spinal musculature, and muscles non-segmental in character, which surround the visceral orifices. This also is true of the anus and external genitalia, where, however, the conditions are simpler. Embryology and comparative anatomy have done much to clear up puzzling features in both regions.

The muscles of the limbs are metamerically arranged in no adult vertebrate. In some of the lower forms a series of axial muscle segments, myotomes, furnishes material from which the musculature of the limbs is differentiated. In the mammals this appears not to be the case, and the muscles are differentiated from the non-segmental tissue of the limb-buds.

Where mammalian musculature is primitively segmental, each segment becomes associated with a corresponding spinal nerve or, in the head, with a nerve which corresponds in series with a spinal nerve. Even when subsequent differentiation brings about marked alterations in the axial musculature, the nerves maintain to a considerable degree a segmental distribution.

Into each of the limbs, where the intrinsic musculature is at no time segmental, there extends during embryonic development a series of segmental spinal nerves, so that in them, as in the region of the body axis, a certain segmentation in the nerve-supply can be made out in the adult. That part of the limb nearest the head in early embryonic development has its muscles supplied by the most cranial, that part nearest the caudal extremity of the body by the most caudal, of the nerves which supply the limb musculature. There is here, however, considerable overlapping of the segmental areas.

Variation.—In man some variation in the arrangement of the muscles is met with in every individual, and often marked deviations from the normal conditions are found. The muscles vary in their mode of origin or insertion, and in the extent to which muscles of a given group are fused with one another or to which the chief parts of a complex muscle are isolated from one another. Some muscles, like the palmaris longus and the plantaris, are frequently entirely absent, and other muscles generally absent are frequently present.

In addition to these frequent variations there are others so rare that many authors prefer to speak of them as anomalies rather than variations. Sometimes muscles may be found doubled by longitudinal division, or two or more muscles normally present may be fused into a single indivisible muscle. Occasionally there occur muscles constantly present in some of the lower animals, but normally not met with in the human body (anomalies of reversion or of convergence). In such instances the muscle may be normally represented by a tendon or fascia. At times the anomalies are supposed to be not a reversion to an ancestral condition, but a distinct step in advance. This, however, is difficult to prove. At other times no phylogenetic relation is apparent, and the anomaly is looked upon as a monstrous sport or as the result of some pathological condition.

The nerve-supply of the muscles is of value in the study of muscle variations. There is, however, not infrequent variation in the nerves with relation to the supply of the muscles.

Physiology.—From the standpoint of morphology the muscles are grouped according to their intimate relations to one another and to the peripheral nerves, relations, as noted above, that are made more clear by a study of comparative anatomy and embryology. From the physiological aspect a different grouping of the muscles is required, because muscles belonging morphologically in one group may have different physiological functions in the animal body. The chief features of the mechanical action of muscles may be briefly considered here.

Most muscles act on the bones as levers. In physics three types of levers are recognised In levers of the first type (fig. 339, I) the fulcrum (F) lies between the place where power (P) is exerted on the lever and the point of resistance or load (L). Levers of this kind are frequently met with in the body. A good example is seen in the attachment of the skull to the vertebral column. The fulcrum lies at the region of attachment; the weight of the skull tends to bend the head forward, while the force exerted by the dorsal muscles of the neck serve to keep the head upright or to bend it back.

In levers of the second class (fig. 339 II) the point on which power is exerted moves through a greater distance than the point of resistance. Speed of movement is thus sacrificed to power. Levers of this type are exceedingly rare in the animal body. An example in the human body is the foot when the body is raised on the toes.

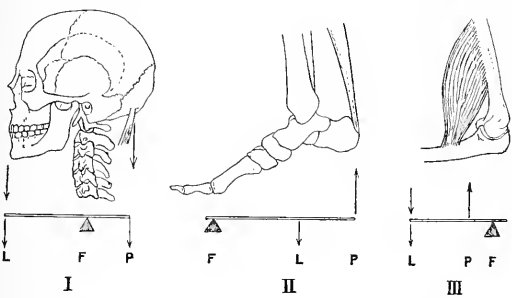
In levers of the third class (fig. 339, III) the point on which force is exerted moves a less distance than the point of resistance. Power is thus sacrificed to speed. This is the common form of leverage found in the body. A good example is found in the action of the muscles which flex the forearm on the arm. The region in which the biceps and brachialis are attached is but a short distance from the elbow-joint or fulcrum, while the hand may be looked upon as the region of resistance to the force exerted. A movement of the point P through a short distance will cause L to move through a great distance.

The more the angle between a muscle or its tendon and the bone on which it acts approaches a right angle, the greater is the power of movement exerted by the muscle. The arm in fig. 339, III, is in the position of greatest advantage for the action of the biceps on the forearm. All boys know that it is easier to 'chin' oneself after the arm is partly bent than when hanging straight from a bar. Many of the muscles run nearly parallel with the parts on which they act, but the tendons before their attachment are usually either carried over a bony prominence or some fascia or ligament acts as a pulley so that the tendon is inserted at an oblique angle. At other times a process for the attachment of the tendon projects from the bone and causes the force of the contracting muscle to be more advantageously exerted on the bone. It may, of course, readily be seen that the greater the distance of the attachment of a muscle from the joint over which it acts, the greater will be the power exerted by the muscle.

In considering the movements of the body, it is convenient to recognise two groups, simple and complex. To the former, which alone can be considered in a text-book of anatomy, belong such movements as flexion, extension, adduction, rotation, etc., while to the latter belong those associated movements which give rise to changes in the positions of the body as a whole or of extensive regions of the body.

In **flexion** the extremities of the trunk or limbs or special portions of these regions are bent near to one another; in **extension** the reverse movement is brought about. The parts are straightened or even bent beyond the straight position (over-extension).

Fig. 339.—Three Diagrams (after Testut) to Illustrate Different Types of Levers in their Relations to the Mechanical Action of the Muscles.



In **abduction** transverse movements are made, a part being bent away from the median line of the body or limb; in **adduction** the reverse movement is brought about.

In **rotation** a part is turned on its longitudinal axis. The rotation of the femur at the hip-joint is called medial rotation when the toes are turned medialward, lateral rotation when the toes are turned lateralward. Rotation at the shoulder-joint is called medial when the thumb is turned forward and medialward toward the body, lateral when the reverse movement takes place. These movements are also carried out at the elbow-joint, but here medial rotation is called **pronation**, lateral rotation, **supination**. Fick prefers these terms also for the rotation at other joints as at the shoulder, hip and knee.

At the shoulder-joint the swinging of the arm toward the back is called extension; toward the front, flexion; and from the side, abduction. Moving the arm toward the mid-dorsal or mid-ventral line is called adduction.

Taking the body as a whole the musculature may be divided into two main divisions, an *expander division* and a *contractor division*. In general the extensors, abductors and lateral rotators expand, the flexors, adductors and medial rotators contract.

In the most expanded condition the head and spine are extended or even slightly hyper-extended (flexed dorsally), and the limbs project laterally from the body with the backs of the hands and feet facing dorsalward, the palms and soles ventralward, and the digits spread out. In the fully formed human body it is not possible to put the lower extremity in the completely expanded position, although it is in this position early in embryonic development. As development proceeds the lower extremity is adducted and rotated medialward and the girdle is so fixed that full abduction becomes no longer possible. In many of the lower vertebrates full abduction is possible throughout life in the lower extremities just as it is throughout life in the upper extremities in man. Full extension of the spinal column in man is also hindered in the thoracic region by the thorax, and in the sacro-coccygeal region by the osseous union of the vertebræ with one another as well as by the attachment of the hip girdles. The lumbar region in man is in a condition of permanent hyper-extension.

In the fully contracted condition the head and spinal column are strongly flexed, and the digits are adducted, the various segments of the limbs are flexed and the limbs are adducted, flexed and rotated medialward toward the middle of the trunk. The body approaches a ball in form. It is the position taken by a gymnast when turning a somerset in the air, and is in marked contrast to the fully expanded condition which would be assumed could man fly like a bat or glide like a flying squirrel.

In general, the muscles which tend to put the body or a part of the body into the expanded position form a distinct group as contrasted with those which tend to put the body into the contracted position. The chief musculature which extends the head and trunk lies dorso-lateral to the spinal column and is supplied by the dorsal divisions of the spinal nerves. The chief musculature which flexes the head and trunk lies ventro-lateral to the spinal column and is supplied by ventro-lateral divisions of the spinal nerves. The chief muscles which abduct, extend and rotate the limbs lateralward arise during embryonic development on the dorsal sides of the limb buds and are innervated by branches from the dorsal sides of the brachial and lumbo-sacral nerve plexus. The chief muscles which flex, adduct and rotate the limbs medialward arise on the ventral sides of the limb buds and are supplied by nerves which arise from the ventral sides of the limb plexuses. To these general rules there are some exceptions, the most marked of which is at the hip-joint where rotation of the girdle has brought about a condition in which the primitive action of the flexor and extensor groups is partly reversed. The chief flexors (the ilio-psoas and rectus femoris) belong to the dorsal division and some of the chief extensors (the hamstring muscles) belong to the ventral division. At the ankle-joint the exception is more apparent than real. What is usually called flexion at the ankle-joint is really hyper-extension and the reverse movement is the nearest we can come to real flexion. In the extremely contracted position of the body as a whole the feet are extended (flexed plantarward) at the ankle-joint.

Muscles which produce a movement in a common direction are called **synergists,** while those whose contraction produces opposite movements are called **antagonists;** e. g., the flexors and extensors are antagonists. In the actual working of the muscular system, however, when a set of muscles is contracting to produce a movement, the antagonists also contract to a certain degree. The movement is the result of nerve impulses sent simultaneously to all the muscles which act on the part moved.

The relation of the internal architecture of a muscle to the movements to which its contraction gives rise is a complex subject, the details of which cannot be entered into here. In general it may be said that when the fibre-bundles run directly from one attachment to the other, as in fig. 338, a and f, the force exerted by the contraction of the individual muscle-fibres is most efficiently utilised and the extent of the movement varies directly as the length of the fibres, while the force exerted varies directly with the number of the fibres.

In muscles of the types indicated in fig. 338, g, h, i, a certain amount of the extent of movement and of the force exerted by the contraction of the individual fibres is not effectively exerted on the parts moved by the muscles, as may be seen by applying to this action the laws of the parallelogram of forces. In such muscles, however, the great number of short muscle-fibres composing them makes possible the exertion of great power with some loss of speed of contraction in the muscle as a whole.

The direction of the movements which result from muscular contraction is in large part determined by the shape of the articular surfaces, none of which are to be looked upon as simple fulcra, but instead, during a given movement, the fulcrum shifts from one region to another of the joint.

In different muscles the extent of contraction of the constituent fibre-bundles during activity varies considerably. While usually the length of the contracted fibre-bundles is half that of those in the extended state, the amount of shortening in some muscles is only 25 to 35 per cent.

Functional activity is necessary for the full development or for the maintenance of development in muscles. Muscles atrophy if their nerve supply is injured or if they are passively prevented from contracting.

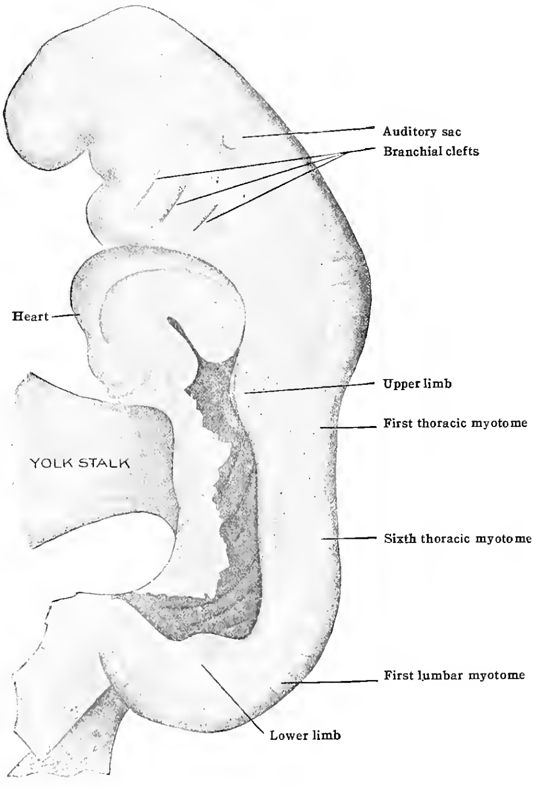
Order of treatment.—The muscles and fasciæ are here treated in the following order:—(1) those of the head and neck and shoulder girdle (p. 323); (2) those of the upper extremity (p. 360); (3) those of the back (p. 410); (4) those of the thorax and abdomen (p. 422); (5) those of the pelvic outlet (p. 439); (6) those of the lower extremity (p. 452). The reason for taking up the musculature in the order named is, that during embryonic development musculature belonging primitively to the head comes to overlap that of the neck; that of the neck spreads over the region of the back and thorax, and becomes attached to the shoulder girdle; that of the arm extends over the region of the thorax, abdomen, and back; that of the back partially over the region of the thorax; while that of the abdomen enters into intimate relation with the pelvic girdle. So far as practicable the musculature of these various regions will be taken up according to fundamental morphological relationships.

Since a morphological grouping of the muscles does not accord perfectly with a physiological grouping, there is given at the end of this section a table showing what muscles are concerned in performing the simpler voluntary movements.

The topographical relations of the muscles in various regions of the body are illustrated in the series of cross-sections given for each region.

Tables illustrating the relations of the central nervous system and the peripheral nerves to the muscles are given in the section on the nervous system (Section VI).

FIG. 340.—HUMAN EMBRYO (LR) 42 MM. LONG. (After His.)



I. MUSCULATURE OF THE HEAD, NECK AND SHOULDER GIRDLE

PHYSIOLOGICAL AND MORPHOLOGICAL ASPECTS

The head, situated at the anterior end of the trunk in bilaterally symmetrical animals, is primitively that part of the body first brought into contact with new surroundings as the animal moves forward. We therefore find developed here the most highly differentiated organs of special sense, those of vision, hearing, and smell, through which the animal is put in touch with an environment more or less removed from immediate contact with the body. In connection with these organs of special sense, the brain is developed. In most animals the head also is the chief organ for the prehension of food and for attack and defense. The neck is a part of the trunk differentiated to give freedom to the movements of the head. The forelimbs, relatively unimportant as the forefins in the fishes, become important organs of locomotion in the land animals. In the fishes there is no true neck, but the forefins are developed at the sides of the cervical part of the trunk. In the higher vertebrates the forelimbs are also first differentiated at the sides of the cervical region (fig. 340) but, as embryonic development goes on, they shift caudalward to the sides of the cranial (anterior) part of the thorax. The cervical region is thus left free for movement but the musculature and nerves of the upper extremity remain intimately related to it.

In man, with the assumption of the erect posture, the head no longer has to bear the brunt of the new surroundings as the body moves forward. There is, however, a distinct advantage in having those organs of special sense, which put the individual into touch with the more distant parts of the environment, situated high above the ground, and a motile neck is of great value in directing the organs of special sense toward various parts of the environment. The development of the superior extremities as organs for the prehension of food and as organs of attack and defense reduces the value of the head for these purposes, but still leaves it the important functions of the reception of food and air and the preparation of food for gastric and intestinal digestion. The head, furthermore, assumes a new and most important function as an organ for the expression of the emotions and of speech.

The expression of the emotions, such as anger, fear, affection and the like,* is brought about largely through the action of flat, subcutaneous "facialis" muscles which underlie most of the skin of the face and head and extend down under that of the neck (figs. 341 and 344). They also line the mucous membrane of the lips and cheeks. Most of them arise from the surface of the skull and are inserted into the skin, which they pull in various directions causing it to become smooth or wrinkled, according to the direction of the pull. The various muscles are grouped about the buccal, nasal and aural orifices and about the orbit of the eye. Some of the fibre-bundles are arranged so as to constrict the orifices, others radiate out so as to dilate them.

The chief groups of muscles of the head and neck, in addition to the facialis group just mentioned, are the muscles of the orbit and middle ear, the muscles used in mastication and swallowing (cranio-mandibular, supra- and infrahyoid groups, muscles of the tongue, soft palate and pharynx), the muscles of the larynx, and the ventral and dorsal groups of muscles which lie in the region of neck, extend over the thorax and move the head, neck and shoulder girdle. A brief summary of these groups will be given before proceeding to a more detailed account.

Facialis group.—The muscles are especially well developed about the mouth, a sphincter muscle (*orbicularis oris*) serving to close, the radiating muscles to open the lips (*quadratus labii superioris* and *inferioris*), to pull the corners of the mouth in various directions, as, for instance, upward to express bitterness (*caninus*) or pleasure (*zygomaticus*), or lateralward and downward to express grief or pain (*risorius, triangularis, platysma*) or to protrude the lips as in pouting (*mentalis* and *incisive* muscles). The *buccinator*, which radiates out from the corner of the mouth and lines the mucous membrane of the cheek, is used in mastication and whistling.

About the **orbit** and in the **eyelids** a circular musculature (*orbicularis oculi*) is broadly developed. It is used to close the eyes, and to contract the skin about the orbit. Associated with the orbicularis are muscles which produce perpendicular furrows in the skin of the forehead above the nose (*procerus, corrugator*). The skin is drawn upward from the orbit and horizontal furrows are caused in the skin of the forehead by muscles attached to the **scalp** (epicranius). Two of these muscles, the *occipitales*, arise one on each side from the occipital bone and are attached to an aponeurosis which lies beneath the scalp to which it is firmly united. Two of the muscles, the *frontales*, extend one on each side from this aponeurosis to the skin above the eyebrows.

About the **nasal orifices** there are weak constrictors (*alar part* of the *nasalis, depressor alæ nasi*) and dilators (*dilator naris anterior* and *posterior, transverse part* of the *nasalis, angular head* of the *quadratus labii superioris*). From the ear (auricle) three flat muscles radiate, one backward (*auricularis posterior*), one upward (*auricularis superior*) and one forward (*auricularis anterior*). These muscles are seldom functionally developed. They pull the auricle in their respective directions. They may be looked upon as (primitively) dilators of the aural orifice. On the cartilage of the auricle are several rudimentary "intrinsic" muscles which may be looked upon as remnants of a constrictor of this orifice.

*See Darwin: The Expression of the Emotions in Man and Animals.

In the **orbital** cavity there are six muscles which are attached to and move the eyeball and one muscle (the *levator palpebræ superioris*) which extends into and raises the upper lid (fig. 341). Of the muscles which move the eyeball five arise like the levator of the lid, from the back of the orbit. Four of these, the *rectus muscles*, are inserted respectively into the superior, inferior, medial and lateral sides of the eyeball and direct the pupil upward, downward, medialward and lateralward. One, the *superior oblique*, sends a tendon through a loop at the upper, front part of the nasal side of the orbit and thence to the upper surface of the eyeball. Another muscle, the *inferior oblique*, arises from the nasal side of the front of the lower part of the orbit and is attached to the lower part of the eyeball. The oblique muscles prevent the rectus muscles from rotating the eyeball. These muscles are supplied by the third, fourth and sixth cranial nerves. They are described in the section on the eye, p. 1067. In the **middle** ear are two small muscles (the *tensor tympani* and the *stapedius*) attached respectively to the malleus and stapes and supplied by fifth and seventh cranial nerves. They are described in the section on the ear, p. 1091.

Mastication and swallowing.—The complex musculature used in biting, masticating and swallowing food is used also in speech in conjunction with the muscles of the larynx and the lips. The two movable bones of the skull concerned with these functions are the mandible and the hyoid bone. The mandible articulates with the skull on each side, just in front of the external auditory meatus. The hyoid bone is connected on each side by the stylo-hyoid ligament with the styloid process of the temporal bone, which descends just behind the external auditory meatus. A powerful group of muscles, the **cranio-mandibular** *muscles* (figs. 344, 345, 346, 347 c), or muscles of mastication, arise from the temporal fossa (*temporal* muscle), the zygomatic arch (*masseter* muscle) and the pterygoid process (*external* and *internal pterygoid* muscles) and are inserted into the coronoid process of the mandible (*temporal* muscle), the outer side of the ramus (*masseter* muscle), the inner side of the ramus (*internal* pterygoid), and into the condyle of the jaw (*external pterygoid*). These muscles raise the jaw, move it forward and from side to side, and are used in biting and chewing the food. They are innervated by the fifth cranial (masticator) nerve.

Another less powerful group of muscles, the **suprahyoid** group (fig. 348), is divisible into two subdivisions, **hyo-mandibular** which extends in front between the hyoid bone and the ramus of the jaw (anterior belly of the *digastric, genio-hyoid, mylo-hyoid*) and a **hyo-temporal** group which extends between the hyoid bone and the temporal bone back of the external auditory meatus (*stylo-hyoid*, posterior belly of the *digastric*). Two of the hyo-mandibular muscles (the anterior belly of the digastric and the mylo-hyoid) are innervated by the trigeminal; the genio-hyoid by the hypoglossal nerve. The two hyo-temporal muscles (posterior belly of the digastric and stylo-hyoid) are innervated by the facial nerve. Morphologically therefore, as indicated by this innervation, the muscles of this group are diverse. Physiologically they are closely united. The group, acting as a whole, elevates the hyoid bone and with this the larynx and the tongue. If, however, the hyoid bone be fixed by contraction of the neck muscles (infrahyoid muscles) attached to its lower border, the suprahyoid muscles act as antagonists of the cranio-mandibular muscles and depress the jaw. The hyo-mandibular muscles form, together with the tongue, the muscular floor of the mouth. When acting with the hyo-temporal muscles they help the tongue to pass food into the pharynx. When acting alone the hyo-mandibular muscles draw forward the hyoid bone and with it the base of the tongue and the larynx and thus open the passage from the pharynx into the œsophagus. The two hyo-temporal muscles, acting in conjunction with the middle and inferior constrictors of the pharynx, draw the hyoid bone and larynx backward, as well as upward, and thus constrict the pharynx while giving free passage for air from the naso-pharynx into the larynx. The chief functions of the suprahyoid group are, therefore, to play a part in deglutition and respiration.

Closely associated with the muscles of the suprahyoid group in the performance of these important functions are the muscles of the tongue, the pharynx and the soft palate. The bulk of the **tongue** (fig. 349) is made up of muscles which have their origin on each side from the inner surface of the front part of the mandible (*genio-glossus*), the hyoid bone (*hyo-glossus* and *chondro-glossus*) and the styloid process of the temporal bone (*stylo-glossus*). Muscles also connect the tongue with the palate (*glosso-palatinus*) and with the pharynx (*glosso-pharyngeus*). These muscles, together with intrinsic longitudinal, transverse and perpendicular fibre-bundles, enable the tongue to perform the complex activities associated with mastication and swallowing and with speech. During mastication the tongue passes the food from side to side between the teeth. When the food has been masticated the tongue forms a bolus of it and then this is passed into the pharynx by a sudden elevation of the dorsum of the tongue produced in part by the muscles of the tongue, in part by the suprahyoid group of muscles. The muscles of the tongue are described on p. 345.

The **pharynx** is the dilated upper part of the alimentary canal into which open the Eustachian tubes, the nasal passages, the mouth and the larynx. The walls of the side and back of the pharynx are composed mainly of muscular tissue. The chief muscles are three "**constrictor**" muscles on each side, a *superior*, a *middle* and an *inferior*, and an elevator and dilator, the *stylo-pharyngeus* (fig. 894). The three constrictor muscles are attached to the median raphe* which extends in front of the spinal column from the base of the occipital bone to the sixth cervical vertebra. The *superior constrictor* muscle is attached to the pterygoid process, the pterygo-mandibular ligament, the mandible and the side of the root of the tongue (fig. 343); the *middle constrictor* to the hyoid bone; and the *inferior constrictor* to the larynx. These muscles constrict the pharyngeal orifice and thus force food into the œsophagus. The *stylo-pharyngeal* muscle, which extends from the styloid process into the lateral wall of the pharynx, serves to

* The attachments to the raphe are usually spoken of as the insertions, those to the bones in front as the origins of these muscles. The raphe is, however, a more fixed structure than most of the structures to which the constrictors are attached in front.

elevate and dilate the pharynx and elevate the larynx. The muscles of the pharynx are described on page 1134.

The orifices of the various passages into the pharynx are dilated or constricted by muscular action. The orifices of the nasal passages, the Eustachian tubes, and the mouth are controlled mainly by the musculature of the soft palate and pharynx. The orifice of the larynx is controlled by special muscles which act in conjunction with those of the suprahyoid group, the tongue, and the pharynx.

The soft palate is a muscular partition which is continued backward from the hard palate between the buccal cavity and the naso-pharyngeal orifice and then bends downward between the back part of the mouth and the nasal part of the pharynx, terminating in a median projection, the uvula. Above, on each side, back of the fold of tissue (*plica salpingo-palatinus*) which descends from the ventral border of the orifice of the Eustachian tube and which marks laterally the passage from the nose into the pharynx, there is a muscle, the *levator veli palatini* (fig. 343). This arises from the petrous portion of the temporal bone and from the Eustachian tube descends to the middle of the side of the soft palate and then spreads out broadly on its dorsal side. The muscle from each side interdigitates to some extent with that of the other side. These muscles raise the soft palate toward the upper part of the posterior wall of the naso-pharynx and thus shut off the nose from the buccal portion of the pharynx during deglutition. The sides of this portion of the pharynx are, meanwhile, constricted by the superior constrictors of the pharynx and by the pharyno-palatinus muscles described below. Contraction of the levator veli palatini tends to cause folds of tissue to close firmly the opening of the Eustachian tube. This is counteracted by the *tensor veli palatini* muscles (fig. 343). One of these arises on each side from the pterygoid region of the sphenoid bone, and is inserted into the anterior part of the soft palate by a tendon which passes beneath the hamular process of the pterygoid process. Contraction of this pair of muscles flattens the anterior part of the soft palate and exerts a traction which dilates the orifice of the Eustachian tube. Most authorities state that the Eustachian tube is thus opened each time we swallow. As air is admitted into the middle ear the tensor tympani muscle contracts so as to prevent too sudden an effect on the ear drum (Jonnesco.)

Dorsal to the fibres of the elevator of the palate in the soft palate next the median line on each side there extends from the hard palate into the uvula a small muscle, the *muscle of the uvula*, which lifts the tip of this and shortens the soft palate from front to back thus enlarging the opening from the mouth into the pharynx. On each side of the uvula the posterior edge of the soft palate is continued backward and downward into a fold, the *arcus pharyngo-palatinus*, which contains a muscle, the *pharyngo-palatinus* (fig. 865). This arises from the soft palate, passes downward and backward on the inner side of the lateral wall of the pharynx and divides into two fasciculi, one of which is attached to the larynx, the other to the median raphe. The muscle constricts the pharynx at the junction between the nasal and buccal portions and elevates the larynx. As the bolus of food is passed from the dorsum of the tongue into the pharynx the bucco-pharyngeal opening is dilated by the contraction of the elevators of the palate and uvular muscles and the opening into the naso-pharynx is closed not only by the soft palate being raised against the posterior wall of the naso-pharynx but also by the lateral folds raised on each side by the pharyngo-palatinus against the uvula. Meanwhile the larynx is raised by the pharyngo-palatinus and the stylo-pharyngeus, as well as by the suprahyoid muscles, and carried forward by the hyo-mandibular subdivision of the latter muscles so that the opening from the pharynx into the œsophagus is dilated for the passage of food. At the same time the opening into the larynx is constricted from above, the larynx being carried forward beneath the tongue so that the epiglottis slants somewhat backward. This backward slant is aided by the constriction of the thyreo-hyoid muscle which raises the thyreoid cartilage toward the hyoid bone and by the stylo-glossus muscle which pulls the tongue backward over the larynx. The opening into the larynx is constricted at the sides and behind by the contraction of muscles which run in the aryepiglottic folds and by the thyreo-arytenoid and transverse arytenoid muscles. At the end of deglutition the larynx is pulled back from beneath the base of the tongue by the middle and inferior constrictors of the pharynx and the opening is again dilated. The buccal cavity may be shut off from the pharynx by the action of the muscles which pass in the glosso-palatal folds from the soft palate to the mouth in front of the tonsils. These *glosso-palatal* muscles elevate the folds in which they lie, depress the soft palate, and, if the dorsum of the tongue be raised, shut off the buccal cavity. The muscles of the soft palate are described on p. 1134.

The uvular muscle, the levator veli palaini, the glosso-palatinus and the pharyngo-palatinus muscles are supplied by the pharyngeal plexus. The tensor veli palatini is supplied by the mandibular division of the fifth nerve. The pharyngeal muscles are supplied by the glosso-pharyngeal, the vagus, and the spinal accessory cranial nerves.

The **larynx** lies in the neck, but since the intrinsic muscles of the larynx from the standpoint of embryology and comparative anatomy belong with the musculature of the head, it is convenient to refer to them briefly here rather than to treat of them with the intrinsic muscles of the neck. A full description of the laryngeal muscles is given in the section on the larynx (fig. 981). They develop from tissue which corresponds with that which in fishes gives rise to the muscles of the gills and are innervated by the nerves which in the fishes innervate the gills, the tenth pair (vagus) of cranial nerves. The movements of the laryngeal cartilages are such as to approximate or draw apart the vocal cords and to loosen or make them tense. The approximation of the vocal cords is produced by the rotation medialward of the vocal processes of the arytenoid cartilages brought about by the *lateral crico-arytenoid* and *transverse arytenoid* muscles. The drawing apart of the vocal cords is produced by the *posterior crico-arytenoids*. The vocal cords are made long, thin and tense by the *crico-thyreoid*. They are shortened and thickened by the *thyreo-arytenoid* (externus) and the *vocalis*. The inferior laryngeal branch of the vagus supplies all the muscles but the crico-thyreoid. This is supplied by the superior laryngeal branch of the vagus.

Metamerism.—The muscles thus far considered are essentially visceral muscles, although all are composed of striated muscle cells and all are more or less directly under the control of the will. From the morphological standpoint the muscles of the orbit, the tensor tympani, the muscles of mastication, the hyo-mandibular muscles and the muscles of the tongue have been grouped with the ordinary voluntary skeletal muscles while the facialis musculature, the stapedius, the hyo-temporal muscles and the muscles of the soft palate, pharynx and larynx are looked upon as of a more purely visceral origin. A primitive characteristic of the voluntary skeletal muscles is metameric segmentation. This is maintained through life in the trunk musculature of fishes and of tailed amphibia and is passed through as a temporary stage in all the higher vertebrates. The embryonic segmented muscles are called myotomes (see fig. 340). In some regions the metamerism is retained throughout life even in the higher forms, as, for instance, in the intercostal muscles and the intertransverse muscles. But for the most part the primitive metamerism is so lost during the differentiation of the definitive trunk musculature that only traces of it remain here and there as, for instance, in the segments of the rectus abdominis muscle. In the lower forms the myotomes give rise during embryonic development to material utilized in the formation of the limb musculature, but even in the fishes all traces of trunk metamerism are lost in the differentiated limb musculature and in the higher forms, as in man, the limb musculature appears to differentiate directly from the unsegmented tissue in the limb-buds. In the head the musculature is differentiated directly, as in the limbs, without undergoing a preliminary metameric or myotomic stage. Attempts have been made to show that in primitive forms the cranial voluntary skeletal musculature, in the narrower morphological sense mentioned above, passes through a metameric stage comparable with the myotomic metamerism of the trunk. This attempt has been partially successful as regards the development of the muscles of the eye in some of the lower forms. There is also good evidence that the spinal region of the skull and associated structures represent a part of the metameric trunk fused with a more primitive head so that the musculature of the tongue and the hyo-mandibular muscles belongs morphologically with the primitively metameric trunk musculature. The rest of the cranial musculature gives little evidence of a primitive metameric segmentation and hence is probably to be classed morphologically with the unsegmented visceral musculature.

Of the **muscles of the neck,** the most superficial, the **platysma** (fig. 341), is a subcutaneous muscle belonging to the facialis group of the head from which it grows down during embryonic development. It is supplied by the seventh cranial (facial) nerve. It extends from the corner of the mouth and the side of the mandible over the clavicle. It depresses the corner of the mouth, wrinkles up the skin of the neck and aids the circulation by relieving pressure on the underlying veins.

Beneath the platysma there lies a layer composed of two flat muscles (fig. 344) which extend from the base of the skull behind the ear to the shoulder girdle. One of these muscles, the **sterno-cleido-mastoid,** arises in front from the sternum and clavicle and is inserted into the mastoid process of the temporal bone and the skull behind this. The other, the **trapezius,** arises from the base of the skull, and from the ligamentum nuchæ and vertebral spines of the cervical and thoracic regions, and is inserted into the spine of the scapula, the acromion and the lateral third of the clavicle. These two muscles constitute the **superficial shoulder-girdle musculature.** They extend the head, bend it toward the same side and rotate it toward the opposite side. The sterno-cleido-mastoid and the upper part of the trapezius raise the shoulder girdle and thorax and hence are of use in forced inspiration. The trapezius draws the scapula toward the spine and rotates the inferior angle of the scapula lateralward. The lower part of the trapezius acting alone draws the scapula downward and dorsalward while rotating the inferior angle lateralward. The trapezius is therefore used when the arm is raised high or carried backward. The two muscles of this group are innervated partly by the spinal accessory, and partly by the ventral divisions of the second, third and fourth cranial nerves. They represent in part musculature which in the lower vertebrates is associated with the visceral musculature of the gills (hence the innervation by the spinal accessory, a derivative of the vagus nerve) and in part metameric musculature of the second, third, and fourth cervical segments. During embryonic development this musculature therefore spreads out widely from its origin, the upper cervical region. The lower part of the trapezius varies greatly in the extent of its development caudalward. It may reach only half way down the thoracic region or it may extend into the lumbar region. The deeper musculature of the neck is derived from the cervical myotomes.

The primitive segmental musculature of the neck, like that of the whole trunk, becomes divided at an early embryonic stage into two divisions, a dorsal, supplied by the dorsal divisions of the spinal nerves, and a ventro-lateral supplied by the ventral divisions. The trapezius, although it covers the intrinsic dorsal musculature of the cervical region, insofar as it is of cervical origin, belongs to the ventro-lateral musculature and is derived, apparently, from the first three cervical myotomes. There is also a deeper layer of muscles attached to the shoulder girdle which arise from the ventro-lateral divisions of the lower five or six cervical myotomes but which, with one exception, the *levator scapulæ* (fig. 353), wander over the thorax during embryonic development. This group is described below as the deep shoulder-girdle musculature. The rest of the muscles derived from the ventro-lateral divisions of the cervical myotomes are divisible into three groups, the infra-hyoid, the scalene and the prevertebral.

The **infra-hyoid** group lies at the front of the neck, superficial to the larynx and trachea (fig. 348), and is composed of four flat muscles, the *sterno-hyoid, sterno-thyreoid, thyreo-hyoid* and *omo-hyoid* (scapulo-hyoid), the names of which indicate the origin and insertion. The chief function of this group of muscles is to depress the hyoid bone, the larynx and the associated structures. When the supra-hyoid group of muscles contracts at the same time, the infra-hyoid muscles help to depress the lower jaw, or if this in turn is fixed by the cranio-mandibular group, to flex the head. The muscles of this group are derived from the ventral portions of the first three cervical myotomes and are innervated by the first three cervical nerves through the ansa hypoglossi. The primitive segmental origin of these muscles is frequently indicated by transverse tendons (inscriptiones tendineæ). They correspond morphologically with the rectus abdominis musculature.

The scalene group (fig. 352) lies at the side of the neck and extends to the first and second ribs from the transverse processes of the lower six cervical vertebræ. The muscles of this group bend the neck toward the side, or if the neck be fixed, elevate the thorax. They come from the lateral parts of the ventro-lateral divisions of the lower five cervical myotomes and are innervated by the lower five cervical nerves. They correspond morphologically with the intercostal and with the lateral abdominal musculature.

The **prevertebral** group lies back of the pharynx and œsophagus and in front of the bodies and transverse processes of the cervical vertebræ. The muscles of this group arise not only from the transverse processes and bodies of the cervical vertebræ, but also in part from the bodies of the first three thoracic vertebræ and are inserted in part into the cervical vertebræ (*longus colli*) and in part into the base of the occipital bone (*longus capitis*). This musculature flexes the neck and the head. When acting on one side it rotates the head toward the same side. It is innervated by the first six cervical nerves.

The deep shoulder-girdle musculature.—This becomes differentiated from the ventro-lateral divisions of the lower five or six cervical myotomes. Like the muscles of the superficial layer those of the deeper layer spread out widely from their origin. There are four muscles in the deeper group, all of which become attached to the dorsal border of the scapula. Of these, one, the *levator scapulæ* (fig. 353), remains in the cervical region, extending from the upper cervical transverse processes to the medial angle of the scapula. Two, the *rhomboids* (fig. 353), extend over the intrinsic dorsal musculature and are attached to the upper thoracic and lower cervical vertebral spines; while the fourth, the *serratus anterior* (fig. 354), extends over the side of the upper part of the thorax beneath the scapula and is attached to the first nine ribs. These muscles all, however, through their innervation, reveal in the adult their primitive cervical origin. They are supplied by branches from the third to the seventh cervical nerves. The levator scapulæ elevates the scapula, the rhomboid muscles retract it and the serratus anterior draws it forward. The levator and rhomboid muscles rotate the shoulder girdle so as to depress the shoulder, the serratus anterior, like the trapezius, rotates it so as to raise the shoulder. The two former muscles are an aid in extending the arm, the latter in flexing and abducting it. When the group, as a whole, contracts action is exerted on the ribs so that the group is of use in forced inspiration.

The **intrinsic dorsal musculature** of the neck, innervated by the dorsal divisions of the cervical nerves, is separated from the scalene muscles by the levator scapulæ. Dorsally it is covered by the trapezius and the rhomboid muscles. It is to be looked upon as a specialized portion of the system of intrinsic dorsal muscles which extend from the sacrum to the base of the skull on each side of the vertebral column. The primary function of this muscle system is to extend and to rotate the spine and the skull. In the thoracic region three main subdivisions may be recognised, a lateral, the *ilio-costal;* an intermediate, the *longissimus;* and a medial, the *transverse-spinal* group (fig. 381). In the cervical region these three groups may likewise be recognised and, in addition, there is a superficial group, the *splenius* (fig. 380), not represented in the lower thoracic region. The splenius arises from the upper thoracic and lower cervicla spines and is inserted into the transverse processes of the upper cervical vertebræ and into the mastoid processes of the temporal bone and the neighbouring part of the occipital. It acts with the sterno-cleido-mastoid, by which it is crossed near the head, in extending the head, bending it toward the side, but tends to rotate it toward the same side instead of toward the opposite side. Laterally beneath the splenius the *ilio-costalis cervicis* extends from the upper part of the thorax to the transverse processes of the sixth to the fourth cervical vertebræ, and the *longissimus cervicis* and *capitis* extend from the same region to the transverse processes of the mid-cervical vertebræ and to the mastoid process of the temporal bone (fig. 381). These muscles likewise extend and bend the head and neck laterally and rotate it toward the same side. Medially on each side the strong *semispinalis capitis* (fig. 381), arises from the upper thoracic and the lower cervical vertebræ, spreads out and is inserted into the squamous portion of the occipital bone. It is a powerful extensor of the head. Beneath it numerous fasciculi extend from the transverse processes to the spines of the cervical vertebræ. These fasciculi, the more superficial of which are the longest, constitute the *semispinales cervicis, multifidus,* and *rotatores* muscles. They extend and rotate the neck.

Between the successive spines and the transverse process there are **short muscles** (*interspinales, intertransversares*). The *rectus capitis anterior* and the *rectus capitis lateralis* between the transverse process of the atlas and the lateral part of the occipital belong with the latter series.

Between the base of the skull behind and the first two vertebræ there are four deep-seated specialized muscles which constitute the **suboccipital group** (fig. 382). The *rectus capitis posterior major* and *minor* spread out respectively from the spines of the atlas and epistropheus and are inserted beneath the inferior nuchal line of the occipital. The *obliquus capitis inferior* arises from the spine of the epistropheus and is inserted into the transverse process of the atlas; the *obliquus capitis superior* arises from this and is inserted into the lateral part of the inferior nuchal line of the occipital. These muscles extend and rotate the head. A detailed description of the intrinsic muscles of the back is given on page 410.

The **muscle fasciæ** in the head and neck are well developed in connection with most of the groups of muscles except the facialis group and are described in detail in connection with each of these groups. In the head we may here call attention merely to the dense temporal fascia which covers over the temporal fossa and hides from view the temporal muscle. In the neck the fasciæ are of considerable practical importance. It is convenient to think of them as divisible into several layers although the various layers fuse to some extent. The external layer (fig. 350) may be looked upon as completely ensheathing the neck and as dividing on each side into two layers which ensheath the sterno-cleido-mastoid and trapezius muscles. As a free fascia it is attached to the lower jaw, to the clavicle and sternum, and to the hyoid bone which divides it into a submaxillary and an infra-hyoid portion. It is connected with the fibrous sheath of the parotid and submaxillary glands. The middle layer of cervical fascia is composed of two laminæ, one extending between the sterno-hyoid and omo-hyoid and another more delicate one beneath this, ensheathing the thyreo-hyoid and sterno-thyreoid muscles and fused with the fibrous sheath which encloses the carotid artery, internal jugular vein and the vagus nerve. The deeper muscles of the side and front of the neck and the intrinsic muscles of the back of the neck are likewise ensheathed by muscle fasciæ.

Of the various groups of muscles mentioned above, some, for the sake of convenience, are treated in connection with the organs to which they belong. Thus the muscles of the eye and ear are taken up in Section VIII; those of the palate, pharynx and lärynx in Sections IX and X; the deep dorsal musculature of the neck will be taken up in the section on the intrinsic muscles of the back, p. 410, The remaining groups of muscles will be taken up in the following order:—

1. The facial group p. 329.
2. The cranio-mandibular group p. 338.
3. The supra-hyoid musculature p. 343.
4. The muscles of the tongue p. 345.
5. The superficial shoulder-girdle musculature p. 347.
6. The infra-hyoid musculature p. 350.
7. The scalene musculature p. 353.
8. The prevertebral musculature p. 355.
9. Anterior and lateral intertransverse muscles p. 356.
10. Deep musculature of the shoulder girdle p. 356.*

1. THE FACIALIS MUSCULATURE

(Figs. 341, 344)

The muscles of this group are intimately connected with the scalp, with the skin of the face and neck, and with the mucous membrane lining the lips and the cheeks. Most of the muscles have an osseous origin and a cutaneous insertion, but there are exceptions. Both origin and insertion may be cutaneous, or the attachment may be to an aponeurosis instead of directly to the skin. The deeper musculature about the mouth is attached to the mucous membrane.

The muscles are composed of interdigitating muscle-fibres which are grouped in bundles that take a nearly parallel or slightly converging course and give rise to thin muscle-sheets. The extent of development of the various muscles of the group and their independence varies greatly in different individuals.

The region from which the facial musculature originates in the embryo is, in the main at least, that of the hyoid arch immediately below the ear. From here the musculature spreads with the development of the facial nerve, dorsally to the occipital region behind the ear, distally over the neck, ventrally over the face, and upward toward the eye, forehead, and the side of the skull. The course of the development is indicated by the branches of the facial nerve. A somewhat similar phylogenetic development is indicated by conditions found in the inferior mammals and lower vertebrates. According to Ruge and Gegenbaur, the facial musculature is to be looked upon as derived from two muscle-sheets, of which in man the deeper has disappeared in the region of the neck while it is differentiated into the deeper facial muscles in the region of the head. The deeper layer of transverse fibres in the neck, the *sphincter colli*, is found in several of the mammals. The complex development of the facial muscles in man is characteristic of the human species, and is associated with the use of these muscles as a means of expression of the emotions, a physiological function superadded to the primitive function of opening and closing visceral orifices. There is much individual variation in the differentiation of the muscles.

Fasciæ.—The skin of the head and neck is, in most regions, firmly fused with the **tela subcutanea.** This is composed of a dense fibrous tissue united by a looser areolar tissue to the underlying structures. But a slight amount of fat is embedded in the subcutaneous tissue of the scalp, forehead, and nose. Considerable fat may be embedded in the region of the cheeks, the back of the neck, and the under surface of the chin (double chin). The constantly repeated action of various muscles of the facialis group usually results by middle life in the production of permanent wrinkles due to alterations in the structure of the tela subcutanea and the cutis.

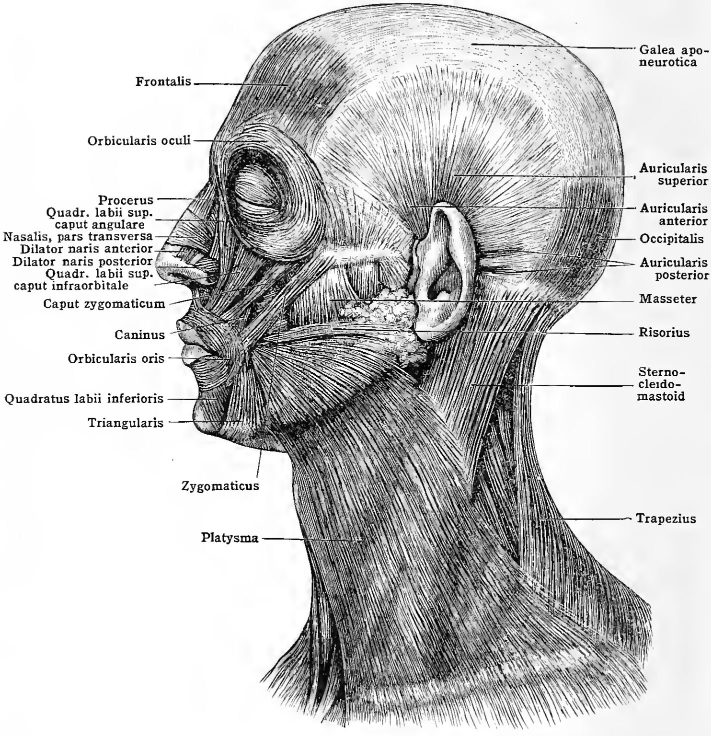
The subcutaneous muscles of the cranial vault and the neck are invested with fascial membranes. That covering the cranial musculature externally is firmly fused to the subcutane-

* The pectoral muscles and the latissimus dorsi, which extend from the skeleton of the limb to the front and side of the thorax and the lower part of the back, arise from the limb-bud during embryonic development, are innervated through the brachial plexus, and will, therefore, be taken up in considering the intrinsic musculature of the upper limb, p. 360.

ous tissue of the scalp. That covering the subcutaneous muscle of the neck is less firmly fused with the subcutaneous tissue. In the facial region the more superficial muscles are so closely embedded in the subcutaneous tissue that no distinct fasciæ intervening between the muscles and the skin can, as a rule, be distinguished. Of the deeper muscles of the facialis group, the buccinator alone possesses a distinct fascia. This muscle lies upon the mucous membrane of the lateral wall of the mouth, and is covered externally by a fascia continued into the fascia investing the superior constrictor of the pharynx.

Bursæ.—Bursa subcutanea prementalis. Between the periosteum at the tip of the chin and the overlying tissue. **Bursa subcutanea prominentiæ laryngeæ.** In front of the junction of the right and left laminæ of the thyreoid cartilage.

FIG. 341.—THE SUPERFICIAL MUSCLES OF THE HEAD AND NECK.



MUSCLES

The muscles of the facialis group may be conveniently subdivided as follows:—

(*a*) **Cervical:** the platysma. (*b*) **Oral:** the orbicularis oris and the incisivus labii superioris and inferioris; the quadratus labii superioris and inferioris; the caninus, zygomaticus, risorius, and triangularis; and the buccinator. (*c*) **Mental.** (*d*) **Nasal:** the nasalis, depressor septi, and the dilatores naris. (*e*) **Periorbital:** the orbicularis oculi, corrugator, and procerus. (*f*) **Epicranial:** the frontalis and occipitalis, with the galea aponeurotica. (*g*) **Auricular:** anterior, superior, and posterior. With these the temporalis superficialis is also described.

(*a*) CERVICAL MUSCLE

The **platysma** is a large, thin, quadrangular muscle which runs obliquely from the chin, the corner of the mouth, and the lower part of the cheek across the mandible and the neck to the proximal part of the thorax and shoulder. The muscles of each side interdigitate across the chin. A short distance below the chin, in the neck, the ventral margins diverge (fig. 341).

Origin.—From the tela subcutanea by somewhat scattered bundles—(1) along a line extending from the cartilage of the second rib to the acromion, and (2) along the dorsal margin of the muscle.

Insertion.—Into—(1) the mental protuberance of the mandible and the inferior margin of the mandible; and (2) into the skin of the lower part of the cheek and at the corner of the mouth, where it fuses more or less with the quadratus labii inferioris and the orbicularis oris.

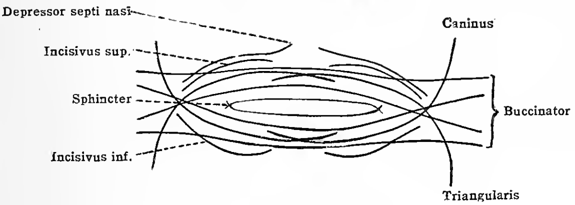
Nerve-supply.—The cervical branch (ramus colli) of the seventh cranial nerve forms beneath the muscle a plexus to which the cutaneus colli nerve contributes sensory branches.

Relations.—The muscle is situated beneath the panniculus adiposus, to which in the neck it is not very firmly attached. For the most part it is separated from the external layer of the cervical fascia by loose areolar tissue. The main cutaneous rami of the cervical plexus and the external jugular vein lie beneath the muscle.

Action.—It wrinkles up the skin of the neck, depresses the corner of the mouth, and thus plays a part in expression of sadness, fright, and suffering. It aids the circulation by relieving pressure on the underlying veins.

Variations.—Either the facial or the distal development of the muscle may be more extensive than that described above. On the other hand, it may be less developed than usual, and rarely it is absent. Accessory slips have been seen going to the zygoma, the auricle, or the mastoid process, etc., and to the clavicle and sternum. Rarely a deep transverse layer is found in man.

Fig. 342.—Diagram to Illustrate the Architecture of the Orbicularis Oris. (After T. D. Thane.)



(*b*) ORAL MUSCLES

The muscles of the mouth belonging to the facialis system include several *intralabial* muscles:—a sphincter, the **orbicularis oris**; a transverse, the **compressor labii**; and four deep submucous muscles which pass from the sides of the lips to the alveolar juga of the upper canine and lower lateral incisor teeth, the **incisivi labii superioris** and **inferioris.** From each corner of the mouth there radiate out several muscles; the **caninus** and **zygomaticus** upward to the maxilla and zygomatic bone; the **risorius** lateralward over the cheek; the **platysma** and the **triangularis** downward over the side of the jaw; and the **buccinator,** lateralward over the side of the oral cavity. From each of these fibre-bundles are continued into the more peripheral and superficial portions of the orbicularis. In addition to these muscles there are two retractors or quadrate muscles, one of which, the **quadratus labii superioris,** extends from the upper lip medial to the angle to the bridge of the nose, the lower margin of the orbit, and the zygomatic bone; while the other, the **quadratus labii inferioris,** extends from a corresponding position in the lower lip to the side of the chin. The orbicularis oris, compressor labii, and incisive muscles close the lips; the other muscles open them and pull them in various directions. The buccinator, however, plays a part in the closing of the mouth by offering support for the orbicularis.

Intralabial Muscles

The **orbicularis oris** (figs. 308, 341, 342, 343) is a complex muscle which surrounds the oral orifice and forms the chief intrinsic musculature of the lips. Immediately about the orifice, and on the deep surface of the muscle, is a fairly well-defined sphincter, although at the corners of the mouth the fibre-bundles of one lip cross those of the other and are inserted into the mucosa, and to a less extent into the skin. In the mid-line the fibre-bundles end partly in the perimysium, partly in the skin. About this sphincter area aud between its outer margin and the skin is a complex musculature comprised partly of fibre-bundles prolonged from the muscles which radiate from the corners of the mouth. The more superficial portion of the muscle in the upper lip is composed of fibre-bundles from the triangularis (depressor anguli oris), the more superficial portion of that in the lower lip by fibre-bundles from the caninus (levator anguli oris). These fibre-bundles form commissures at the angles of the mouth and extend toward the median line, where many of them interdigitate with those of the opposite side, and are attached to the skin of the lips. The deeper portions are partly formed by fibre-bundles prolonged from the buccinator, the mandibular fibre-bundles of the latter muscle going mainly to the upper lip, the maxillary fibre-bundles mainly to the lower lip. These fibre-bundles are attached chiefly to the mucosa, near the corners of the mouth.

The **compressor labii**, or muscle of Klein, is composed of bundles of fibres which take a course transverse to those of the orbicularis, and pass obliquely from the skin surrounding the oral orifice toward the mucosa which bounds its inner margin. It is said to be best marked in infants.

The **incisivus labii superioris** is a small muscle-bundle which passes from the alveolar jugum of the upper canine tooth to the back of the orbicularis near the corner of the mouth.

The **incisivus labii inferioris** passes similarly from the alveolar jugum of the lower lateral incisor tooth to the back of the orbicularis in the lower lip.

Nerve-supply.—These muscles are supplied by the buccal branches of the facial nerve which enter the orbicularis on the lateral border.

Relations.—The main mass of intrinsic musculature of the lips is placed slightly nearer the mucosa than the skin. On its deep surface lie the labial arteries.

Action.—The orbicularis draws the upper lip downward, the lower lip upward. The incisive muscles draw the corners of the lips medialward, and the compressor flattens the lips. Together they serve to close the mouth. Acting separately they may draw different parts of it in the directions indicated by their structure. The circumferential portion of the orbicularis acting with the incisive muscles makes the lips protrude. The central portion of the orbicularis draws the lips together, and when the buccinator also acts, draws them against the teeth. It is this portion of the muscle that has chiefly to do with nutritive functions. The more peripheral parts of the muscle are chiefly utilised in the expression of the emotions.

Retractors of the Lips or Quadrate Muscles (Fig. 341)

The **quadratus labii superioris** is a thin, quadrangular muscle with three heads, all of which are inserted into the skin and musculature of the upper lip.

The **caput zygomaticum** (zygomaticus minor) is long and slender and arises from the lower part of the external surface of the zygomatic bone beneath the lower border of the palpebral portion of the orbicularis oculi. It passes obliquely forward over the caninus and orbicularis oris muscles, and extends to a cutaneous and muscular insertion in the upper lip medial to the corner of the mouth. It lies medial to the zygomaticus.

The **caput infraorbitale** (levator labii superioris), a broad, flat muscle, arises from the infra-orbital margin of the maxilla, where it is concealed by the orbicularis oculi. It extends obliquely forward over the caninus and beneath the caput angulare to the skin and musculature of the lateral half of the upper lip.

The **caput angulare** (levator labii superioris alæque nasi) arises from the root of the nose, where it is fused with the frontalis. As it descends it divides into two fasciculi, one of which is attached to the skin and the alar cartilage of the nose; the other passes obliquely downward over the caput infraorbitale to the skin and musculature of the lateral half of the upper lip.

Nerve-supply.—The zygomatic ramus of the seventh nerve sends branches to enter the deep surface of each of the divisions of the muscle.

Actions.—It raises the lateral half of the upper lip and the wing of the nose. It is of value in inspiration, serves to express the emotion of discontent, and comes into play in violent weeping.

Variations.—The caput zygomaticum is often absent. It may be fused with the zygomaticus (major). It may be doubled. Its origin may extend to neighbouring structures. The other heads, though more stable, vary considerably, especially in the extent of their fusion with neighbouring muscles.

The **quadratus labii inferioris** (depressor labii inferioris) is a thin, rhomboid muscle which arises below the canine and bicuspid teeth from the base of the mandible, between the mental protuberance and the mental foramen, and extends obliquely upward in a medial direction to the orbicularis oris, through which its fibre-bundles pass. Its more medial fibres cross at their insertion with those of the muscle of the other side. It is attached to the skin and mucosa of the lower lip. It is essentially a part of the platysma, and is superficially united to the skin except where covered by the triangularis (depressor anguli oris). It crosses the mental vessels and nerves and a part of the mentalis (levator menti).

Nerve-supply.—The mandibular branch of the facial sends twigs into its deep surface near the lateral border.

Action.—It draws down and everts the lower lip. It is an antagonist of the mentalis (levator menti). It plays a part in the expression of terror, irony, great anger, and similar emotions.

Muscles of the Angle of the Mouth (Figs. 341, 342, 344, 345)

The **caninus** (levator anguli oris) is a flat, quadrilateral muscle which arises from the canine fossa of the maxilla and runs beneath the quadratus (levator) labii superioris to the corner of the mouth, where it becomes attached to the skin and sends some fasciculi into the orbicularis of the lower lip. Between the caninus and the quadratus labii superioris there is a certain amount of fatty areolar tissue through which the infraorbital vessels and nerves run. Its deep surface extends over the canine fossa, the buccinator muscle, and the mucosa of the lip. The external maxillary (facial) artery passes over its inferior extremity.

The **zygomaticus** (z. major) is a long, ribbon-shaped muscle which arises by short tendinous processes from the zygomatic bone near the temporal suture under cover of the orbicularis oculi. It passes obliquely to the corner of the mouth, where it is attached to the skin and mucosa. The body of the muscle is subcutaneous and is usually surrounded by fat. It crosses the masseter and buccinator muscles and the anterior facial vein.

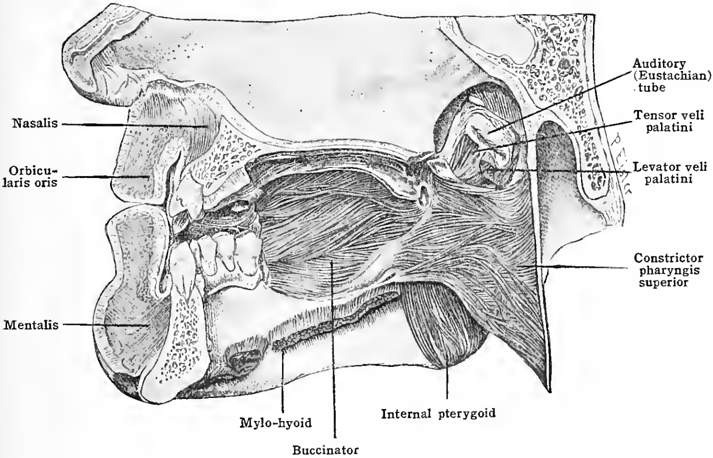
The **risorius** is a thin, triangular, subcutaneous muscle which extends across the middle of the cheek and lies in a more superficial plane than the platysma, with which it is often fused. It arises from the tela subcutanea above the parotid fascia. Its fibres couverge across the masseter muscle toward the angle of the mouth and are attached to the skin and mucosa in this vicinity. It lies above the anterior facial vein and external maxillary artery.

The **platysma** has been described above.

The **triangularis** (depressor anguli oris) is a broad, flat, well-developed, subcutaneous muscle which arises from the base and external surface of the body of the mandible below the canine, bicuspid, and first molar teeth. From here its fibres converge toward the corner of the mouth, where they are in part inserted into the skin and in part are continued into the orbicularis oris of the upper lip. It overlies the buccinator and the quadratus (depressor) labii inferioris muscles. Not infrequently (58 out of 92 bodies—LeDouble) some fasciculi are continued into

Fig. 343. (After Eisler.) Buccinator Muscle and Pterygomandibular Raphe, as seen from the Buccal Side.

The alveolar processes of both jaws have been removed in the region of the molar teeth. The soft palate and its muscles have been removed.



the neck as the **transversus menti**, a fibro-muscular band formed by the interdigitation of the slips prolonged from each side below the chin and superficial to the platysma. Santorini described the *transversus menti* as an independent though inconstant muscle. According to Eisler the true transversus menti muscle is to be distinguished from aberrent slips of the triangularis or of the platysma in this region. In one instance Eisler found a slender nerve emerging through the platysma and passing to this muscle.

Nerve-supply.—The zygomatic branch of the seventh nerve supplies the canine (levator anguli oris) and zygomatic (major) muscles. Branches enter the middle of the deep surface of the latter muscle and the superficial surface of the former near its lateral border. The risorius is supplied by branches from the buccal rami of the seventh nerve, which enter its deep surface. The triangularis (depressor anguli oris) is supplied by the buccal branch through branches which enter its deep surface near the posterior margiu.

Action.—The caninus (levator anguli oris) and zygomatic (z. major) muscles raise the corner of the mouth, the former at the same time drawing it medially, the latter, laterally. The caninus gives rise to expression of bitterness or menace. The zygomaticus is active in smiling or laughing. When contracted greatly it elevates the cheek and the lower eyelid and produces crow's-foot wrinkles at the corner of the eye. The risorius draws the angle of the mouth laterally. In spite of its name it is not used to express pleasure, but instead gives rise to an expression of pain. The triangularis (depressor anguli oris) depresses the corner of the mouth and draws it laterally, giving rise to the expression of grief.

Variations.—The risorius is very inconstant in its development, and in its relations to neighbouring muscles, and is not infrequently quite small. The zygomaticus is rarely absent Its origin may extend to the temporal or masseteric fasciæ. It may be doubled throughout its length or at one extremity. Frequently the triangularis is divided into three fasciculi.

The **buccinator** (fig. 343) arises from—(1) the molar portion of the alveolar process of the maxilla; (2) the buccinator crest of the mandible, and (3) the pterygo-mandibular raphe of the bucco-pharyngeal fascia. This narrow fibrous band, which separates the buccinator from the superior constrictor of the pharynx, extends from the pterygoid hamulus to the buccinator crest of the mandible. The fibre-bundles are divisible into four sets. The most cranial extend directly into the orbicularis of the upper lip. The next pass through the commissure at the corner of the lips into the orbicularis of the lower lip; the third through the commissure into the orbicularis of the upper lip, and the fourth directly into the orbicularis of the lower lip. The muscle is attached chiefly to the mucosa of the lips near the angle of the mouth. Some fibre-bundles extend to the more medial portion of the mucosa and some through the orbicularis to the skin.

Nerve-supply.—By the buccal branch of the facial nerve through filaments which enter the posterior half of its outer surface.

Relations.—The muscle is covered externally by the thin bucco-pharyngeal fascia; internally by the mucosa of the mouth. Above its outer surface lie the zygomatic (z. major), risorius, and masseter muscles. Between the last and the buccinator lies a large pad of fat (the buccal fat pad). The parotid duct passes forward over the muscle, and slightly in front of its centre pierces it and passes into the mouth. It is crossed by the external maxillary (facial) artery and anterior facial vein and by the buccal artery and nerve.

Actions.—It draws the corner of the mouth laterally, pulls the lips against the teeth, and flattens the cheek. It is of use in mastication, swallowing, whistling, and blowing wind-instruments.

Variations.—Occasionally it consists of two laminæ, a condition found in many mammals. It may be continuous in part with the superior constrictor of the pharynx, as in the cat.

(*c*) MENTAL MUSCLE

The **mentalis** (levator menti) (fig. 343) is a short, thick muscle which arises from the alveolar jugum of the lower lateral incisor tooth and the neighbouring region of the mandible under cover of the quadratus (depressor) labii inferioris and beneath the oral mucosa, where this is reflected from the lips to the gums. It extends to the chin, where it is fused with the muscle of the opposite side and is attached to the skin of the chin.

Nerve-supply.—The mandibular branch of the seventh nerve sends terminal twigs into this muscle.

Actions.—It draws up the skin of the chin and thus indirectly causes the lower lip to protrude. It is of use in articulation, in forcing bits of food from between the gums, and in the expression of various emotions (muscle of pride).

Variations.—It varies greatly in size and generally is fused with the platysma.

(*d*) NASAL MUSCLES
(Figs. 341 and 344)

Toward the nasal apertures several muscles converge. Those extending from above elevate and dilate, those from below depress and contract, the nostrils. To the former belongs the **pars transversa** of the **nasalis** (compressor naris), a triangular muscle extending from the bridge of the nose to the naso-labial sulcus; the **caput angulare** of the **quadratus labii superioris** (levator labii superioris alæque nasi), which arises from the root of the nose and sends a fasciculus to the wing of the nose; and the **dilatores naris**, described below; to the latter, the **pars alaris** of the **nasalis** (depressor alæ nasi), which extends from the alveolar juga of the upper lateral incisor and canine teeth to the dorsal margin of the nostril; and the small **depressor septi nasi.**

The **nasalis** consists of two parts, the pars transversa and the pars alaris. The **pars transversa** (compressor naris) is triangular. It lies on the side of the nose above the wing. Its fibre-bundles arise from an aponeurosis which overlies the bridge of the nose, is adherent to the skin, and is not closely attached to the underlying cartilage. From this aponeurosis the fibre-bundles converge toward the back of the wing, where they are attached to the skin along the line which separates the wing from the cheek (naso-labial sulcus). Its insertion is covered by the nasal process of the caput angulare (levator labii superioris alæque nasi) of the quadratus labii superioris (p. 332), with which its fibres interdigitate. An attachment (origin) is also described by many as taking place in the lower part of the canine fossa of the maxilla.

The **pars alaris** (depressor alæ nasi) (fig. 343), is a small quadrangular muscle situated below the aperture of the nose, between this and the alveolar portion of the maxilla. It is covered by the mucosa of the gum, by the orbicularis oris and the quadratus (levator) labii superioris, and laterally is fused with the pars transversa (compressor naris). It arises from the alveolar juga of the lateral incisor and the canine teeth. Its fibre-bundles extend vertically to the skin of the dorsal margin of the nostril, from the dorsal part of the cartilage of the wing to the septum

The **depressor septi** is a flat, triangular muscle which extends from the orbicularis oris to the lower edge of the nasal septum. It may arise from the jugum alveolare of the medial incisor.

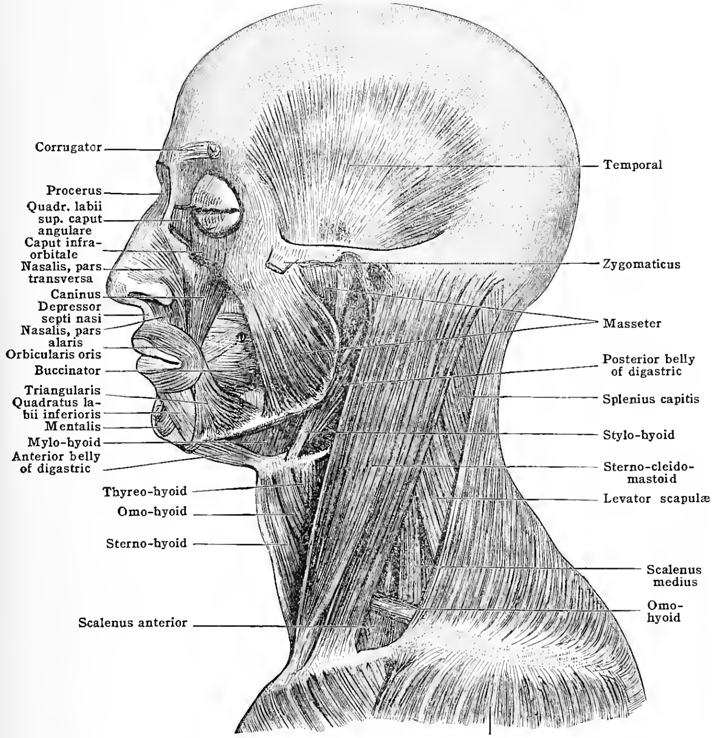
The **dilator naris posterior** is a thin, triangular muscle which lies on the side of the wing of the nose. It arises from the skin of the naso-labial groove and is attached to the inferior border of the wing of the nose.

The **dilator naris anterior** is a very small, thin muscle which runs from the lower margin of the cartilage at the front of the wing of the nose to the skin. It is not usually clearly marked.

Nerve-supply.—The muscles of this group are supplied by the infra-orbital and buccal branches of the facial nerve.

Actions.—The transverse portion of the nasalis (compressor naris) acts with the angular head (levator labii superioris alæque nasi) of the quadratus labii superioris in drawing lateral-

Fig. 344.—The Deeper Muscles of the Face and Neck.



ward and up the lateral margin of the wings of the nose, and gives rise to the expression of sensuality. (Poirier.) This accords with the electrical experiments of Duchenne. However, acting in conjunction with the alar portion, the transverse portion of the nasalis may constrict the nostrils. The alar portion (depressor alæ nasi) of the nasalis and the depressor septi nasi draw down the nostril. The former tends to contract it from side to side, the latter from front to back, and at the same time to depress the tip of the nose. They play a part in the expression of anger and of pain. The functions of the other muscles are indicated by their names.

Variations.—The muscles of the nose vary considerably in extent of development, and one or more may be absent. Authors differ considerably in their description of several of the muscles. The **anomalus** is a longitudinal muscle strip occasionally found running from the frontal process to the body of the maxilla near the lateral margin of the nasal aperture.

(*e*) PERIORBITAL MUSCLES
(Figs. 341, 344)

The muscles which encircle the orbit constrict the entrance of the orbit so as to shut out light and protect the eye against foreign bodies. To these belong the orbicularis oculi, the corrugator, and the procerus. The **orbicularis oculi** is a large, flat, elliptical muscle which lies in the eyelids and over the bone surrounding the orbit. **Three parts** are recognised, a **palpebral**, an **orbital** and a **lacrimal.** The quadrangular **corrugator** extends from the nasal portion of the frontal bone to the skin of the middle half of the eyebrow; the narrow **procerus** (pyramidalis nasi) from the bridge of the nose to the skin at the root. The muscles which have an antagonistic action are the levator palpebræ superioris and the epicranius. The levator palpebræ is described in the chapter on the Eye (see Section VIII), the epicranius in the following subsection.

The **orbicularis oculi.**—The **palpebral portion** arises from the ventral surface and margins of the lateral portion of the medial palpebral ligament (tendo oculi), and from the covering of the lacrimal sac. The fibre-bundles spread out as they pass into the eyelids and again are concentrated toward their insertion into the outer surface of the lateral palpebral ligament. Many of the fibre-bundles interdigitate here without being inserted into the ligament. The muscle in each eyelid lies between the tarsal plate and the skin, separated from both by loose tissue. The superficial muscle-fibres nearest the margin of the lids constitute the ciliary muscle, or muscle of Riolan. They are very small fibres and probably act on the eyelashes and Meibomian glands.

The **orbital portion** arises by a superior origin from the medial palpebral ligament (tendo oculi), the nasal portion of the frontal bone, and the anterior lacrimal crest of the maxilla, and by an inferior origin from the medial palpebral ligament and the medial portion of the inferior rim of the orbit. The fibre-bundles form a flat ring which surrounds the orbit for a considerable distance, especially inferiorly. The muscle is adherent to the overlying skin. It lies over the bones surrounding the margin of the orbit and over the attachments of several of the facial muscles attached to these bones. With these muscles some of the fibre-bundles are usually continuous.

The **lacrimal portion** (tensor tarsi or Horner's muscle) arises from the posterior lacrimal crest of the lacrimal bone and passes down on the dorsal surface of the lacrimal sac and the medial palpebral ligament (tendo oculi). It bifurcates and furnishes a fasciculus attached to each tarsal plate. Some of the fibre-bundles surround the lacrimal canaliculi and some surround the ducts of the tarsal glands and the roots of the eyelashes.

The **corrugator** arises from the frontal bone near the fronto-nasal suture. It extends obliquely upward to be inserted into the skin of the middle half of the eyebrow. The fibre-bundles of insertion interdigitate with those of the frontalis. The muscle lies relatively deep. It is covered by the procerus (pyramidalis nasi), the frontalis, and the orbicularis. Under it lie the supra-orbital vessels and nerves.

The **procerus** (pyramidalis nasi) overlies the nasal bone. It arises from the lateral cartilage of the nose through a fibrous membrane and also directly from the nasal bone, and is attached to the skin over the root of the nose, where its fibres interdigitate with those of the frontalis. The medial margins of the muscles on each side are more or less fused.

Nerve-supply.—The muscles of this group are supplied by temporal and infraorbital branches of the facial nerve which enter the deep surfaces near the lateral margins.

Action.—The palpebral portion of the orbicularis closes the eyelids, of which the upper moves more freely than the lower. It also serves to dilate the lacrimal sac and allow the tears to flow away readily. The tensor tarsi probably contracts the sac and forces the tears into the nose. The upper half of the orbital portion of the orbicularis contracts and depresses the tissue overhanging the orbit, and stretches the skin of the forehead. The corrugator draws the skin of the brow downward and medially, thus aiding the preceding muscle. It causes the perpendicular furrows characteristic of frowning. The procerus (pyramidalis nasi) draws down the skin of the forehead and wrinkles the skin across the root of the nose. The lower half of the orbital portion of the orbicularis raises the skin of the cheek, causing the wrinkles seen to radiate from the corner of the eye. The whole set of muscles comes into play in the forcible closure of the eyes. In case of violent expiratory efforts, as in shouting, sneezing, coughing, etc., the eye is thus usually forcibly closed. The pressure thus exerted on the eyeball prevents a too violent flow of blood to the vessels of the eye. Pressure is thought at the same time to be exerted on the lacrimal gland so as to cause the excessive flow of tears often experienced at such times.

Variations.—The muscles of this group vary in extent and differentiation, and may be more or less fused with one another or with neighbouring muscles. The orbital portion of the orbicularis, the corrugator, and the procerus have been found absent.

(*f*) THE EPICRANIAL MUSCULATURE
(Fig. 341)

The **epicranius** (occipito-frontalis) is formed of the two **frontal** muscles, which lie on each side of the forehead, the two **occipital** muscles, which occupy corresponding positions on the occipital bone, and of the epicranial aponeurosis, the **galea aponeurotica,** which extends between these. The occipital muscles arise from the supreme nuchal line and are inserted into the galea aponeurotica. The frontal muscles arise from the latter and are inserted into the skin near the eyebrows. The chief function of these muscles is to elevate the brows. The muscles and the intervening aponeurosis lie between two layers of fascia, the external of which is fused to the skin, while the internal moves freely over the periosteum, to which it is loosely attached. Hæmorrhages and abscesses spread freely between the deep layer of fascia and the periosteum.

The **frontalis** is a large, thin muscle with convex upper and concave lower border. It arises from the epicranial aponeurosis midway between the coronal suture and the orbital arch, and is inserted into the skin of the eyebrow and of the root of the nose. The medial fibre-bundles take a sagittal direction; the lateral converge obliquely toward the brow. The medial margins of the muscles of each side are approximated near the attachment. The more medial fibre-bundles are continuous with those of the procerus (pyramidalis nasi) and the angular portion (levator labii superioris alæque nasi) of the quadratus labii superioris; the more lateral interlace with those of the corrugator and orbicularis muscles. The branches of the vessels and nerves of the frontal region pierce the muscle and are distributed between it and the skin.

The **occipitalis,** flat and quadrangular, lies on the occipital bone above the supreme nuchal line. It rises by tendinous fibres from the lateral two-thirds of this line and from the posterior part of the mastoid process of the temporal bone, and is inserted into the epicranial aponeurosis. The medial fibre-bundles run sagitally, while the lateral run obliquely forward. The occipital artery and nerve lie between the muscle and the skin. The lateral border of the muscle comes in contact with the posterior auricular muscle. The muscles of each side are usually separated by a strip of aponeurosis.

The **galea aponeurotica** (epicranial aponeurosis) is a fibrous membrane which extends between the occipital muscles and from them anteriorly to the frontal muscles. In the area between these two sets of muscles it is composed largely of sagitally running fibres into which coronal fibres radiate from the region of the muscles of the ear. Between the two occipital muscles the aponeurosis is attached to the supreme nuchal line and external occipital protuberance. Laterally the fascia covering it is continued as a special investment of the auricular muscles, beyond which it is attached to the mastoid process, the zygoma, and to the external cervical and the masseteric fasciæ.

Nerve-supply.—The frontalis is supplied by the temporal branches of the facial nerve, the occipitalis by the posterior auricular branch. The branches enter the deep surface of each of these muscles near its lateral border.

Action.—The occipitalis serves to draw back and to fix and make tense the epicranial aponeurosis. The frontalis, with its aponeurotic extremity fixed, elevates the brows and throws the skin of the forehead into transverse wrinkles as in the expression of attention, surprise, or horror. When both muscles contract forcibly there is, in addition, a tendency to make the hair stand on end because the hair-bulbs of the occipital region slant forward, those of the frontal region backward. The frontalis when fixed below pulls the scalp forward.

Variations.—The occipitalis is occasionally absent, a condition normal in ruminants. The muscles of the two sides may be fused in the median line (normal in dogs). It may be fused with the posterior auricular. The frontalis is rarely missing. The frontalis may send slips to the medial or lateral angles or the orbital arch of the frontal bone, to the nasal process of the maxilla or to the nasal bone. The fibre-bundles of the frontalis may interdigitate across the median line.

The **transversus nuchæ,** or occipitalis minor, is a small muscle, frequently present (27 per cent., Le Double), which runs from the occipital protuberance toward the posterior auricular muscle, with which it may be fused. It may lie over or under the trapezius.

(*g*) AURICULAR MUSCLES
(Fig. 341)

The intrinsic muscles of the auricle are described in Section VIII. There are three 'extrinsic' auricular muscles which converge from regions anterior, superior, and posterior to the auricle and are inserted into it.

The **auricularis anterior** (attrahens aurem) is a small, flat, triangular muscle which arises between the two layers of the fascia of the galea aponeurotica, extends over the zygomatic arch, and is attached to the ventral end of the helix. The fibre-bundles converge from the origin toward a tendon of insertion. The area of origin of this muscle is often marked by a fibrous band tangential to its component fibres. From this band muscle fibre-bundles radiate out toward the frontal region of the skull. To the muscle formed of these radiating fibres the names **epicranio-temporalis** (Henle), **temporalis superficialis** (Sappey) and **auriculo-frontalis** (Gegenbaur) have been given.

The **auricularis superior** (attollens aurem) is a large, thin, triangurar muscle which, from its tendinous insertion on the eminence of the triangular fossa of the ear, radiates upward into the fascia of the galea aponeurotica, between the layers of which it takes oigin near the temporal ridge. It lies over the temporal fascia and the periosteum of the parietal bone.

The **auricularis posterior** (retrahens aurem) is a thin, band-like muscle which extends over the insertion of the sterno-cleido-mastoid from the base of the mastoid process and the aponeurosis of the sterno-cleido-mastoid muscle to the convexity of the concha, where it has a tendinous insertion. It is usually composed of two fasciculi, and is contained between two layers of fascia derived from the galea aponeurotica.

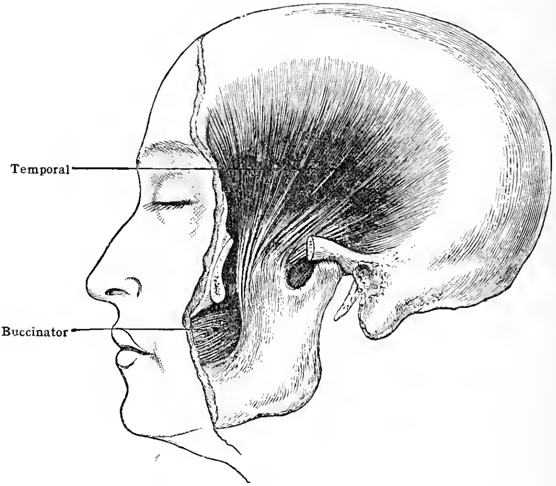
Nerve-supply.—The auricularis anterior and superior are supplied by the temporal branch of the facial, the auricularis superior and posterior by the posterior auricular branch. The twigs of supply run to the deep surface of the muscles.

Relations.—The superficial ascending branch of the auriculo-temporal nerve usually runs superficial to the anterior and superior auricular muscles. The superficial temporal vessels run at first beneath these muscles and the lateral expansion of the galea aponeurotica, then between the two fascial layers which enclose the muscles. Their branches of distribution finally come to lie between the muscles and aponeurosis and the skin. The posterior auricular artery and nerve usually run under cover of the auricularis posterior.

Action.—The anterior muscle is a protractor, the superior an elevator, and the posterior a retractor of the ear, but usually in man they are inactive.

Variations.—These muscles vary much in development. The most constant of them is the superior. The posterior frequently is increased in size and may be fused with the occipitalis, which originally was probably an ear muscle. From the anterior muscle a special deep fasciculus is occasionally isolated. Each of the muscles is occasionally, though rarely, absent, the anterior most frequently. An inferior auricular muscle is very rarely found in man, though present in many of the lower mammals. A slip of the posterior auricular may run beneath the ear to the parotid fascia.

FIG. 345.—THE TEMPORAL MUSCLE.



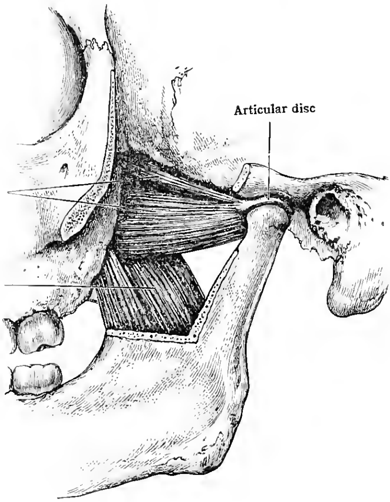
2. CRANIO-MANDIBULAR MUSCULATURE

(Figs. 344, 345, 346, and 347)

The cranio-mandibular muscles, or muscles of mastication, pass from the base of the skull to the lower jaw. They are represented in the selachians by a single muscle mass, the adductor mandibulæ (Gegenbaur), but in the higher vertebrates this muscle mass becomes variously subdivided during embryonic development. The muscles are innervated by the masticator nerve (motor root of the trigeminal cranial nerve, the nerve of the mandibular arch). In man four muscles are recognised, the temporal, masseter, and internal and external pterygoids.

The **temporal** and **masseter** muscles are situated on the lateral surface of the skull, partly under cover of muscles of the facialis group. The **temporal** muscle (fig. 345), which resembles the quadrant of a circle, arises from the temporal fossa and is inserted into the coronoid process of the mandible; the thick, quadrilateral **masseter** (fig. 344) muscle arises from the zygomatic arch and is inserted into the lateral surface of the ramus and angle of the mandible. The **pterygoids** (fig. 346) are more deeply seated. The cone-shaped **external pterygoid** arises from the lateral side of the pterygoid process and lower surface of the great wing of the sphenoid and is inserted into the condyloid process of the mandible and the capsule of the joint. The thick, quadrilateral **internal pterygoid** parallels the masseter. It arises from the pterygoid fossa of the sphenoid and is inserted into the inner side of the angle of the mandible. It will be noted that the temporal, masseter, and internal pterygoid muscles have approximately vertical axes of contraction and adduct the lower jaw, while the external pterygoid has an approximately horizontal axis of contraction and draws the jaw forward and, when acting on one side, toward the opposite side.

FIG. 346.—THE PTERYGOID MUSCLES.



FASCIÆ

The **temporal fascia** arises from the temporal line of the frontal bone and from the superior temporal line of the parietal and the periosteum immediately below this. It extends to the zygomatic arch. In its inferior quarter the fascia divides into two lamellæ, one of which passes to the outer, the other to the inner, surface of the arch, but at the superior margin of the arch these two lamellæ are united by dense fibrous tissue. Between the two lamellæ above the arch lies a fatty areolar tissue in which the middle temporal artery often runs. The outer surface of the fascia is covered by the superficial temporal and anterior and superior auricular muscles, and by a thin layer of fascia from the galea aponeurotica, with which, toward the zygomatic arch, it becomes merged. The superficial temporal artery and auriculo-temporal nerve cross it.

The **masseteric fascia** represents essentially a continuation of the temporal fascia from the inferior margin of the zygomatic arch over the masseter muscle which it covers. It is less thick than the temporal fascia, but is firm and strong. It is attached dorsally to the dorsal margin of the mandible, inferiorly to the inferior margin, and ventrally to the body and to the ventral margin of the ramus and the coronoid process of the mandible. In part it extends over the fat pad of the cheek to the buccinator fascia. The parotid gland, covered by the parotid extension of the external cervical fascia, extends over the posterior portion of this fascia. The **parotid fascia** becomes fused to its external surface at the anterior margin of the gland. Over it lie the parotid duct, the transverse facial artery, branches of the facial nerve, the zygomaticus (major), risorius, and platysma muscles.

The pterygoid muscles are each surrounded by a delicate membrane. In addition an **interpterygoid fascia** separates the two muscles. This arises from the sphenoidal spine and follows the internal surface of the external pterygoid to the mandible. Medially it is attached to the lateral lamella of the pterygoid process; posteriorly and laterally it presents a free margin which forms with the neck of the mandibular condyle, an orifice for the passage of the internal maxillary artery, the auriculo-temporal nerve, and several veins. Its posterior margin is strengthened into the spheno-mandibular ligament, which runs from the spine of the sphenoid to the lingula of the mandible.

The pharyngeal region is separated from the pterygoid by a dense membrane, the **lateral pharyngeal fascia.** This extends from the depth of the pterygoid fossa to the prevertebral fascia, and separates the tensor veli palatini from the internal pterygoid muscle. It is attached above along a line extending from the external margin of the carotid canal to the internal margin of the oval foramen.

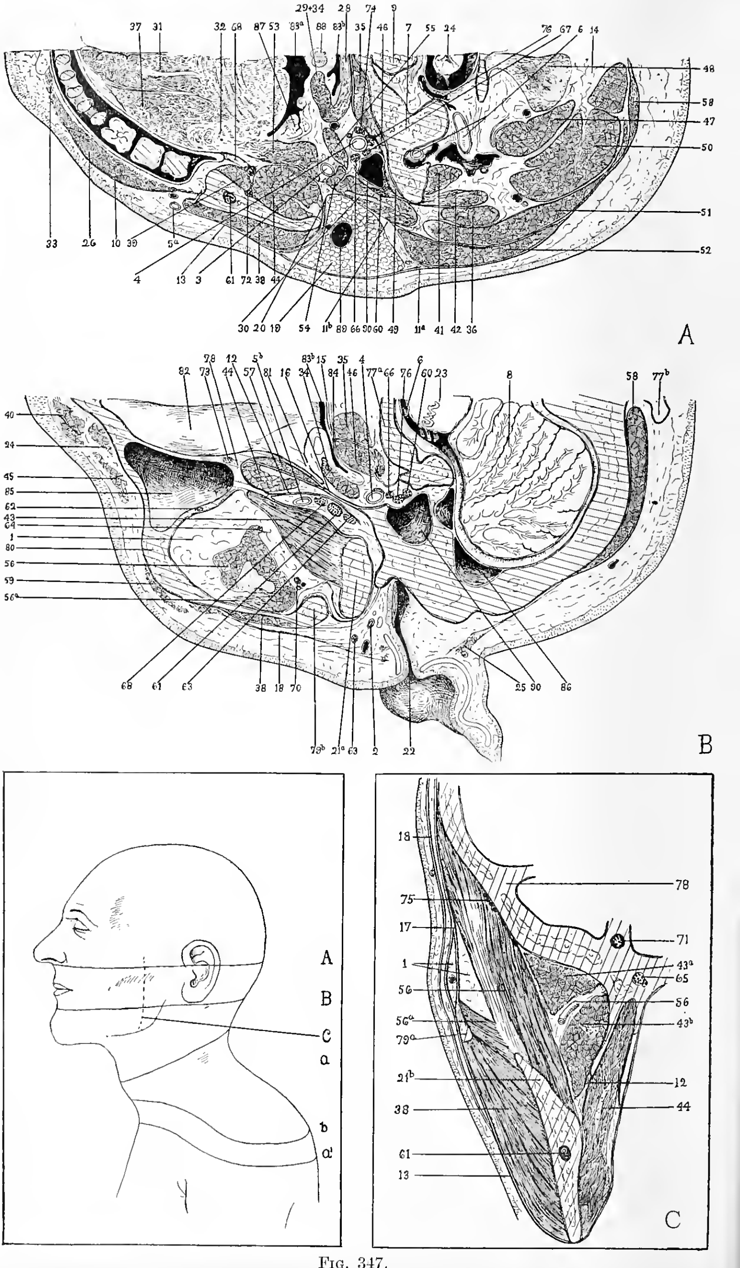


FIG. 347.

The **sigmoidal septum** is a thin membrane which occupies the incisura mandibulæ and separates the masseter from the external pterygoid muscle.

MUSCLES

The **temporalis** (fig. 345).—**Origin.**—(1) From the whole of the temporal fossa, with the exception of that part formed by the body and temporal process of the zygomatic (malar) bone; and (2) from the fascia covering the fossa. **Insertion** is into the tip, dorsal and ventral borders, and the whole internal surface of the coronoid process of the mandible and the ventral portion of the medial surface of the ramus.

In *structure*, the muscle is thin near its superior margin, but becomes thick as its insertion is approached. The fibre-bundles arising from the medial surface of the fossa and from the fascia converge upon the medial and lateral surfaces and the margins of a thick, broad tendon which begins very high in the muscle, becomes visible laterally some distance above the zygomatic arch, and is inserted into the tip, edges, and internal surface of the coronoid process. On the ventral and dorsal margins of the tendon the insertion of fibre-bundles continues to the coronoid process, while medially the insertion of the fibre-bundles is continued on the medial surface of the coronoid process and often on the ramus as far as the body of the bone.

Nerve-supply.—Usually three branches from the anterior branch of the mandibular division of the fifth nerve curve upward over the temporal surface of the great wing of the sphenoid and enter the deep surface of the muscle. The posterior and middle nerves pass above the external pterygoid; the anterior, which springs from the buccinator nerve, passes between the two heads of the external pterygoid before curving upward.

Relations.—The muscle is covered by the temporal fascia and the zygomatic arch. Below the temporal fossa the pterygoid muscles and the buccinator lie medial to it. The temporal fossa in front of the muscle is filled with a fatty areolar tissue and this also extends between the muscle and the temporal fascia. Fatty tissue likewise lies between the muscle and the buccinator. Medial to the muscle run the deep temporal vessels and nerves, the buccinator nerve and the spheno-mandibular ligament. The masseteric nerve passes lateralward behind and below the tendon.

The **masseter** (fig. 343) is composed of two layers. The **superficial layer** arises by an aponeurosis from the anterior two-thirds of the lower border of the zygomatic (malar) bone. The fibre-bundles arise from the deep surface of this aponeurosis and its tendinous prolongations pass obliquely downward and backward, and are inserted into the lower half of the external surface of the ramus, into the angle, and into the neighbouring portion of the body of the man-

* This and the following series of cross-sections are taken from a thin, not very muscular, adult male. The fasciæ are represented in most instances disproportionately thick.

dible—the more anterior directly, the posterior by means of an aponeurosis. The **deep layer** arises from the lower border and internal surface of the zygomatic arch. The fibre-bundles pass nearly vertically downward, and are inserted upon the upper half of the external surface of the ramus. The origin and insertion are by tendinous bands, to which the fibre-bundles are attached in a multipenniform manner. The two layers are fused near the origin and insertion and in front. From the temporal surface of the zygomatic bone and the neighbouring part of the deep layer of the temporal fascia there arises a fasciculus which is separated by a pad of fat from the main body of the temporal muscle, and is inserted into the lateral surface of the lower extremity of the tendon of the temporal muscle and into the ventro-lateral surface of the tip of the coronoid process. This fasciculus, sometimes described as a part of the temporal muscle, is innervated by the masseteric nerve.

Nerve-supply.—The branch arises in common with the posterior nerve to the temporal muscle from the motor root of the trigeminal (the masticator nerve). It passes above the external pterygoid, through the mandibular (sigmoid) notch, and enters the deep surface of the muscle near the dorsal margin.

Relations.—It is covered by the masseteric fascia (see above). It lies upon the ramus of the jaw and ventrally is separated by a pad of fat from the buccinator muscle. At the mandibular (sigmoid) notch the sigmoid septum separates it from the external pterygoid muscle. The parotid gland partly overlaps its posterior border.

The **pterygoideus externus** (figs. 343–346) consists of two fasciculi. Each is thick and triangular. The superior is flattened in a horizontal, the inferior in a vertical, plane. At their origin they are separated by a narrow cleft. Near the insertion they become more or less fused. The **superior fasciculus** arises by short tendinous processes from the infratemporal (pterygoid) crest and from the neighbouring portion of the under surface of the great wing of the sphenoid. Its fibre-bundles converge toward the insertion, which takes place by short tendinous processes into—(1) the capsular ligament in front of the articular disc and (2) the upper third of the front of the neck of the condyle. The **inferior fasciculus** is the larger. It arises by short tendinous processes from the lateral surface of the lateral lamina of the pterygoid process, from the pyramidal process of the palate bone, and from the adjacent portions of the maxillary tuberosity. The fibre-bundles converge toward their insertion into a depression on the front of the neck of the condyle.

Nerve-supply.—A branch from the masticator nerve (motor root of the trigeminus) approaches the muscle near the upper border of the medial surface of the superior fasciculus and gives branches to both portions.

Relations.—It is partly covered by the maxillary fasciculus of the internal pterygoid and by the temporal and masseter muscles. Medial to it lies the chief fasciculus of the internal pterygoid muscle. The masseteric and the posterior and middle temporal nerves usually pass above the muscle, the anterior temporal and the buccinator nerves and frequently the internal maxillary artery between the two fasciculi. The internal maxillary vessels usually pass below the lower border of the muscle and across its external surface; and the auriculo-temporal, lingual, and inferior alveolar (dental) nerves cross the deep surface of the muscle.

The **pterygoideus internus** (fig. 346).—*Origin.*—From (1) the pterygoid fossa, and (2) from the maxillary tuberosity and the pyramidal process of the palatine, where these adjoin.

Structure and Insertion.—From the medial and lateral laminæ of the pterygoid process there arise aponeuroses and from the palatine bone at the lower margin of the fossa, and from the maxillary tuberosity and palatine bone in front of the external pterygoid, there arise short tendons. From these aponeuroses and tendons and directly from the fossa the fibre-bundles take a nearly parallel course downward, backward, and outward, and are inserted in part in a multi-penniform manner into the lower half of the internal surface of the ramus of the mandible. The insertion extends to the mylo-hyoid ridge. The muscle is divided at its origin into two fasciculi by the distal margin of the external pterygoid.

Nerve-supply.—The internal pterygoid nerve arises from the back of the mandibular nerve near the foramen ovale. It passes near or through the otic ganglion, and thence to the medial surface of the muscle near the dorsal edge. Both the buccinator and lingual nerves are also described as sending filaments to this muscle.

Relations.—Laterally the muscle is covered by the interpterygoid fascia and the spheno-mandibular ligament, the external pterygoid, temporal, and masseter muscles, and the ramus of the mandible. The inferior alveolar (dental) and lingual nerves and the corresponding vessels run across this surface. Medial to the muscle lie the lateral pharyngeal fascia, the tensor veli palatini muscle, and the superior constrictor of the pharynx.

Action.—The muscles of this group adduct the lower jaw and serve to carry it forward and backward and from side to side. The elevation is produced by the masseter, temporal, and internal pterygoid muscles. The suprahyoid muscles and the external pterygoid are the feeble antagonists. The forward movement of the jaw is produced by the simultaneous action of the two external pterygoids (slightly by the superficial layer of the masseter, and the anterior fibres of the temporal) while the inferior posterior portions of the temporal muscles carry the jaw at the temporo-discoidal joint somewhat backward. Oblique lateral rotatory movements are produced chiefly by the action of one of the external pterygoids. The alternate action of these two msucles associated with the elevating action of the other muscles of the group, gives rise to the grinding movement of the molar teeth. Purely lateral movements of the jaw may be produced by the internal pterygoids, acting alternately. Lord (Anat. Rec., vol. 7, p. 355, 1913) states that in ordinary opening of the mouth the external pterygoids pull the articular discs and condyles forward while the jaw rotates about an axis passing through the insertions of the stylo-mandibular ligaments.

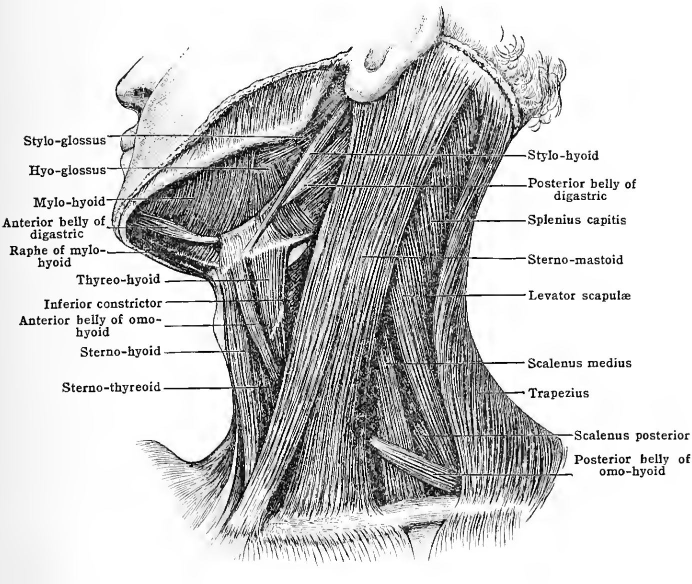
Variations.—The temporal muscle may have a more extensive cranial origin than usual. It may be formed of two superimposed layers. It may be more or less fused with the external pterygoid, or send a fasciculus to the coronoid process. The masseter may be completely divided into two fasciculi, a condition normal in many mammals. A special fasciculus may arise from the temporo-mandibular articulation or from the zygomatic (malar) bone. Its deepest fibres may be fused with the temporal muscle. The two fasciculi of the external pterygoid may be distinct, as in the horse. It has been seen fused with the temporal and with the digastric muscle. The internal pterygoid may send a fasciculus to the masseter. It may give origin to the stylo-glossus. Inconstant fasciculi (*accessory pterygoids*) extending from the body of the sphenoid to the pterygoid process represent perhaps remnants of the muscles which act on the movable pterygoids possessed by many inferior vertebrates.

3. SUPRAHYOID MUSCULATURE

(Fig. 348)

From the hyoid bone there extend to the base of the skull on each side four muscles which form a fairly well-defined group. They are situated external to

Fig. 348.—Anterior and Lateral Cervical Muscles.



the musculature of the tongue and pharynx. They elevate the hyoid bone and larynx and depress the mandible. The most superficial of the group is the slender, fusiform **stylo-hyoid,** which arises from the styloid process of the temporal bone and is inserted into the body of the hyoid. Immediately behind this is the flattened posterior belly of the **digastric,** which extends from its origin in the mastoid notch to a tendon that runs between two divisions of the tendon of the stylo-hyoid and is attached to the hyoid bone by an aponeurotic process. From the digastric tendon the flat, triangular anterior belly is continued to the back of the ventral portion of the inferior margin of the mandible. Internal to this anterior belly the thin, quadrangular **mylo-hyoid** arises from the inner surface of the body of the mandible and is inserted into a median raphe extending from the mandible to the hyoid. Still more internally the triangular **genio-hyoid** extends from the hyoid to the mental spine of the mandible. The last two muscles form the muscular floor of the mouth. The motor innervation of the posterior belly of the digastric and of the stylo-hyoid is from the seventh cranial nerve, the sensory innervation probably from the glosso-pharyngeal cranial nerve. The mylo-hyoid and the anterior belly of the digastric are supplied by the masticator (fifth) cranial nerve; the genio-hyoid from the hypoglossal by a branch, the fibres of which are possibly derived through anastomosis from the first cervical nerve.

From the morphological standpoint, therefore, the stylo-hyoid and the posterior belly of the digastric belong to the facialis group; the anterior belly of the digastric and the mylo-hyoid to the group of mandibular muscles, and the genio-hyoid to the muscles of the tongue innervated by the hypoglossal, or, if we consider the nerve-fibres of the nerve to the genio-hyoid as derived from the first cervical nerve, to the same group as the infra-hyoid muscles. It is convenient, however, to follow the usual custom of considering these muscles as a suprahyoid group.

FASCIÆ

The muscles of this group lie internal to that portion of the external cervical fascia which extends above the hyoid bone. This fascia, which is described on p. 347, comes into contact merely with the tendon, the anterior belly, and to a slight extent with the posterior belly of the digastric muscle. Above the tendon it sends inward a process which curves down internal to the tendon, and is inserted into the external surface of the hyoid bone. The individual muscles of the group are covered by delicate adherent membranes. An aponeurotic membrane usually extends between the anterior bellies of the digastric muscles of each side.

MUSCLES
(Fig. 348)

The **stylo-hyoideus.**—*Origin.*—From the lateral and dorsal part of the base of the styloid process by a rounded tendon which soon becomes a hollow cone to the internal surface of which the fibre-bundles of the muscle are attached. *Structure and Insertion.*—The fibre-bundles are inserted on both sides of a slender tendon which divides to let the tendon of the digastric pass through and then is attached to the ventral surface of the body of the hyoid bone near its junction with the great cornu.

Nerve-supply.—From the facial nerve as it emerges from the stylo-mastoid foramen a small twig is given off which enters the proximal third of the deep surface of the muscle. The glosso-pharyngeal nerve also gives to it a small twig, probably sensory.

Relations.—It descends immediately in front of the posterior belly of the digastric. Externally lie the parotid and submaxillary glands. Medially it crosses the internal and external carotid artery, the hypoglossal nerve, the stylo-pharyngeus muscle, the superior constrictor of the pharynx, and the hyo-glossus muscle. The posterior auricular artery passes between it and the posterior belly of the digastric and the external maxillary artery crosses over it.

The **digastricus.**—The **posterior belly** arises by tendinous processes from the mastoid (digastric) notch of the temporal bone. The fibre-bundles form a ribbon-like belly which converges on the intermediate tendon. This begins as a semiconical laminar process on the outer surface of the muscle a short distance above the hyoid bone. The **anterior belly** arises by short tendinous processes from the digastric fossa of the mandible. This attachment is often described as an insertion. The fibres converge on both surfaces of the flattened anterior end of the intermediate tendon. The **intermediate tendon** lies a variable distance above the hyoid bone, usually less than a centimetre. It curves upward toward each belly of the muscle. It is united to the outer surface of the body and to the base of the great cornu of the hyoid bone by an aponeurotic expansion from its inferior margin. Other expansions are usually continued into the interdigastric aponeurotic membrane. Occasionally the intermediate tendon of the digastric is bound to the hyoid bone by a fibrous loop which allows the tendon free play.

Nerve-supply.—The facial nerve near the stylo-mastoid foramen gives off a branch which enters the proximal third of the anterior margin of the muscle. From this a ramus may be continued through the muscle to the glosso-pharyngeal nerve. The anterior belly is supplied by a branch of the nerve to the mylo-hyoid muscle. This enters the middle of the lateral part of the deep surface. Very rarely the vagus may supply the anterior belly, the hypoglossal, the posterior belly.

Relations.—The posterior belly of the digastric lies internal to the mastoid process and the longissimus capitis (trachelo-mastoid), splenius, and sterno-cleido-mastoid muscles. Posteriorly near its origin are the rectus capitis lateralis and obliquus cap. sup. muscles, the occipital artery and the spinal accessory nerve. It helps to form the deep wall of the cavity in which the parotid gland is placed. Internally it crosses the origin of the styloid muscles, the carotid arteries, the internal jugular vein, and the twelfth cranial nerve. The intermediate tendon of insertion lies below the inferior margin of the submaxillary gland, and crosses the hyoglossus and mylo-hyoid muscles. The relations to the stylo-hyoid muscle have been described above. The anterior belly lies on the mylo-hyoid and is covered by the external cervical fascia and the platysma.

The **mylo-hyoideus.**—*Origin.*—From the mylo-hyoid ridge of the mandible. *Structure and Insertion.*—Its fibre-bundles take an oblique course and are inserted into—(1) a median raphe extending from the middle of the ventral surface of the hyoid bone nearly or quite to the dorsal surface of the inferior margin of the mandible, and (2) into the ventral surface of the hyoid bone. Some of the fibre-bundles may cross the median line. The muscles of the two sides form a sheet with a downward convexity which lies between the inner surface of the body of the mandible and the hyoid bone. On the diaphragm thus formed rests the tongue.

Nerve-supply.—From the mylo-hyoid branch of the inferior alveolar (dental) nerve several filaments enter the under surface of the muscle.

Relations.—The mylo-hyoid muscle is covered externally by the submaxillary gland, the anterior belly of the digastric, and the external cervical fascia. It is crossed by the submental artery. With the genio-hyoid and the genio-glossus muscles it helps to bound a compartment in which are lodged the sublingual gland, the duct of Wharton, and the deep portion of the submaxillary gland. Its deep surface also faces the stylo-glossus and hyo-glossus muscles, the lingual and hypoglossal nerves, and to a slight extent the buccal mucosa.

The **genio-hyoideus** (fig. 349).—*Origin.*—By short tendinous fibres from the mental spine of the mandible. *Structure and Insertion.*—The fibre-bundles diverge and are inserted into the ventral surface of the body of the hyoid bone. Usually a special fasciculus goes to the great cornu of the hyoid bone.

Nerve-supply.—The hypoglossal nerve sends a filament to the middle third of the deep surface of the muscle. The nerve-fibres are thought to be derived chiefly from the first cervical nerve.

Relations.—It lies between the genio-glossus and mylo-hyoid muscles. It adjoins its fellow of the opposite side and is often fused with it. Lateral to it lie the sublingual and submaxillary glands and the hypoglossal nerve.

Action.—The muscles of this group all elevate the hyoid bone and, through this, the larynx and inferior part of the pharynx, and thus play a part in the act of swallowing. The stylohyoid and posterior belly of the digastric serve also to draw the hyoid bone in a dorsal direction; the ventral belly of the digastric and the genio-hyoid, in a ventral direction. The digastric, genio-hyoid, and mylo-hyoid depress the mandible, when the hyoid bone is fixed. The posterior belly of the digastric has a slight power to bend the head backward.

Variations.—The stylo-hyoid tendon frequently passes entirely in front of and less frequently entirely behind the digastric muscle. Its insertion may be of greater extent than usual. A special fasciculus to the lesser cornu is not very infrequent; more rarely one extends to the angle of the jaw or to other regions. The muscle may arise from the petrous portion of the temporal or from the occipital bone, as in some lower vertebrates. It may be doubled or absent, or fused with the posterior belly of the digastric. The anterior belly of the digastric may be missing; the posterior belly may be inserted into the angle of the jaw. The intermediate tendons of the digastric of each side may be connected by a fibrous arch. The anterior bellies of the muscles of each side may be united by a fasciculus or fused. The anterior belly is frequently doubled. The posterior belly may be divided by a tendinous inscription. Fasciculi may pass from either belly to neighbouring structures. The mylo-hyoid may not extend quite to the hyoid bone. It may be more or less fused with neighbouring muscles. Rarely it is absent. The genio-hyoid is frequently more or less fused with the muscles of the tongue or with the genio-hyoid of the opposite side. A considerable number of infrequently found muscles have been described superficial to the stylo-hyoid and digastric muscles. Most of them are innervated by the glosso-pharyngeal nerve or by the facial nerve.

4. MUSCLES OF THE TONGUE

(Fig. 349)

The tongue is a flexible organ, composed chiefly of various muscles, some of which lie entirely within its substance, while others extend to be attached to neighbouring parts of the skeleton. To the former the term **intrinsic,** to the latter the term **extrinsic,** is frequently applied. In this section the extrinsic muscle will alone be taken up. The intrinsic muscles are described in the section on the Digestive System. Certain pharyngeal and palatal muscles which are continued into the tongue are described in connection with the pharynx. The extrinsic musculature of the tongue is concealed below by the suprahyoid musculature and the sublingual gland. It is covered on the free surface of the tongue by the mucosa.

The musculature of the tongue is supplied by the hypoglossal nerve, which is in series with the motor roots of the spinal nerves. It is, primitively at least, derived from the ventral portion of myotomes in series with the spinal myotomes.

Four extrinsic muscles are recognised on each side. The **stylo-glossus** is a slender muscle, which arises from the styloid process and is inserted into the side of the tongue. It is cylindrical near its origin, flat and triangular near its insertion. The thin, quadrilateral **hyo-glossus** arises from the body and great cornu of the hyoid bone and is inserted into the dorsum of the tongue. The **chondroglossus** arises from the lesser cornu of the hyoid bone and joins the superior and inferior longitudinal muscles of the tongue. The **genio-glossus** (genio-hyoglossus), which forms the main part of the body of the tongue, arises from the mental spine of the mandible, from which the fibre-bundles radiate out toward the whole length of the dorsum of the tongue and to the hyoid bone.

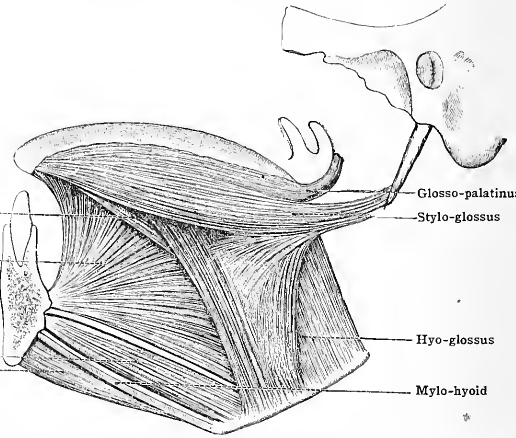
Under the mucous membrane of the tongue is a dense layer of fibrous tissue, the **lingual fascia.** In the body of the tongue there is a sagittal **septum linguæ,** which separates the two genio-glossus muscles. A transverse fibrous **lamella,** the **hyo-glossal membrane,** helps to unite the tongue to the hyoid bone. Delicate membranes invest the free portions of the extrinsic muscles of the tongue.

MUSCLES

The **stylo-glossus.**—This *arises* from the front of the lower end of the styloid process of the temporal bone and from the upper part of the stylo-mandibular ligament. *Insertion.*—It runs obliquely downward, forward, and medially, with slightly diverging fibre-bundles, to the lateral margin of the tongue, where it gives rise near the anterior pillar of the fauces to two fasciculi. The larger, lateral, longitudinal fasciculus runs superficially along the lateral margin of the tongue to the tip. The fibre-bundles are attached to the overlying mucosa and underlying musculature. The smaller, inferior, transverse fasciculus gives rise to diverging fibre-bundles which pass medially through the hyo-glossus into the base of the tongue. The most posterior of these diverging bundles may extend to the hyoid bone.

The **hyo-glossus.**—This *arises* from—(1) the lateral part of the ventral surface of the body of the hyoid bone and (2) from the upper border of the great cornu. The fibre-bundles take a nearly parallel course upward, diverging, however, slightly. Near the upper margin of the back

FIG. 349.—SIDE VIEW OF THE MUSCLES OF THE TONGUE.



part of the tongue they curve medianward and interlace with the intrinsic musculature of this region. The dorsal fibre-bundles pass transversely, the middle obliquely, the ventral longitudinally. They are inserted into the fibrous tissue which forms the skeletal framework of the tongue.

The **chondro-glossus** is a small muscle which arises from the lesser cornu of the hyoid bone and gives rise to fasciculi which join the longitudinalis inferior and the longitudinalis superior of the tongue described in Section IX.

The **genio-glossus.**—This *arises* from the mental (genial) spine of the mandible partly directly, partly by means of a short, triangular tendon. The more inferior fibre-bundles radiate toward the tip of the tongue; the intermediate extend directly toward the dorsum of the tongue, where they are *inserted* into the lingual fascia and skeletal framework. The inferior curve back to be inserted on the median part of the superior border of the hyoid bone.

Nerve-supply.—Twigs from the hypoglossal nerve enter the lateral surfaces of the muscles of this group.

Action.—The chief of the muscles, the genio-glossus, performs various services according to the part which contracts. The anterior portion serves to withdraw the tongue into the mouth and depress the tip; the middle portion to draw the base of the tongue forward, depress the median portion of the tongue, and make the tongue protrude from the mouth; the inferior fibres to elevate the hyoid bone and carry it forward. The stylo-glossus retracts the tongue, elevates its margin, and raises the hyoid bone and base of the tongue. The hyo-glossus draws down the sides of the tongue and is also a retractor. The chondro-glossus aids in both these movements.

Relations.—The main portion of the tongue is composed of the two genio-glossus muscles, which are separated in the median line by the lingual septum. The genio-glossus is covered inferiorly by the genio-hyoid and the mylo-hyoid muscles; along the lateral margin of the tongue by the glosso-palatinus, the stylo-glossus, the longitudinalis inferior, and the glosso-pharyngeus muscles; and posteriorly by the hyo-glossus, and the chondro-glossus. Below it forms a part of the medial wall of the space in which the sublingual gland is lodged. Over the dorsum and tip of the tongue it is covered by the mucosa. This likewise covers laterally, in the region of the base of the tongue, the stylo-glossus, hyo-glossus, and the longitudinalis inferior. The lingual artery runs between the hyo-glossus and the genio-glossus, and along the boundary between the longitudinalis inferior and the genio-glossus to the tip of the tongue. The lingual vein, which lies lateral to the hyo-glossus muscle, takes a similar although much more irregular course. The glosso-pharyngeal nerve passes down medial to the stylo-glossus muscle to the root of the tongue. The lingual nerve passes along the lateral margin of the tongue external to the stylo-glossus, hyo-glossus, and inferior longitudinal muscles. The hypoglossal nerve lies lateral to the inferior portion of the hyo-glossus muscle and then sinks into the genio-glossus.

The hyo-glossus muscle is covered laterally below the free portion of the tongue by the mylo-hyoid, digastric, and stylo-hyoid muscles and by the deep part of the submaxillary gland. Medially it covers in part the middle constrictor of the pharynx.

The stylo-glossus muscle above the tongue lies medial to the stylo-hyoid and the internal pterygoid muscles and the parotid gland, and between the internal and external carotid arteries. It lies lateral to the superior constrictor of the pharynx.

Variations.—The genio-glossus often sends a slip to the epiglottis (**levator epiglottidis**). It may send some bundles into the superior constrictor of the pharynx (**genio-pharyngeus**) or to the stylo-hyoid ligament. Various parts of the muscle may be more or less isolated. Of these, a fasciculus from the mental (genial) spine to the tip of the tongue is the most frequent (**longitudinalis linguæ inferior medius**). The hyo-glossus exhibits considerable variation in structure. Some authors consider the chondro-glossus but a portion of this muscle, while Poirier considers it merely the origin of the longitudinalis inferior. The stylo-glossus may be absent on one side or on both. Its origin varies considerably and may be from the angle of the jaw. The muscle may be doubled.

5. SUPERFICIAL MUSCULATURE OF THE SHOULDER GIRDLE AND THE EXTERNAL CERVICAL FASCIA

(Figs. 348, 355)

The **sterno-cleido-mastoid** is a strong, band-shaped muscle, bifurcated below, which arises from the medial third of the clavicle and the front of the manubrium and is inserted into the mastoid process of the temporal bone and the neighbouring part of the occipital. The large, flat, triangular **trapezius** arises from the occipital bone and the spines of the cervical and thoracic vertebræ and is inserted into the lateral third of the clavicle and into the acromion and spine of the scapula. The two muscles lie in a well defined layer of fascia which ensheaths the neck beneath the platysma, the external cervical fascia. Both muscles bend the head and neck toward the shoulder, rotate and extend the head, and raise the shoulder. The sterno-cleido-mastoid also elevates the thorax and flexes the neck.

These two superficially placed muscles represent differentiated portions of a musculature found in elasmobranchs and in the amphibia and all higher vertebrates. In sharks this musculature is associated with the musculature of the branchial arches, and, like them, is innervated by the vagus nerve. In the higher vertebrates it is innervated by the vagus or by the spinal accessory nerve, developed in connection with the vagus. To this innervation by a cranial nerve, innervation by cervical nerves is added in those higher vertebrates in which the musculature is more extensively developed. In the human embryo the muscles migrate from their origin in the upper lateral cervical region to the positions found in the adult.

FASCIÆ

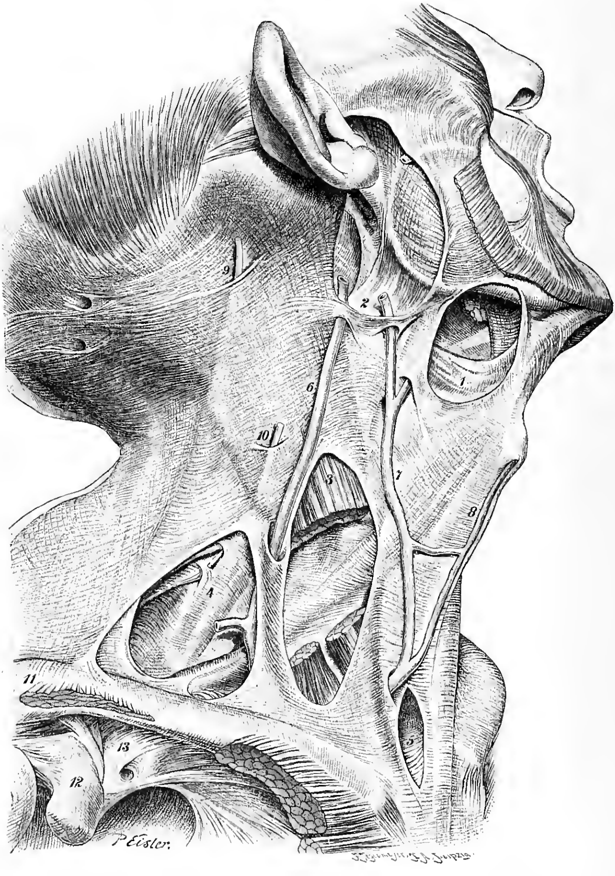
The **fasciæ** of the neck and the relations of the muscles are shown in cross-section in figs. 347, and 351.

The tela subcutanea of the head and neck in the upper dorsal region is thick, fibrous, and closely adherent to the underlying muscle fascia. Ventrally in the cervical region it contains the platysma.

The **external cervical fascia** (fig. 350) lies beneath the subcutaneous tissue and the platysma, completely invests the neck and extends cranialward over the parotid gland to the zygoma and the masseteric fascia. The trapezius lies between two closely adherent laminæ of the fascia. From the ventral margin of the trapezius it is continued as a thin but strong membrane across the posterior triangle of the neck, between this muscle and the sterno- cleido-mastoid, and is attached below to the clavicle. It invests the sterno-cleido-mastoid with two adherent laminæ and extends from the ventral margin of this muscle across the anterior triangle to the mid-line where it is continued into that of the opposite side. In this triangle the fascia is bound to the hyoid bone, and is thus divided into a submaxillary and an infrahyoid portion. The **infrahyoid portion** is simple and is attached below to the front of the manubrium. The **submaxillary portion** is attached to the inferior margin of the mandible. It covers the submaxillary gland, and along the inferior margin gives rise to a strong, membranous process which passes inward below the gland and, after extending around the tendon of the digastric muscle, becomes united to the superior margin of the hyoid bone. This process ventrally becomes fused with the perimysium of the ventral belly of the digastric. Dorsally it extends over the posterior end of the submaxillary gland and becomes attached to the angle of the jaw. Here it is strengthened by fibrous tissue which extends in from the ventral margin of the sterno-cleido-mastoid and serves to separate the parotid from the submaxillary gland. This 'mandibular process' is continued into the stylo-mandibular ligament.

Fig. 350.—Fasciæ of the Neck. (After Eisler.) The superficial fascia has been removed in places in order to show the deeper fasciæ; the sterno-cleido-mastoid has been partly removed; the submaxillary gland, almost wholly; the parotid gland, as far as the duct.

1. Submaxillary space. 2. Parotid space. 3. Sterno-cleido-mastoid. 4 Supra-clavicular fossa. 5. Supra-sternal space. 6. External jugular vein. 7. Anterior jugular vein. 8. Median colli vein. 9. N occipitalis minor. 10. N. auricularis magnus. 11. Deltoid. 12. Proc. coracoideus. 13. Fascia coraco-clavicularis.



The **parotid gland** is enclosed between two laminæ of the external cervical fascia. These are continued over the gland from the fascial investment of the sterno-cleido-mastoid, and unite ventrally to become fused to the masseteric fascia along the anterior margin of the gland. They unite below the inferior margin of the gland, and are continued into the mandibular process mentioned above. The external layer, which is the thicker and stronger, is attached above to the cartilage of the auditory canal and to the zygoma. The inner lamina is attached above to the base of the temporal bone. It is incomplete and is more or less fused to the posterior belly of the digastric muscle, the styloid process, and the muscles arising from this process. Between the styloid process and the angle of the jaw this lamina is strengthened to form the stylo-mandibular ligament.

In the back, beyond the spine of the scapula, the fascia arising from the investing adherent fascial sheath of the trapezius muscle is continued laterally across the fascia investing the infraspinatus muscle, and becomes fused with the most superficial layer of this fascia and more distally with that of the latissimus dorsi muscle. Near this lateral line of fusion it is usually closely adherent to the tela subcutanea.

MUSCLES

The **sterno-cleido-mastoideus** (fig. 348).—*Origin.*—By a medial (sternal) head from the front of the manubrium and by a lateral (clavicular) head from the upper border of the median third of the clavicle. Between the two origins there intervenes a triangular area covered by the external cervical fascia. Its *insertion* is—(1) on the anterior border and outer surface of the mastoid process, and (2) on the lateral half of the superior nuchal line of the occipital bone.

Structure.—The tendons are comparatively short, the longest being that on the anterior surface of the sternal attachment. The fibre-bundles of the muscle take a nearly parallel course from origin to insertion. Five fasciculi may be more or less clearly recognised. In a superficial layer—(1) a superficial sterno-mastoid; (2) a sterno-occipital; and (3) a cleido-occipital. In a deep layer—(4) a deep sterno-mastoid and (5) a cleido-mastoid.

Nerve-supply.—(1) From the spinal accessory nerve, which gives it branches during its course through the deep portion of the muscle, and (2) by branches from the anterior primary divisions of the second and third (?) cervical nerves. These branches enter the deep surface of the upper half of the muscle.

Action.—To bend the head and neck toward the shoulder and rotate the head toward the opposite side. When both muscles act, the neck is flexed toward the thorax and the chin is raised; or, with fixed head, the sternum is raised, as in forced respiration. When the head is bent back, the two muscles may further increase the hyperextension.

Relations.—The muscle and its sheath are covered externally by the tela subcutanea, which here contains the platysma and the external jugular vein, as well as the superficial branches of the cervical plexus. Beneath the muscle lie the sterno-hyoid, sterno-thyreoid, omo-hyoid. levator scapulæ, scaleni, splenius, and digastric muscles, the cervical plexus, the common carotid artery, internal jugular vein, and the vagus nerve. The spinal accessory nerve usually runs through its deep cleido-mastoid portion.

Variations.—There is considerable variation in the extent of independence of the main fasciculi of the muscle. In many of the lower animals the cleido-mastoid portion of the muscle is quite distinct from the sterno-mastoid portion, and this condition is frequently found in man. The cleido-occipital portion of the muscle is that most frequently absent (Wood found it present in 37 out of 102 instances). The clavicular portion of the muscle varies greatly in width. The sternal head has been seen to extend as far as the attachment of the fifth rib. Slips from the muscle may pass to various neighbouring structures. The main fasciculi of the muscle may be doubled. Sometimes one or more tendinous inscriptions cross a part or the whole of the superficial layer of the muscle.

The **trapezius** (fig. 355).—*Origin.*—By a flat aponeurosis from the superior nuchal line and external protuberance of the occipital bone, the ligamentum nuchæ, and the vertebral spines and supraspinous ligament from the seventh cervical to the twelfth thoracic vertebra. The aponeuroses of the right and left muscles are continuous across the middle line. Between the middle of the ligamentum nuchæ and the second thoracic vertebra, the aponeuroses give rise to an extensive quadrilateral tendinous area. At the distal extremity of the muscle they are also well developed.

Structure and Insertion.—The superior fibre-bundles pass obliquely downward, lateralward, and forward to the postero-superior aspect of the lateral third of the clavicle; the middle fibre-bundles, transversely to the medial edge of the acromion and the upper border of the spine of the scapula; the lower fibre-bundles, obliquely upward and laterally to terminate through a flat, triangular tendon on a tubercle at the medial end of the spine of the scapula.

Nerve-supply.—The external branch of the spinal accessory nerve descends for a distance near the superior border of the trapezius muscle and then along the ventral surface. Soon it gives rise to ascending branches for the superior portion of the muscle and descending branches for the middle and inferior portions. The main branches of distribution run about midway between the origin and insertion of the fibre-bundles. The branches from the second (?), third and fourth cervical nerves anastomose with the trunk of the spinal accessory, sometimes as it passes along the margin of the muscle, at other times within the substance of the upper portion of the muscle.

Action.—When the whole muscle contracts, it draws the scapula toward the spine and turns it so that the inferior angle points laterally, the lateral angle upward. In addition the upper portion draws the point of the shoulder upward, and with the scapula fixed extends the head, bends the neck toward the same side, and turns the face to the opposite side. The lower portion of the muscle tends to draw the scapula downward and inward and at the same time to rotate the inferior angle of the scapula outward.

Relations.—It is covered merely by skin and fascia. It lies external to the semispinalis, splenii, rhomboidei, latissimus dorsi, levator scapulæ, supraspinatus, and a small portion of the infraspinatus muscles.

Variations.—The lower limit of attachment of the muscle may be as high as the fourth thoracic vertebra. The right and left muscles are seldom symmetrical. The upper attachment may not extend to the skull. The clavicular attachment may be much more extensive than normal or may be missing. The attachments to the scapula show considerable variations. Occasionally the cervical and thoracic portions are separate, a condition normal in many mammals. Ventrally the trapezius may become continuous with the sterno-cleido-mastoid in the neck, or send a fasciculus to it or to the sternum. Aberrant fasciculi are not infrequent. Rarely a transverse tendinous inscription is found in the cervical or in the thoracic portion of the muscle. Sometimes a fasciculus is sent into the deltoid. The innervation of either the sterno-cleido-mastoid or the trapezius may be by cervical nerves only. The *omo-cervicalis* (*levator claviculæ*) is a fasciculus frequent in the lower mammals, but rarely found in man. It usually extends from the acromial end of the clavicle to the atlas and axis, but may extend to more distal cervical vertebræ. It is innervated by a ramus from the cervical branches to the trapezius. The *supra-claviculatis proprius* is a muscle rarely found. It extends on the cranial surface of the clavicle from the sternal to the acromial end and is innervated by the third cervical nerve. It is said to make tense the superficial layer of the cervical fascia.

A **bursa** is often found between the base of the spine of the scapula and the tendon of insertion of the thoracic portion of the trapezius. Another bursa is also frequently found between the insertion of the transverse portion and the supraspinous fascia.

6. INFRAHYOID MUSCULATURE

(Figs. 348 and 351)

The four **infrahyoid muscles** constitute a well-defined group of muscles which depress the hyoid bone, the larynx, and the associated structures. They lie beneath the sterno-cleido-mastoid muscle and the external cervical fascia. Two strata may be recognised. In the superficial stratum are comprised the **omo-hyoid,** a narrow, ribbon-like digastric muscle which arises from the superior margin of the scapula and is inserted into the hyoid bone; and the thin, quadrangular **sterno-hyoid,** which arises from the superior margin of the sternum and the medial end of the clavicle and is inserted into the hyoid bone. Between these two muscles is an aponeurotic membrane which constitutes the main part of the middle layer of the cervical fascia, and represents possibly a retrograde portion of a single muscle, of which the two above named are but the ventral and dorsal margins. Beneath this superficial musculature the thin, quadrangular **thyreo-hyoid** descends from the hyoid bone to the thyreoid cartilage, and the ribbon-like **sterno-thyreoid** arises from the dorsal surface of the manubrium and is inserted into the thyreoid cartilage.

All these muscles are supplied by branches from the ansa hypoglossi. The nerve-fibres arise from the first three cervical nerves.

The muscles of this group are derived from the ventral portions of the ventro-lateral divisions of the first three cervical myotomes, and correspond with the rectus abdominis muscle, which is derived from the ventral portions of the eighth to the twelfth thoracic myotomes. This musculature is characterised by metameric segmentation, which may be more or less obscured, and by a general longitudinal direction taken by the component fibre-bundles. The course of the fibres in the omo-hyoid may be looked upon as a secondary condition due to the shifting laterally of the distal attachment of the muscle. Musculature of this nature is not derived from the lower cervical and upper thoracic myotomes in man, but in some of the lower vertebrates it forms a continuous ventral band. Even in man occasional traces of this ventral musculature may, however, be seen as muscular and aponeurotic slips on the upper part of the thoracic wall, above the ribs and the aponeurosis of the external intercostal muscles.

FASCIA

(Figs. 351 and 357)

The **middle cervical fascia** is composed of two laminæ. Of these, the superficial, which ensheaths the sterno-hyoid and omo-hyoid muscles and fills in the intervening area, is much the stronger and better differentiated. The more delicate deep lamina ensheaths the thyreo-hyoid and sterno-thyreoid muscles, and laterally extends out to become fused with the superficial lamina. It is also more or less closely bound to the sheath which covers the internal jugular vein, carotid artery, and vagus nerve.

The middle cervical fascia is attached above to the hyoid bone. Beyond the lateral edge of the omo-hyoid it becomes fused with the deep lamina of the external layer of the cervical fascia, beneath the sterno-cleido-mastoid. Posterior to this muscle it usually terminates along the cranial margin of the omo-hyoid in the areolar tissue of the neck. Its distal attachment takes place into the dorsal surface of the upper margin of the sternum, and from here a process is sent over the left innominate vein to the pericardium. Lateral to the sternum the fascia is attached for some distance to the inner margin of the clavicle, and gives rise to processes, one of which extends to the fascia of the subclavius muscle, while the others pass on each side of the subclavian vein to the first rib. Still more laterally the fascia is fused along the lower margin of the scapular belly of the omo-hyoid to the underlying dense, fatty areolar tissue.

MUSCLES

(Figs. 348 and 351)

The **sterno-hyoideus.**—*Origin.*—From (1) the deep surface of the medial extremity of the clavicle; (2) the costo-clavicular (rhomboid) ligament; and (3) the neighbouring part of the sternum. The origin may extend to the cartilage of the first rib. *Structure and insertion*—The fibre-bundles take a nearly parallel course upward. The muscle belly, however, contract. slightly in width and increases slightly in thickness and slants somewhat toward the median line. The insertion takes place directly upon the inferior margin of the body of the hyoid lateral to the mid-line. Not infrequently a tendinous inscription near the junction of the middle and inferior thirds more or less completely divides the muscle into two portions. A second inscription is sometimes found at the level of the oblique line of the thyreoid cartilage. *Nerve-supply.*—One or more branches from the ansa hypoglossi enter the lateral margin of the muscle. Frequently one goes to the upper third, another to the lower third, of the muscle.

The **omo-hyoideus.**—*Origin.*—From the superior margin of the scapula near, and occasionally also from, the superior transverse ligament of the scapula. *Insertion.*—The lower border of the hyoid bone lateral to the sterno-hyoid muscle. *Structure.*—The inferior belly of the muscle near its origin is thick and fleshy. It contracts as it passes ventrally across the posterior triangle of the neck. Beneath the sterno-cleido-mastoid it is attached to a short tendon from which, as it bends upward toward the hyoid bone, the superior belly takes origin and thence expands toward the insertion. The tendon of attachment is short. The fibre-bundles of both bellies take a nearly parallel course. The central tendon of the muscle is held in place by a strong process in the middle layer of the cervical fascia. This process is attached to the dorsal surface of the clavicle and to the first rib. *Nerve-supply.*—The superior belly is supplied by a branch which enters its deep surface near the medial margin somewhat below the centre; the inferior by a branch which enters the proximal third of its deep surface. These branches arise from the ansa hypoglossi.

The **sterno-thyreoideus.**—*Origin.*—Partly directly, partly by tendinous fibres, from—(1) the dorsal surface of the manubrium from the middle line to the notch for the first rib; (2) the dorsal surface of the cartilage of the first rib. Occasionally also from the back of the cartilage of the second rib or from the clavicle. *Structure and insertion.*—The fibre-bundles take a nearly parallel course upward and slightly lateralward. The muscle is inserted by short tendinous fibres into the oblique line on the lamina of the thyreoid cartilage. A transverse tendinous inscription near the upper border of the interclavicular ligament not infrequently divides the belly of the muscle more or less completely into two parts. Sometimes a second transverse inscription is found at the level of the lower margin of the thyreoid cartilage. *Nerve-supply.*—By one or two branches from the ansa hypoglossi, which enter the ventral surface of the muscle near the lateral margin. One branch usually goes to the upper, another to the lower, third of the muscle.

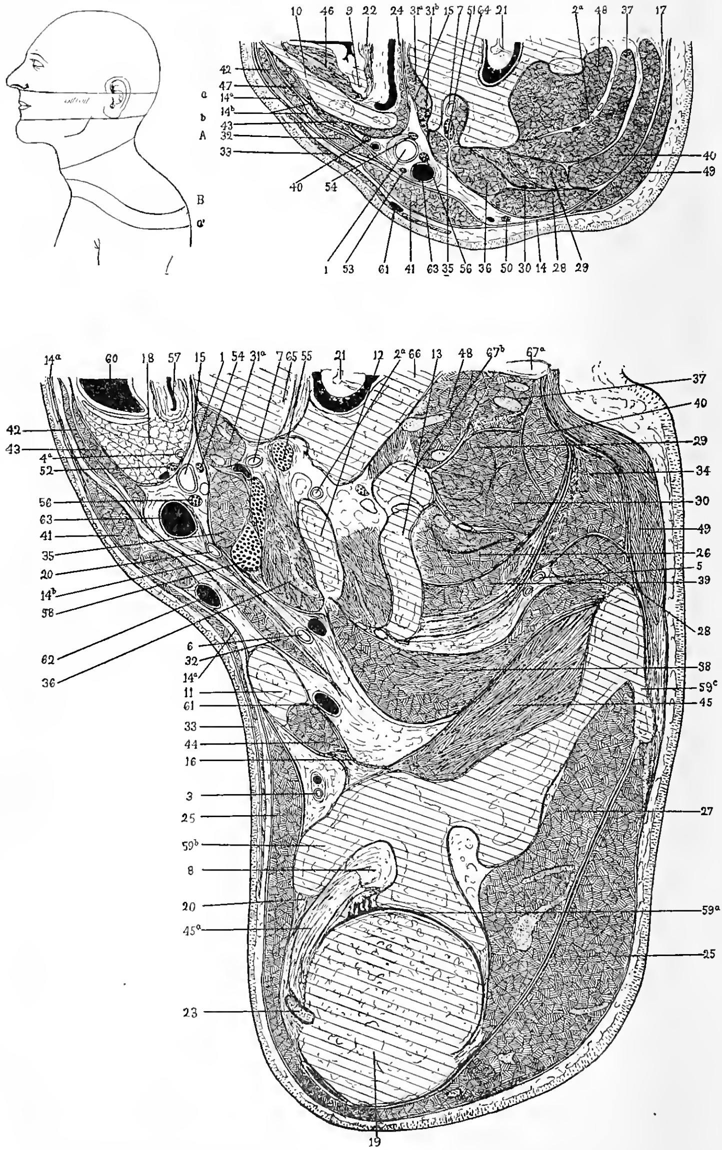
The **thyreo-hyoideus.**—*Origin.*—From the oblique line on the lamina of the thyreoid cartilage. *Structure and insertion.*—The fibre-bundles take a parallel course and are inserted on the inferior margin of the lateral third of the body of the hyoid bone and the external surface of the great cornu. Many fibre-bundles are continuous with those of the sterno-thyreoid. *Nerve-supply.*—By a branch of the hypoglossal which enters the muscle near the middle of its lateral border. The fibres are said to be derived from the first cervical nerve.

Action.—The sterno-hyoid and omo-hyoid depress the hyoid bone; the sterno-thyreoid depresses the thyreoid cartilage; and the thyreoid-hyoid approximates the bone to the cartilage. The omo-hyoid tends to draw the hyoid bone somewhat laterally. In this it is aided by the posterior belly of the digastric and the stylo-hyoid and is opposed by the sterno-thyreoid and thyreo-hyoid muscles, and the anterior belly of the digastric.

Relations.—The muscles of this group lie beneath the external cervical fascia. The sterno-cleido-mastoid muscle crosses the omo-hyoid, the sterno-hyoid, and sterno-thyreoid muscles. The latter two muscles extend for a distance behind the manubrium of the sternum. The omo-hyoid is partly covered by the trapezius, crosses the scalene muscles, the brachial plexus, the internal jugular vein, carotid artery, and the sterno-thyreoid and thyreo-hyoid muscles. The sterno-hyoid extends over the sterno-thyreoid muscle, the thyreoid gland, crico-thyreoid muscle, and the thyreoid cartilage. The sterno-thyreoid lies over the innominate vein, the trachea, and thyreoid gland. It is partly covered by the sterno-hyoid and omo-hyoid muscles. The thyreo-hyoid is largely covered by the omo-hyoid and sterno-hyoid muscles, and lies upon the hyo-thyreoid membrane and the upper part of the thyreoid cartilage.

Variations.—The muscles vary in extent of development and may be more or less fused with one another. The sternal attachment of the sterno-hyoid is more frequently absent than the clavicular attachment. The region between the omo-hyoid and sterno-hyoid may be composed of muscle instead of fascia. Each of the muscles may be longitudinally divided into two distinct fasciculi, may send fasciculi to one another or to the middle layer of the cervical fascia, or may have an abnormal origin or insertion. The omo-hyoid is the one of the group most frequently absent. One of the bellies is much more frequently absent than both. The intermediate tendon of the omo-hyoid may be reduced to a tendinous inscription or even disappear entirely. The distal attachment may take place on the scapular spine, the acromion, the coracoid process, or even the first rib or clavicle. An extra fasciculus from the clavicle is found in 3 per cent. of instances. (Le Double.). Not very infrequently a muscle innervated by a branch of the *descendens hypoglossi* is found extending from the sternum to the clavicle behind the origin of the sterno-cleido-mastoid. It may also extend from the sternum or clavicle in various directions upward toward the head.

FIG. 351, A and B.—TRANSVERSE SECTIONS THROUGH THE LEFT SIDE OF THE NECK AND SHOULDER IN THE REGIONS INDICATED IN THE DIAGRAM.
a and *b* in the diagram indicate sections A and B of fig. 347 (p. 340). *a*, that of section A, fig. 357 (p. 366).



BURSÆ

The **bursa m. sterno-hyoidei** is in constantly found between the lower margin of the hyoid bone and median hyo-thyreoid ligament and the sterno-hyoid muscle and external cervical fascia. It is better developed in men than in women and is found either on each side of the median line or fused in the median line.

The **bursa m. thyreo-hyoidei** is frequently found between the greater cornu of the hyoid bone and hyo-thyreoid membrane and the thyreo-hyoid muscle.

7. SCALENE MUSCULATURE

(Figs. 348 and 352)

The three muscles which form this group constitute a triangular mass which extends in front of the levator scapulæ and intrinsic dorsal musculature and behind the prevertebral musculature from the first two ribs to the transverse processes of the cervical vertebræ. They cover laterally the apex of the pleural cavity. They bend the neck and fix the first two ribs or raise the thorax. In front lies the **scalenus anterior,** which extends from the first rib to the fourth to sixth vertebræ. Behind this the **scalenus medius** extends from the first rib to the lower six vertebræ. The most dorsal of the group, the **scalenus posterior,** extends from the second rib to the fifth and sixth vertebræ.

These muscles are supplied by direct branches of the cervical nerves. They are probably derived from the lateral portions of the cervical myotomes. According to Gegenbaur, the two more ventral are homologous with intercostal muscles, the dorsal with the levatores costarum. It is to be noted, however, that the anterior muscle lies in front of the brachial plexus, i. e., in a position similar to that of the subcostal musculature. The scalene musculature is morphologically closely related to the deep shoulder-girdle musculature, p. 356.

FASCIA

(Figs. 351, 357)

From the front of the bodies of the cervical vertebræ the prevertebral fascia is continued laterally over the longus colli and the scalene muscles, and extends dorsally into the fascia covering the levator scapulæ. Between the muscles fascial processes are sent in to become attached to the cervical vertebræ. Inferiorly the fascia extends to the outer surface of the thorax.

MUSCLES

(Fig. 352)

The **scalenus anterior.**—This *arises* from the ventral part of the inferior border of the transverse processes of the fourth, fifth, and sixth cervical vertebræ, usually also from the third, rarely from the seventh, by means of long, slender tendinous processes. From each tendon arises a fasciculus composed of nearly parallel fibre-bundles. The fasciculi soon fuse to form a muscle belly which contracts somewhat toward the insertion. This takes place by means of

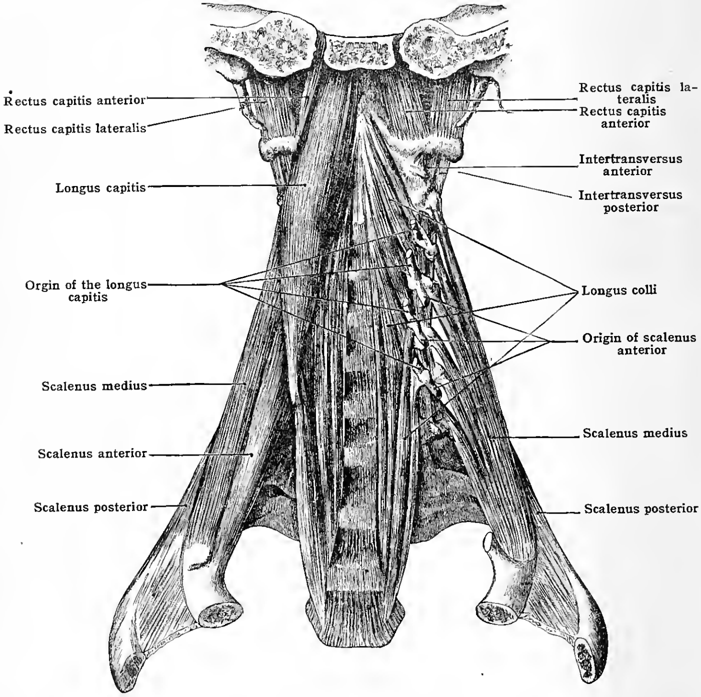
a tendon which sends a fibrous lamina a short distance upward on the outer surface of the muscle. The tendon is *inserted* into the scalene tubercle on the upper surface of the body of the first rib.

The scalenus medius.—This *arises* usually from the third to the seventh, sometimes from all seven or from merely the last four or five cervical vertebræ. The origin takes place from the posterior part of the lateral border of the transverse processes by means of a slender tendon from each of the upper and directly by a muscular fasciculus from each of the lower vertebræ. The fasciculi become combined into a compact muscle belly which is *inserted* in a manner similar to the scalenus anterior into the upper surface of the first rib behind the subclavian groove. The insertion usually extends to the second rib.

The scalenus posterior *arises* by short tendons from the posterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. The origin may extend as high as the fourth vertebra, or as low as the seventh. It is *inserted* by a short tendon into the lateral surface of the second rib. Occasionally it extends to the third rib.

FIG. 352.—THE DEEP VENTRAL MUSCLES OF THE NECK.



Nerve-supply.—The scalenus anterior is innervated by branches from the fifth, sixth, and seventh cervical nerves; the middle by the fourth, fifth, sixth, seventh, and eighth cervical nerves; the posterior by the seventh or eighth nerves.

Action.—With the thorax fixed the scalene muscles bend the neck to the side and slightly forward and turn it slightly toward the opposite side. With the neck fixed they serve to lift the first two ribs and are of use in enforced inspiration. In quiet inspiration they serve to fix the first two ribs.

Relations.—The longus colli lies medial to the scalenus anterior. Dorsally the scalene muscles; medially the pharynx, thyreoid gland, and trachea; ventro-laterally the sterno-cleido-mastoid, infra-hyoid, and subclavius muscles and the clavicle bound a space filled with dense fatty areolar tissue in which are contained the subclavian and carotid arteries, the subclavian and internal jugular veins, the vagus, phrenic, and sympathetic nerves, and numerous smaller blood-vessels and nerves. The main branches of the lower five cervical nerves pass laterally between the scalenus anterior and medius. The subclavian artery passes behind, the subclavian vein in front, of the attachment of the scalenus anterior. The scalenus medius above and the scalenus posterior below enter into relations dorsally with the levator scapulæ and the intrinsic dorsal musculature, from which they are separated by fascial septa.

Variations.—The scaleni present numerous variations in the extent of the costal and vertebral attachments. The degree of fusion of the various fasciculi likewise varies so much that different authors have described varying numbers of muscles into which the scalenus mass should be subdivided. A muscle frequently present is the **scalenus minimus.** This arises from the anterior tubercle of the sixth or sixth and seventh cervical vertebræ, and is inserted into the first rib behind the sulcus for the subclavian artery. It sends a process (Sibson's fascia) to the pleural cupola and serves to make the pleura tense. Zuckerkandl found it in 22 out of 60 bodies on both sides; 12 times on the right side only, 9 times on the left. It is innervated by the eighth cervical nerve. When absent, a ligamentous band takes its place. An *intertransversarius lateralis longus,* may extend from the posterior tubercles of the 3–5 transverse processes to the tip of the seventh transverse process and divide the muscle fasciculi near their origin into dorsal and ventral divisions.

8. THE PREVERTEBRAL MUSCULATURE

(Fig. 352)

This deep-seated musculature extends along the ventro-lateral surfaces of the three upper thoracic and the cervical vertebræ to the skull. It is composed of two muscles. The **longus colli** arises from the bodies of the three thoracic and from the bodies and transverse processes of the third to the sixth cervical vertebræ, and is inserted into transverse processes and bodies of the cervical vertebræ. The **longus capitis** (rectus capitis anterior major) arises from the transverse processes of the fourth, fifth, and sixth cervical vertebræ, and is inserted into the basilar process of the occipital bone. These muscles flex, abduct, and rotate the head and neck. All of them are supplied by direct branches from the anterior divisions of the cervical nerves. They are probably specialised from the ventro-lateral portions of the cervical myotomes. Similar muscles are found in all vertebrates with well-developed necks. The rectus capitis anterior (minor) represents an anterior cervical intertransverse muscle.

FASCIA

(Figs. 351, 357)

The muscles are firmly bound to the vertebral column by the prevertebral fascia described in connection with the scalene muscles and by the septa which extend in between the muscles of this group and between them and the scalenus anterior.

MUSCLES

(Fig. 352)

The **longus colli.**—This muscle may be compared to a triangle, the base of which extends from the anterior tubercle of the atlas to the body of the third thoracic vertebra and the apex of which is the transverse process of the fifth cervical vertebra. The complex construction of the muscle makes it advisable to consider it as divided into three parts.

The **supero-lateral portion** consists of fasciculi which arise from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ and from the body of the third thoracic and become fused into a belly which is inserted into the anterior tubercle of the atlas.

The **median portion** is formed of muscle fasciculi which arise from the antero-lateral parts of the bodies of the first three thoracic vertebræ and the last three cervical vertebræ by tendinous processes. These fasciculi fuse into a belly which terminates by three flat tendinous fasciculi on the antero-lateral surfaces of the bodies of the second, third, and fourth cervical vertebræ.

The **infero-lateral portion** is applied to the inferior lateral surface of the median portion. It arises from the lateral parts of the bodies of the first three thoracic vertebræ and is inserted by tendinous processes into the transverse processes of the fifth and sixth cervical vertebræ.

Nerve-supply.—By branches from the second to sixth cervical nerves which send rami to the various constituent fasciculi of the muscle.

The **longus capitis** (rectus capitis anterior major).—*Origin.*—By cylindrical tendons from the tips of the anterior tubercles of the third, fourth fifth, and sixth cervical vertebræ. The tendons send up aponeurotic expansions on the outside of the fasciculi, which arise from them. These fasciculi fuse into a dense muscular belly to which is usually added a fasciculus from the longus colli. The *insertion* takes place into the impression on the inferior surface of the basilar portion of the occipital bone, extending lateral to the pharyngeal tubercle outward and forward. The insertion of the fibre-bundles from the third vertebra is direct; the other fibre-bundles are inserted largely into a tendinous lamina which covers the middle of the ventral surface of the muscle and from which, in turn, other fibre-bundles arise. It is an incomplete digastric muscle. *Nerve-supply.*—The first, second, third, and fourth cervical nerves send branches into the ventral surface of the muscle.

Actions.—The longus colli serves to bend the neck forward; the supero-lateral portion, when acting on one side only, serves slightly to bend the neck toward that side and to rotate it; the infero-lateral portion serves especially to prevent hyperextension. The longus capitis bends the head forward; one side acting alone rotates the head toward that side.

Variations.—There is considerable variation in the number of vertebræ to which the tendons of origin and insertion of the longus colli and longus capitis may be attached and in the extent of fusion of the different fasciculi composing them. There may be fusion with the scalenus anterior. The *atlantico-basilaris internus* in 4 per cent. of cases extends from the anterior tubercle of the atlas to the base of the skull.

9. ANTERIOR AND LATERAL INTERTRANSVERSE MUSCLES

(Fig. 352)

The **anterior intertransverse** muscles extend successively between the anterior tubercles of the cervical vertebræ. They lie in front of the anterior divisions of the cervical nerves and are supplied by branches from these divisions. They are usually more or less bound up with the insertions of the scalene and prevertebral muscles into these tubercles. The muscle between the atlas and epistropheus is frequently missing; when present, it passes in front of the lateral articulation between these vertebræ. The rectus capitis anterior (minor) may be considered a continuation of the series. The lowest muscle may extend between the seventh cervical vertebra and the first rib. The **lateral intertransverse** muscles lie immediately behind the ventral divisions of the spinal nerves and lateral to the dorsal divisions and are supplied by branches from the ventral divisions. The rectus capitis lateralis belongs to this series. The **rectus capitis anterior** (minor) arises from the lateral mass of the atlas and is inserted into the base of the occipital bone. The **rectus capitis lateralis** runs from the transverse process of the atlas to the lateral part of the occipital. For the posterior intertransverse muscles see p. 417.

The **rectus capitis anterior** (minor).—This *arises* from the upper surface of the lateral mass of the atlas in front of the articular process and partly from the neighbouring transverse process. From a tendon the fibre-bundles extend in a nearly parallel direction upward and medially to be *inserted* on the inferior surface of the basilar portion of the occipital bone in front of the condyle *Nerve-supply.*—From the first (and second) cervical nerves. *Action.*—The rectus capitis anterior (minor) serve to bend the head forward and, when the muscles on one side only are contracted, to rotate the head toward the same side.

Relations.—The muscles of this group are closely applied to the vertebral column. Between the fascia covering them and the fascia surrounding the pharynx which lies in front is a region in which merely a slight amount of loose areolar tissue is found. Dorso-medially the longus colli below and the longus capitis above help to bound the space in which the chief vessels and nerves extend between the thorax and the head.

The rectus capitis lateralis (fig. 352).—*Origin.*—From the upper surface of the transverse process of the atlas.

Structure and insertion.—The fibre-bundles give rise to a quadrilateral sheet which passes upward to be inserted on the under surface of the pars lateralis of the occipital bone.

Nerve-supply.—The ventral branch of the suboccipital (first cervical) nerve gives twigs to its ventral surface.

Action.—To flex the head laterally.

Relations.—In front lie the anterior primary division of the suboccipital nerve and the internal jugular vein. Behind the muscle lie the superior oblique and the longissimus capitis (trachelo-mastoid) muscles and the atlanto-occipital joint.

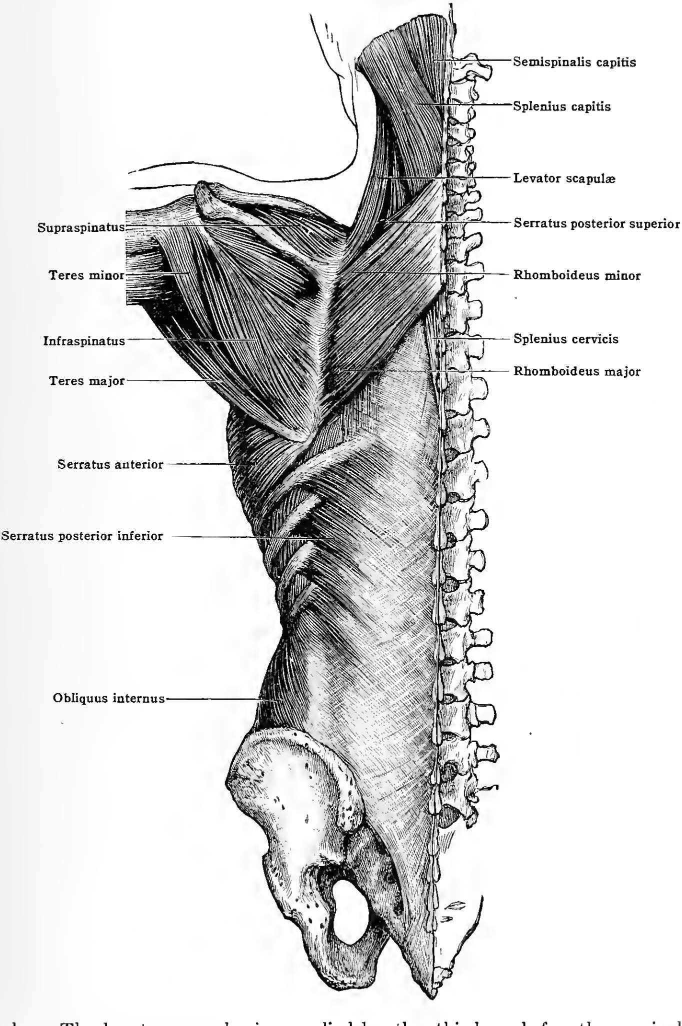
10. DEEP MUSCULATURE OF THE SHOULDER GIRDLE

(Figs. 348, 353, 354, 388)

To this group belong four muscles which arise in the lateral cervical region during embryonic development and become secondarily attached to the vertebral margin of the scapula. One of these muscles, the band-like **levator scapulæ** (fig. 353), remains in the cervical region. It extends beneath the sterno-cleido-mastoid, the trapezius, and the intervening fascia from the transverse processes of the first four cervical vertebræ to the medial angle of the scapula. A second, the large, quadrilateral **serratus anterior** (magnus) (fig. 354), comes to lie beneath the blade of the scapula and wanders with this to the thoracic region. It arises, in the adult, from the first nine ribs and is inserted into the vertebral margin of the scapula. The flat, quadrangular **rhomboideus major** and **rhomboideus**

minor (fig. 353) arise from the spines of the last cervical and first four or five thoracic vertebræ, pass obliquely downward across the deep dorsal muscles beneath the trapezius and are inserted into the vertebral margin of the scapula. The third to the seventh cervical nerves supply this set of

Fig. 353.—The Levator Scapulæ and Rhomboidei.



muscles. The levator scapulæ is supplied by the third and fourth cervical nerves, the rhomboids by the fifth (dorsal scapular), the serratus anterior by the fifth to the seventh (long thoracic nerve). The muscles of this group elevate the scapula, rotate it, and draw it backward (rhomboidei) or forward (serratus anterior). When all contract together they raise the thorax.

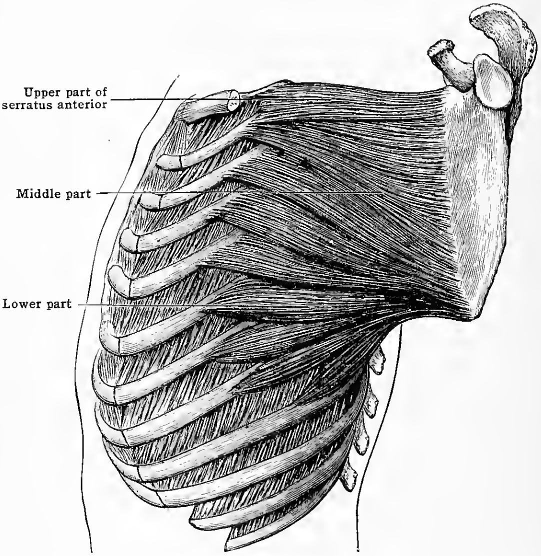
The levator scapulæ and the serratus anterior (magnus) are two differentiated parts of a muscle which is a continous mass in many of the lower mammals. A muscle corresponding to the rhomboideus is found in some of the reptiles and many of the higher vertebrates. In some of the mammals it has a more extensive cervical attachment than in man.

FASCIÆ

The fasciæ investing these muscles are shown in cross-section in fig. 357.

The levator scapulæ is invested by fascial membranes, the external and stronger of which is continued dorsally from the fascial investment of the scalene muscles. The thinner layer on its deep surface lies next the fascial investment of the intrinsic muscles of the back. Cranialward from the rhomboid muscles the fascial investment of the levator scapulæ is fused dorsally with the fascia covering the splenius cervicis. Where the dorsal margin of the levator comes in contact with the rhomboideus minor, the fascia is continued over into the thin fascial mem-

Fig. 354.—Serratus Anterior.



brane which invests both surfaces of the rhomboidei. Similarly the investing fascia of the levator is continued ventrally into the fascia investing both surfaces of the serratus anterior (magnus). Within the internal fascial investment of this group of muscles, near the insertion of the levator, run the transversa colli artery and the dorsal scapular nerve.

MUSCLES

The **rhomboideus minor** (fig. 353).—*Origin.*—Lower part of the ligamentum nuchæ, the spines of the seventh cervical and first thoracic vertebræ, and the intervening supraspinous ligament. *Insertion.*—Vertebral border of the scapula near the spine.

The **rhomboideus major** (fig. 353).—*Origin.*—Spines of the first four or five thoracic vertebræ. *Insertion.*—Vertebral border of the scapula opposite the infraspinous fossa.

Structure.—The two muscles are included between two adherent fascial layers which bridge over the greater or less space that may intervene between them. The fibre-bundles take a parallel course obliquely downward and lateralward from the vertebræ. From the vertebral spines the muscles arise by an aponeurosis which varies in width. The attachment to the scapula is by short tendinous processes. The attachment of the rhomboideus major is firmest toward the inferior angle of the scapula.

Nerve-supply.—The dorsal scapular nerve, which usually arises chiefly from the fifth cervical nerve, enters the superior margin of the rhomboideus minor and then courses distally near the deep ventral surface of the two muscles and about midway between the tendons of origin and insertion.

Action.—The two muscles draw the scapula upward and medialward toward the spine and rotate it so as to depress the shoulder.

Relations.—Over the muscles lies the trapezius. Under them lie the serratus posterior superior and the splenius cervicis, the longissimus dorsi, the ilio-costalis, serratus posterior superior and external intercostal muscles. The descending ramus of the transversa colli artery descends on the deep surface. Blood-vessels for the trapezius pass to this muscle between the two rhomboids.

Variations.—There is much variation in the extent of the vertebral attachment. The minor is frequently, the major occasionally, absent. The two rhomboids are frequently fused with one another or may be divided into several distinct fasciculi. Frequently (80 per cent., Balli) a fasciculus extends obliquely on the deep surface of the R. major from the cranial part of the origin to the distal part of the insertion. Slips may be sent to the latissimus dorsi or the teres major. An accessory slip may pass between the trapezius and splenius muscles to the occipital bone (**occipito-scapularis**). A muscle corresponding to this fasciculus is normally found in many mammals.

The levator scapulæ (figs. 353, 388).—*Origin.*—By short tendons from the dorsal tubercles of the transverse processes of the first four cervical vertebræ, between the attachments of the splenius cervicis and scalenus medius muscles. The tendons from the third and fourth cervical vertebræ are fused for a short distance with those of the longissimus cervicis. *Structure and insertion.*—The fibres run in parallel bundles in a dorso-lateral direction downward to the vertebral border of the scapula opposite the supraspinous fossa. The fibre-bundles are inserted directly into the periosteum. As a rule, the flat fasciculi arising from the different vertebræ are easily separated.

Nerve-supply.—By rami chiefly from the third and fourth cervical nerves. These rami enter the ventral margin of the muscle and extend obliquely across the dorsal surface of the constituent fasciculi about midway between the tendons of origin and insertion. Frequently anastomosing branches pass between the nerves. The lowest fasciculus is usually supplied by branches from the nerve to the rhomboid muscles (dorsal scapular).

Action.—Draws the scapula upward and tends to rotate it so that the inferior angle approaches the spine. When the scapula is fixed, the muscle serves to bend the neck laterally and slightly to rotate it toward the same side and extend it.

Relations.—Externally the sterno-cleido-mastoid and, in part, the splenius capitis cover it above; the trapezius, below; and the external cervical fascia, its middle portion. Internally lie the splenius cervicis, longissimus and iliocostalis cervicis (transversalis cervicis), and serratus posterior superior muscles and the ramus descendens of the transversa colli artery. In front lie the scalene muscles.

Variations.—The number of cervical vertebræ from which the muscle springs varies from two to seven. The most constant are the slips of origin from the first two vertebræ. The muscle may send slips to the temporal or the occiptal bone or to the trapezius, the serratus anterior (magnus), serratus posterior superior, and other muscles, or to the clavicle, first or second rib, etc. Often the parts of the muscle running to each vertebra are separated for the whole distance. A bundle of fibres that appears to be a detached slip of the levator scapulæ may run from the first two or from lower cervical vertebræ to the lateral end of the clavicle and to the acromion. This represents the **levator claviculæ** found normally in many vertebrates. According to Le Double, it is innervated by a branch from the cervical branches to the trapezius group.

The serratus anterior (magnus) (figs. 354, 388).—*First Part.*—The origin is by two digitations from the first and second ribs and from a fibrous arch uniting these two attachments. The fibre-bundles converge to be inserted on an oval space on the costal surface of the scapula near its medial angle. *Second Part.*—This arises by two or three digitations from the second, third, and sometimes the fourth ribs. The fibre-bundles spread out into a thin sheet which is inserted along the vertebral border of the scapula. *Third Part.*—This, the strongest part of the muscle, arises by digitations from the fourth or fifth to the eighth or ninth ribs. The attachments of the digitations are longest on the upper border of each rib. The interdigitate with the attachments of the external oblique muscle of the abdomen. The fibre-bundles converge to be inserted on the large oval space on the costal surface near the inferior angle of the scapula.

Nerve-supply.—From the proximal portions of the anterior divisions of the fifth, sixth, seventh, and sometimes the eighth cervical nerves branches arise which fuse into the long thoracic nerve. This nerve usually passes laterally through or behind the scalenus medius muscle, courses along the outer surface of the serratus anterior midway between the origin and insertion, and gives rise to numerous twigs to supply the various divisions. The fibres to the upper portion come mainly from the fifth cervical nerve; those to the middle from the fifth and sixth; and those to the lower from the sixth and seventh.

Action.—The muscle holds the scapula against the thorax and draws it forward and laterally and, by its highly developed inferior portion, rotates the bone so as to raise the point of the shoulder. It is of especial importance in abduction of the arm. It also aids, to a slight degree, in forced inspiration.

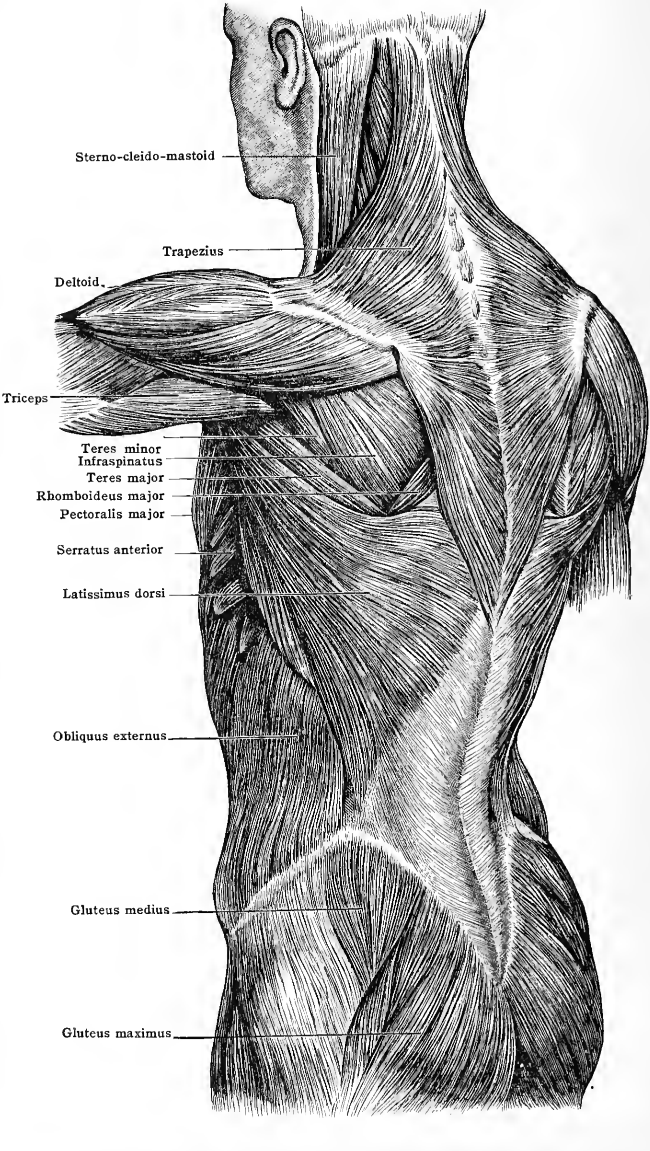
Relations.—Superficial to the muscle lie the pectoralis major and minor, subscapularis, teres major, and latissimus dorsi muscles, the subclavian and axillary vessels, and the brachial plexus. Between the latissimus dorsi and pectoral muscles it is covered by skin and fascia inferiorly, and superiorly by the fatty areolar tissue of the axillary fossa. Under it lie the external intercostal, serratus posterior superior, and the lower extremity of the scalenus medius and posterior muscles.

Variations.—The digitations may extend to the tenth or only to the seventh rib. The muscle may be continuous with the levator scapulæ as it is in the carnivora, or some of its upper digitations may be wanting. Slips may be continued into neighbouring muscles. The lower digitations may be partially replaced by digitations innervated by intercostal nerves.

II. MUSCULATURE OF THE UPPER LIMB

The upper limbs in man, relieved of the function of locomotion which is their chief office in most of the lower mammals, have become endowed with great

FIG. 355.—FIRST LAYER OF MUSCLES OF THE BACK.



freedom of movement which permits their developing many important functions. Primitively of value in climbing, in seizing food, preparing it for eating and carrying it to the mouth, in attack and defense, their importance has been greatly increased through the invention and use of tools, at first simple but constantly increasing in complexity. They are also used as a means of social expression, as seen primitively in the shrugging of the shoulders, or in the varied movements of the arms which accompany heated discourse, and as finally developed in the art of writing. In order to understand the muscles which are called into play in the performance of these varied functions it is necessary to consider the various types of movement which take place at each of the joints. Since, however, most muscles act on more than one joint and the different parts of a muscle may act differently on the same joint, it is convenient to take up the muscles of each region of the limb in groups, based not so much upon the action of the muscles on any one joint as upon the development of the group and the innervation of the muscles composing it.

Movement of the scapula is of essential importance in the movements of the arm. The scapula is kept against the thorax by muscular attachments and atmospheric pressure, but it may be moved forward, backward, upward, and downward, and may be rotated so that the glenoid fossa, with which the head of the humerus articulates, is pointed forward when the arms are carried forward, lateralward when the arms are abducted, upward when the arms are raised high and somewhat downward when the arms are carried backward, thus greatly increasing the extent of movement in these various directions. The acromio-clavicular, and sterno-clavicular joints both allow limited movements in various directions so that they resemble physiologically limited ball and socket joints. The part played by the superficial and deep shoulder-girdle muscles in the various movements has been described above, p. 356, in connection with these groups of muscles. The action of these muscles is aided by the "pectoral muscles," (figs. 360, 388) and by the latissimus dorsi (fig. 355) described below. These muscles depress the scapula*

At the humero-scapular or shoulder-joint the arm may be carried outward or abducted, bodyward or adducted, forward or flexed and backward or extended. The last is much more limited in degree than the other two. The arm may also be partially rotated at this joint. These various movements are brought about by the scapulo-humeral muscles (figs. 355, 356, 363) and by the latissimus dorsi (fig. 355) and the pectoralis major, (fig. 360) assisted by the muscles of the arm which arise from the scapula. They are produced in association with the movements of the scapula described above. At the ulno-humeral joint the movements are relatively simple, consisting of flexion and extension. Extension is produced at the elbow by the dorsal muscles of the arm (fig. 363), flexion is produced not only by the ventral muscles of the arm, which are inserted into the radius and ulna (fig. 364), but also by the more superficial of both the main groups of muscles of the forearm. The pronation of the forearm, whereby the palm is turned downward, and supination, whereby it is turned upward, take place in the joints between the radius and ulna at each extremity and between the radius and the lower end of the humerus. At the upper radio-ulnar joint the radius is turned on its long axis, at the lower joint it is carried about the lower end of the ulna. Pronation is produced chiefly by muscles belonging to the ulno-volar group of forearm muscles (fig. 370); supination is produced by the biceps of the arm (fig. 364) in conjunction with some of the muscles of the radio-dorsal group of the forearm (fig. 367). At the wrist joints (radio-carpal, intercarpal), the movements are those of flexion, extension, radial abduction and ulnar abduction. Volar flexion takes place chiefly at the radio-carpal joint, dorsal flexion at the intercarpal joint (Frohse). Extension is produced by those muscles of the radio-dorsal group of the forearm, which send tendons to the wrist and digits, flexion by the corresponding muscles of the ulno-volar group, radial abduction is produced by the radial carpal extensors (fig. 367), and flexor ulnar abduction by the ulnar carpal extensor and flexor (fig. 370). The varied movements of the thumb and fingers, flexion, extension, abduction, and adduction are produced partly by muscles of the two chief groups of forearm muscles, partly by the intrinsic muscles of the hand. Of chief interest here are the free movements of the metacarpal of the thumb and the limited movements of the other metacarpals, that of the little fingers being the most movable, as seen in spreading or cupping the hand. In flexion and extension of the metacarpal of the thumb the movement is such as to bring the thumb into opposition to the fingers. In the metacarpo-phalangeal joints those of the fingers admit of much greater freedom of movement, flexion, extension, abduction, and adduction, than that of the thumb. The interphalangeal joints are pure hinge joints and permit merely flexion and extension.

Divisions.—The muscles described in this section as the muscles of the upper limb are all differentiated from the blastema of the embryonic limb bud. Most of them are differentiated in connection with the skeleton of the limb and extend between the various bones which compose it, but a few grow out from the limb bud over the trunk and become secondarily attached at one extremity to the trunk, while the other extremity remains attached to the skeleton of the limb. Thus the pectoral muscles (fig. 360), extend from the limb bud over the front of the thorax and the latissimus dorsi extends over the side and back of the trunk

* The upper sternal part of the pectoralis major, however, acting alone elevates the scapula. and the glenoid fossa, the latissimus dorsi draws the scapula backward, the pectoral muscles draw it forward.

as far as the iliac crest (fig. 355). The muscles of the limb may be divided into two great divisions, a dorsal division, innervated by nerves arising from the back of the brachial plexus (supra- and subscapular, axillary and radial nerves) and a ventral division innervated by nerves arising from the front of the plexus (subclavian, anterior thoracic, musculo-cutaneous, median and ulnar). The former, which correspond with the musculature on the back of the shark's fin, are in the main extensors; the latter, which correspond with the musculature on the front of the shark's fin are in the main flexors. The bellies of the muscles of each division are found in the region of the shoulder and thorax, the arm, the forearm, and the hand.

The **shoulder muscles** belong to the dorsal division. They arise from the lateral third of the clavicle and from both surfaces of the scapula and are inserted into the upper part of the humerus. They include the *deltoid* (fig. 355), the chief abductor of the arm; the *supraspinatus*, the *infraspinatus* and the *teres minor* (fig. 363), all lateral rotators; the *subscapularis* (fig. 356), the chief medial rotator; and the *teres major* (fig. 355), a medial rotator and adductor. With these may be classed the *latissimus dorsi* (a medial rotator, adductor and extensor) (fig. 355), which arises from the dorsolumbar fascia and the crest of the ilium and is inserted into the upper part of the shaft of the humerus. These muscles are supplied by the suprascapular, the subscapular, and the axillary nerves.

The **pectoral group** belongs to the ventral division. It includes the *pectoralis major* (fig. 360), a powerful flexor and adductor of the arm arising from the anterior chest wall and inserted into the shaft of the humerus; the *pectoralis minor* (fig. 388), which arises from the chest wall and is inserted into the coracoid process of the scapula, and the *subclavius* (fig. 361), which extends from the first rib to the clavicle. These muscles are supplied by the subclavian and the anterior thoracic nerves.

In the **arm the dorsal division** is represented by the triceps and anconeus, (fig. 363). The *triceps* arises from the scapula and the back of the humerus and is inserted into the olecranon process of the ulna. The *anconeus* arises from the radial epicondyle of the humerus and is inserted into the olecranon process. Both muscles extend the forearm. The triceps also adducts the arm. They are supplied by the radial nerve.

The **ventral division** is made up of the coraco-brachialis (fig. 365); the biceps (fig. 364); and the brachialis (fig. 365). The *coraco-brachialis* (fig. 365), arises from the tip of the coracoid process of the clavicle and is inserted into the shaft of the humerus. It adducts and flexes the arm. The *biceps* (fig. 364), arises by a short head from the coracoid process and by a long head from the scapula above the glenoid fossa and is inserted into the radius and the fascia of the forearm. It flexes and supinates the forearm. The long head is an abductor, the short head an adductor and flexor of the arm. The *brachialis* (fig. 365), arises from the lower part of the shaft of the humerus and is inserted into the ulna. It is a flexor of the forearm.

The two main divisions of the musculature of the **forearm** give rise to the prominences on each side of the elbow-joint. Their peculiar arrangement with respect to the humerus is because in man, as in most tetrapods, the normal position of the forearm is one of pronation and in this position the back of the forearm is in line with the radial epicondyle, the front with the ulnar epicondyle. The dorsal or extensor muscles, springing from the lower end of the humerus (fig. 367), get the most direct purchase when attached to the radial epicondyle, and the ventral or flexor muscles (fig. 370), the most direct purchase when attached to the ulnar epicondyle. The two divisions of the musculature may therefore here be designated the radio-dorsal and the ulno-volar or volar divisions. The main bulk of the musculature is found in the upper part of the forearm. At the wrist numerous tendons pass over to the wrist, palm and digits. This arrangement facilitates movement of the hand.

The muscles of the **dorsal division** (figs. 367, 368, 369), are divisible into two groups, a superficial and a deep group. Those of the superficial group arise from the radial side of the lower end of the humerus and are inserted into the dorsal end of the radius (*brachio-radialis*), the radial and ulnar sides of the metacarpus (*extensor carpi radialis longus* and *brevis* and *extensor carpi ulnaris*) and into the backs of the digits (*extensores digitorum*). The deeper muscles arise chiefly from the ulna and are inserted into the radius (*supinator*), the thumb (*abductor pollicis longus, extensor pollicis longus* and *brevis*) and index-finger (*extensor indicis proprius*, fig. 369). All are supplied by the radial nerve. The chief function of the brachio-radialis is to flex the forearm. The chief functions of the other muscles are indicated by their names.

The **volar musculature** (figs. 370, 371, 372, 375) arises from the medial side of the lower end of the humerus and from the front of the radius and ulna and is divisible into four planes. The muscles of the most superficial plane, *pronator teres, flexor carpi radialis, palmaris longus*, and *flexor carpi ulnaris*, arise from the humerus and are inserted respectively into the radius, the radial side of the metacarpus, the palmar fascia and the ulnar side of the metacarpus. In the second layer the *flexor digitorum sublimis* arises from the humerus and the upper part of the radius and ulna and sends tendons to the second row of phalanges of the fingers. In the third layer the *flexor digitorum profundus* and *flexor pollicis longus* arise from the radius and ulna and send tendons to the terminal row of phalanges. In the fourth layer a single muscle, the *pronator quadratus* (fig. 377), extends in the lower part of the forearm from the radius to the ulna. These muscles are supplied mainly by branches of the median nerve but the ulnar nerve supplies the flexor carpi ulnaris and a part of the flexor profundus digitorum. The chief functions of these muscles are indicated by their names.

In the **hand** (figs. 368, 375, 376, 377, 379) there are several sets of intrinsic muscles. About the metacarpal of the thumb is grouped a set of muscles which arise from the carpus and metacarpus and are inserted into the metacarpal and first phalanx of the thumb (*flexor brevis pollicis, opponens pollicis, abductor pollicis brevis, adductor pollicis*). A similar set of muscles is grouped about the metacarpal of the little finger (*abductor digiti quinti, opponens digiti quinti, flexor brevis digiti quinti*). These sets of muscles give rise respectively to the thenar and hypothenar eminences. Between the metacarpals two sets of *interosseous* muscles arise; a *volar*, adductor toward the middle finger and a *dorsal*, abductor group. They are inserted into the sides of the bases of the first row of phalanges and into the extensor tendons. They also flex the first row of phalanges and extend the other two rows. From the tendons of the deep flexor muscle of the fingers, a series of *lumbrical* muscles extends to the radial sides of the extensor tendons. They flex the first row of phalanges and extend the other two. Over the thenar eminence there is a subcutaneous muscle, the *palmaris brevis*. The muscles of the hand are supplied by the ulnar nerve, with the exception of the two more radial *lumbricals* and the *abductor, opponens,* and *flexor brevis* of the thumb, which are supplied by the median nerve.

Fasciæ.—The muscle fasciæ of the upper extremities are well developed. The deltoid and latissimus dorsi are contained in a fascial sheet which extends between them. The deeper muscles which arise from the scapula are covered by strong fasciæ. Of the pectoral muscles the pectoralis major is covered by a delicate fascia, while the subclavius and pectoralis minor are contained within the dense *costo-coracoid membrane* (fig. 358) which extends into the fascia covering the axillary fossa. The latter (fig. 359), is thin and is intimately fused to the tela subcutanea. The muscles of the arm are enveloped in a cylindrical sheath which in the lower half of the arm is united to the humerus by intermuscular septa.

In the forearm near the wrist and on the back of the hand the tela subcutanea contains little fat. The antibrachial fascia forms a cylindrical enclosure for the muscles of the forearm. Near the wrist it becomes strengthened dorsally to form the dorsal ligament of the carpus (posterior annular ligament). This ligament converts the grooves on the back of the radius into canals for the tendons of the extensors of the wrist and fingers. On the back of the hand and fingers the fascia is intimately connected with these tendons. On the volar side near the wrist the fascia is strengthened to form the volar ligament of the carpus. Beneath the ligament lies the transverse ligament of the carpus which extends from the pisiform and hamate bones to the tuberosities of the navicular and greater multangular bones. It completes an osteo-fibrous canal for the tendons of the long flexors of the fingers. On the palm of the hand the fascia is firmly bound to the bones by intermuscular septa, which separate the thenar and hypothenar regions from a central palmar region. On the volar sides of the fingers the fascia forms the vaginal ligaments of the flexor tendons.

A. MUSCULATURE OF THE SHOULDER

(Figs. 355, 356, 357, 363, 388)

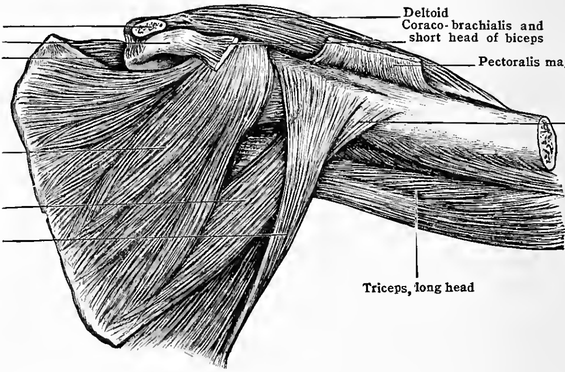
The muscles belonging to this group are the deltoid, the teres minor, the infra- and supraspinatus, the latissimus dorsi, the teres major, and the subscapularis.

The **deltoid** (fig. 355) is a large, shield-shaped muscle which covers the shoulder. It arises from the spine of the scapula, the acromion, and lateral third of the clavicle and is inserted into the deltoid tubercle of the humerus. It abducts the arm.

The teres minor, infra- and supraspinatus form a group of muscles (fig. 363) which arise from the back of the scapula, pass over the capsule of the shoulder-joint, to which their tendons are adherent, and, under cover of the deltoid, are inserted into the top and the dorsal margin of the great tubercle of the humerus. The band-like **teres minor** arises from the upper two-thirds of the axillary border of the scapula, and has the lowest insertion on the tubercle. The triangular **infraspinatus** (fig. 363) arises from the whole infraspinous fossa except the axillary border, and is inserted above the teres minor. The pyramidal **supraspinatus** (fig. 363) arises under cover of the trapezius from the supraspinous fossa, and has the highest insertion on the tubercle. The teres minor, supraspinatus and infraspinatus act as lateral rotators of the arm, the supraspinatus also as an abductor.

The latissimus dorsi, the teres major, and the subscapularis form a group of muscles attached to the lesser tubercle of the humerus and to the crest which

Fig. 356.—Front View of the Scapular Muscles.



extends distally from this ou the medial side of the intertubercular (bicipital) groove. The **latissimus dorsi** (figs. 355, 356) is a large, flat, triangular muscle, which arises from an aponeurosis covering the lumbar and the lower half of the thoracic regions of the back and from the posterior part of the iliac crest, and is inserted into the intertubercular (bicipital) groove. The **teres major** (figs. 355, 356) is a thick, ribbon-shaped muscle which arises from the dorsal surface of the inferior angle of the scapula and is inserted behind the latissimus dorsi into the distal two-thirds of the crest of the small tubercle of the humerus. The **subscapularis** (fig. 355) is a thick, triangular muscle which extends from the subscapular fossa to the small tubercle of the humerus. These muscles adduct the arm and rotate it medialward. The latissmus dorsi is also the chief extensor of the arm.

Near their humeral attachments these two groups of muscles are separated below by the long head of the triceps. The supraspinatus is separated from the subscapularis by the base of the coracoid process and by the intertubercular (bicipital) groove. The tendons of the latissimus dorsi, teres major, and subscapularis are crossed ventrally by the main vessels and nerves of the arm and by the short head of the biceps and the coraco-brachialis.

The supra- and infraspinatus muscles are supplied by the suprascapular nerve. The deltoid and the teres minor are supplied by the axillary (circumflex). The subscapularis, the teres major, and the latissimus dorsi are supplied by subscapular nerves. That to the latissimus dorsi is called the dorsal thoracic nerve.

The deltoid in many of the mammals and the lower vertebrates is represented by separate scapulo-humeral and cleido-humeral portions. The cleido-mastoid in some mammals is continued into the deltoid. The teres minor, which is innervated by the same nerve, may be looked upon as a derivative of the deltoid, although in man it is anatomically more intimately connected with the infraspinatus. The teres major may be looked upon as a specialised portion of the more primitive latissimus dorsi. The comparative anatomy of the shoulder muscles throughout the vertebrate series is a somewhat intricate subject, owing to the great variations exhibited in the form and attachment of the shoulder girdle.

The muscles of this group show more or less marked resemblances to certain muscles of the lower limb. The deltoid and the teres minor probably represent the tensor fasciæ latæ, the gluteal fascia, and the upper part of the gluteus maximus; the latissimus dorsi and teres major, the lower portion of the gluteus maximus; and the subscapularis, the gluteus medius and minimus, and the piriformis. The subscapular and axillary nerves, which supply the arm muscles mentioned, therefore represent in the main the nerves to the gluteal muscles, and the gluteal branch of the posterior cutaneous nerve of the thigh. The infraspinatus muscle probably represents the iliacus; the supraspinatus possibly the pectineus muscle of the lower limb.

FASCIÆ

(Figs. 351, 357, 359, 362)

The **tela subcutanea** covering the regions occupied by these muscles contains considerable fat. In most regions it is not readily separable into two distinct layers. In the neighbourhood of the shoulder-joint it is adherent to the underlying musculature and the axillary fasciæ. Over the acromion there is a well-marked subcutaneous bursa, **bursa subcutanea acromialis.**

Muscle fasciæ.—The deltoid and latissimus dorsi muscles are throughout the greater part of their extent superficially placed. They are covered by an adherent fascial layer, which, above, is attached to the clavicle and to the spine of the scapula. Ventrally it is continued over and fuses with the fascia covering the pectoralis major, serratus anterior, and external oblique muscles. On the back it extends as a thin sheet between the dorsal margin of the deltoid and the upper margin of the latissimus dorsi, and is continued dorsally into the fascial investment of the rhomboid muscles. The lateral fascial extension of the trapezius becomes fused to the dorsal surface of this sheet. Toward the armpit the fascial investment of the deltoid and latissimus dorsi muscles is continued into the axillary fascia, and on the back of the arm it is continued into the fascial investment of the triceps.

The supraspinatus muscle lies beneath the trapezius. It is covered by a dense adherent fascial layer which is separated from the trapezius by loose connective tissue which usually contains a considerable amount of fat.

The infraspinatus and the two teres muscles lie beneath the musculo-fascial layer composed of the deltoid, the latissimus dorsi, and the fascial sheet described above. Each of the three muscles has a special fascial investment which is bound to the scapula about the region of attachment of the muscle to the bone. Where two of the muscles adjoin, their fasciæ gives rise to intermuscular septa. Septa of this nature are found between the infraspinatus and each of the teres muscles, and between the teres minor and the teres major. The intermuscular septum between the infraspinatns and teres minor muscles is often incomplete. The fascia covering the teres major is so delicate as hardly to deserve the name, except near the origin of the muscle. Near the spine the fascia covering the deep surface of the deltoid is often fused to that covering the infraspinatus.

The subscapularis muscle is invested by a moderately dense fascia which is bound to the scapula along the periphery of the attachment of the muscle. For a short distance this fascia is fused with the fascial investment of the teres major near the origin of the latter muscle, so that an intermuscular septum is formed. From the ventro-lateral margin of the fascia covering the subscapularis muscle a sheet of fascia is continued below the axillary fascia into the fascia covering the serratus anterior (magnus).

MUSCLES

The **deltoideus** (figs. 355, 356, 360).—*Origin.*—Fleshy from the lateral border and upper surface of the acromion and from the ventral border and upper surface of the lateral third of the clavicle, and tendinous from the spine of the scapula. Some fibre-bundles also at times arise from the deep fascia of the muscle where it overlies and is fused to the fascia of the infraspinatus muscle near the spine.

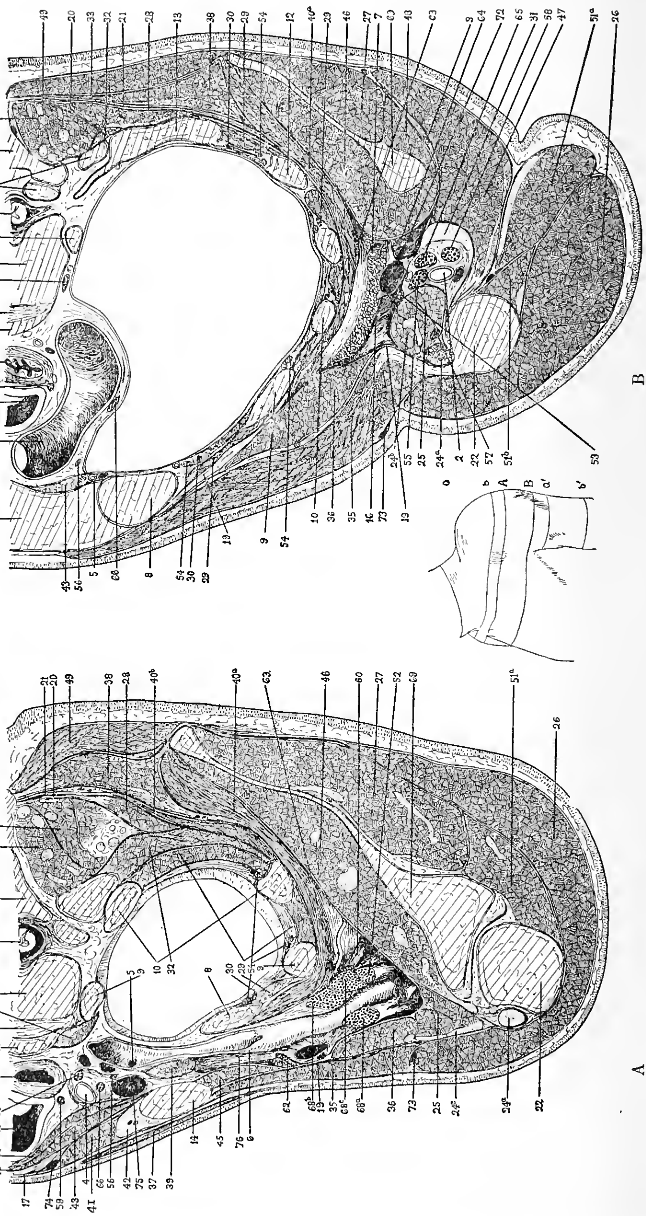
Insertion.—Into the deltoid tuberosity of the humerus by a strong tendon arising from numerous tendinous bands within the muscle (fig. 364).

Structure.—In structure the deltoid muscle is complex. Three portions may be recognised:—a clavicular, an acromial, and a spinous. The first and last are composed of long fibre-bundles which take a slightly converging course and are inserted by aponeurotic tendons respectively on the front and back of the V-shaped area of insertion of the muscle. The acromial portion, on the other hand, is multipenniform in composition. Four or five tendinous expansions descend into the muscle from the acromion, and three up into the muscle from the tendon of insertion. From the acromion and from the descending tendinous processes fibre-bundles run to be inserted on the sides of the ascending processes and into the tendons of insertion of the clavicular and spinous portions of the muscle.

Nerve-supply.—The axillary (circumflex) nerve passes across the costal surface of the muscle near the tendon of insertion and gives off rami which enter lateral to the middle of the muscle. The nerve fibres are derived from the (fourth), fifth, and sixth cervical nerves.

Action.—When the whole muscle contracts, the arm is abducted (raised laterally) to a

Fig. 357



horizontal position. When the clavicular and acromial parts act, the arm is raised and flexed (brought forward toward the chest). When the acromial and spinous parts act, the arm is raised and extended (carried toward the back), but in this instance the arm is not brought to a level with the shoulder-joint, but only about 45° from the hanging position. The inferior part of the serratus anterior and the trapezius act in conjunction with the deltoid in abduction. Abduction is greatest when the arm is rotated lateralward. The ventral portion rotates the arm medially, the dorsal portion laterally. When the arm is fixed, the deltoid tends to carry the inferior angle of the scapula toward the spinal column and away from the thorax.

Relations.—On its ventral border the deltoid is in contact with the pectoralis major muscle. Near the clavicle the cephalic vein and a small artery pass between the two muscles. Its dorsal border is continued into a dense fascial sheet which overlies the infraspinatus muscle. Its tendon of insertion passes between the biceps and triceps muscles. The deltoid overlies the coracoid process and upper extremity of the humerus, the coraco-clavicular and coraco-acromial ligaments, and the insertions of the supraspinatus, infraspinatus, and teres minor muscles, the origins of the biceps and coraco-brachialis, and a part of the long and lateral heads of the triceps. Beneath it run the posterior circumflex artery and axillary (circumflex) nerve.

Variations.—The clavicular portion is frequently separate from the rest of the muscle. The three portions may be distinctly separate—a condition normal in some of the lower mammals. The clavicular and acromial portions have been found missing. The deep portion of the muscle may be separated as a distinct layer and inserted either into the capsule of the joint or into the humerus. Accessory fasciculi may pass into the muscle from the fascia over the infraspinatus and from the vertebral and axillary borders of the scapula. Not infrequently fasciculi are continued into the muscle from the trapezius—a condition normal in animals with ill-developed clavicles. An accessory tendon of insertion may extend to the radial side of the forearm. Bundles of fibres from the axillary border of the scapula have been seen to cross the deep surface of the deltoid and be inserted into the deltoid fascia. The deltoid may be fused with neighbouring muscles, the pectoralis major, trapezius, infraspinatus, brachialis, brachio-radialis.

The teres minor (fig. 363).—*Origin.*—From the upper two-thirds of the axillary border of the infraspinous fossa, and from the septa lying between it and the infraspinatus on the one side and the teres major and subscapularis on the other. The origin is in part fleshy, in part from an aponeurotic band on its ventral surface toward the subscapularis muscle.

Structure and insertion.—The fibre-bundles from this origin take a slightly converging course toward a tendon of insertion which extends for some distance on the dorsal surface of the muscle. The muscle is adherent to the capsule of the joint, and terminates on the inferior of the three facets of the great tubercle of the humerus and the postero-lateral aspect of that bone for two or three centimetres below the facet.

Nerve-supply.—From a branch of the axillary (circumflex) nerve which enters the muscle on its lateral margin about midway between its extremities. A 'ganglion' is usually found upon this nerve. A branch from the nerve to the teres major has also been reported. The nerve fibres are derived from the fifth cervical nerve.

Action.—It acts conjointly with the infraspinatus to rotate the arm laterally. It is a flexor when the arm is down and an extensor when it is abducted. It is also an adductor.

Relations.—The muscle is in part covered by the deltoid. Ventrally it enters into relations with the long head of the triceps, the teres major, and the subscapularis. Superiorly, the circumflex (dorsal) scapular vessels run between it and the axillary border of the scapula.

Fig. 357. A and B.—Transverse Sections through the Left Shoulder in the Regions indicated in the Diagram.

In the neighbourhood of the brachial plexus in each section some of the adipose and lymphatic tissue has been removed. In section B the fascia covering the apex of the axillary fossa is thus revealed from above. *a* and *b* in the diagram indicate the regions through which pass sections A and B, fig. 351 (p. 352); *a'* and *b'*, the regions through which pass sections A and B, fig. 362 (p. 375).

Vertebra III. 80. Vertebra IV. 81. Vertebra V. 82. Vertebra VI.

Variations.—Aside from its frequent fusion with the infraspinatus, there has also been reported an isolation of a special fasciculus to the subtubercular attachment.

The **infraspinatus** (fig. 363).—*Origin.*—From the vertebral three-fourths of the infraspinous fossa, from the under surface of the spine, from the enveloping fascia and from intermuscular septa between it and the two teres muscles.

Structure and insertion.—The fibre-bundles converge toward the lateral angle of the scapula to be attached to a deep-seated tendon which is adherent to the capsule of the joint and is attached to the middle facet of the great tubercle. The fibre-bundles arising from the inferior surface of the spine and the fascia near this form a distinct fasciculus which descends on and covers the tendon of insertion.

Nerve-supply.—From the suprascapular nerve, which passes beneath the supraspinatus muscle and enters the deep surface of the infraspinatus in the lateral part of the midde third of its upper margin. From here rami spread out toward the vertebral border of the muscle and toward the humeral insertion. The nerve fibres are derived from the fifth and sixth cervical nerves.

Action.—This muscle is the chief lateral rotator of the arm, a movement that can be carried through 90°. The upper part of the muscle is an abductor, the lower part an adductor of the arm. The muscle is also a flexor.

Relations.—The deltoid and trapezius, and sometimes the latissimus dorsi muscles, cover a portion of the dorsal surface. Over most of it extends the complex fascia described above. Laterally it adjoins the teres minor and major muscles. Under the muscle lie the transverse (suprascapular) and circumflex (dorsal) scapular vessels.

Variations.—These are rare, aside from a greater or less independence of the bundles arising from the spine and a greater or less complete fusion with the teres minor. A fasciculus has been seen extending to the muscle from the deltoid.

The **supraspinatus** (fig. 363).—*Origin.*—Fleshy from the medial two-thirds of the supraspinous fossa and from the deep surface of the enveloping fascia near the vertebral end.

Structure and insertion.—The fibre-bundles converge upon a deep-seated tendon nearly to its attachment into the highest of the three facets on the great tubercle of the humerus.

Nerve-supply.—Two branches from the suprascapular nerve enter the middle third of the deep surface of the muscle. The nerve fibres are derived from the fifth cervical nerve.

Action.—It aids the deltoid in abducting the arm. It is also a weak lateral rotator and flexor. It keeps the head of the humerus in place during abduction of the arm.

Relations.—The muscle is covered by the trapezius, the acromion, and the coraco-acromial ligament. Beyond the base of the spine of the scapula it comes into contact with the infraspinatus muscle. Beneath the muscle pass the suprascapular nerve and transverse scapular (suprascapular) vessels.

Variations.—The muscle shows slight variations. Its tendon may be fused with that of the infraspinatus. Its belly may be reinforced by fibre-bundles from the coraco-acromial ligament.

The **latissimus dorsi** (figs. 355, 356, 387, 388).—*Origin.*—(1) From an aponeurosis attached to the spines and interspinous ligaments of the five or six last thoracic and the upper lumbar vertebræ, to the lumbo-dorsal fascia, and to the posterior third of the external lip of the crest of the ilium; (2) from the external surface and upper margin of the last three or four ribs by muscular slips which interdigitate with those of the external oblique. In the lumbar region the aponeuroses of the right and left muscles are connected by fibrous fasciculi which cross the mid-dorsal line above the supraspinous ligament.

Structure and insertion.—From this extensive area of the origin fibre-bundles converge toward the tendon of insertion. In the region of the dorsal wall of the axillary fossa the muscle is concentrated into a thick, ribbon-like band which winds about the teres major and passes to the ventral surface of that muscle. As this takes place the fibre-bundles become applied to each surface of a flat tendon, which, after emerging from the muscle, is six to eight cm. long and three to five cm. broad, and is inserted into the ventral side of the crest of the lesser tubercle of the humerus and into the depth of the intertubercular (bicipital) groove immediately ventral to the tendon of the teres major. With this it is more or less closely bound, although between the tendons there lies a serous bursa. Some of the fasciculi of the tendon extend to the crest of the greater tubercle. Frequently a tendon slip passes from the inferior margin of the tendon to the tendon on the posterior surface of the long head of the triceps or into the brachial fascia (see *latissimo-condyloideus*, p. 379).

Like the teres major, with which it is closely associated, the latissimus dorsi muscle undergoes a torsion between its origin and its insertion, so that the dorsal surface of the muscle is continued into the ventral surface of the tendon and the most cranially situated of the fibre-bundles are most distally attached to the humerus, and *vice versa*. The muscle either directly or through its fascial extension is often adherent to the inferior angle of the scapula.

Nerve-supply.—From the dorsal thoracic (long subscapular) nerve (from the sixth, seventh and eighth cervical nerves). This nerve, which may arise in conjunction with the axillary nerve, passes to the deep surface of the muscle in the lower part of the axilla, and here gives rise to rami which diverge as the muscle expands toward its tendons of origin. Though soon embedded in the muscle substance, two main branches may be followed for a considerable distance near the deep surface of the muscle. One usually extends near the lateral, the other near the superior, border of the muscle, and from these large rami pass into the intervening region. Branches of the dorsal thoracic artery and vein accompany the nerve.

Action.—With the trunk fixed, the latissimus dorsi draws the raised arm down and backward and rotates it medialward (swimming movement). When the arm is hanging by the side, the action of the muscle is on the scapula. The upper third of the muscle draws the scapula toward the spine, the inferior two-thirds depress the shoulder. When the humerus is fixed, the latissimus serves to lift the trunk and pelvis forward, as in climbing. It also aids in forced inspiration through its costal attachments.

Relations.—The trapezius covers a small portion of the muscle in the mid-thoracic region of the back. Over a large area it is subcutaneous, and its fascial investment is adherent to the skin. As it winds about the teres major its tendon comes to lie behind the coraco-brachialis muscle. The main nerves and vessels of the arm here pass across its ventral surface. The muscle covers in part the rhomboideus major, the infraspinatus, teres major, serratus posterior inferior, the lower ribs, the external intercostal muscles, the dorsal border of the external and internal oblique muscles, and the lower dorsal part of the serratus anterior (magnus).

Variations.—It may show considerable variation in the extent of its fleshy portion and in the attachment of its aponeurosis to the vertebral column, crest of the ilium, the ribs, and the scapula. Its origin may be merely from the ribs. It may be divided into separate fasciculi. Frequently a fasciculus arises from the inferior angle of the scapula. The muscle is often intimately united to the teres major. For an account of the muscular slip which extends from the latissimus dorsi across the axillary fossa to the tendon of the pectoralis major near the intertubercular (bicipital) groove see the latter muscle (p. 374); and for the slip continued from the tendon of the latissimus dorsi to the olecranon see the TRICEPS MUSCLE (p. 379).

The **teres major** (figs. 356, 388).—*Origin.*—Directly from the dorsal surface of the inferior angle of the scapula and from the septa which lie between this muscle and the subscapularis, teres minor, and infraspinatus muscles.

Insertion.—For about five or six cm. from the lower border of the small tubercle of the humerus, along the medial lip of the intertubercular (bicipital) groove. Proximally the fibre-bundles are attached directly to the tubercle; more distally the attachment is by means of a flat tendon which extends for some distance on the dorsal surface of the muscle.

Structure.—The nearly parallel fibre-bundles pass upward in a spiral direction so that the muscle undergoes a torsion on its axis. The fibre-bundles which have the highest attachment to the scapula have the lowest humeral attachment, and *vice versa.*

Nerve-supply.—By a branch of the lower subscapular nerve which enters the muscle near the middle of its scapular border. The nerve fibres are derived from the fifth, sixth (and seventh) cervical nerves.

Action.—It aids the latissimus dorsi in adducting the arm, and in some positions of the arm acts as a medial rotator and as an extensor.

Relations.—Dorsally the muscle is covered by the latissimus dorsi and by the fascia which extends from this muscle to the deltoid and rhomboid muscles. It is also crossed by the long head of the triceps. Its lower border and ventral surface are largely covered by the latissimus dorsi and its tendon. Its upper border helps to bound a triangular space the other sides of which are the borders of the scapula and the humerus. In front lies the subscapularis, and behind, the teres minor. Across this space passes the long head of the triceps. Lateral to this head lie the humeral circumflex vessels and axillary (circumflex) nerve; and medial, the circumflex (dorsal) scapular artery.

Variations.—The teres major may be connected with the latissimus dorsi by a fasciculus, or it may be fused with that muscle or its tendon. Slips have also been seen extending to the triceps and into the fascia of the arm. The muscle is rarely absent.

The **subscapularis** (figs. 356, 388).—*Origin.*—The fibre-bundles spring—(1) directly and by means of tendinous bands from the costal surface of the scapula, except near the neck and at the upper and lower angles; and (2) from intermuscular septa between it and the teres major and teres minor muscles.

Insertion.—The tendon of insertion as it passes over the capsule of the joint is intimately bound to this. It is inserted into the lesser tubercle of the humerus and into the shaft immediately below this.

Structure.—The fibre-bundles arising from the tendinous bands attached to the bone converge upon several tendinous laminæ which extend into the muscle from the tendon of insertion, thus forming small penniform fasciculi. The fibre-bundles arising directly from the bone converge toward the extremities of the tendinous laminæ, thus forming triangular bundles interdigitating with the penniform fasciculi. The fasciculus which arises highest on the axillary border goes directly to the humerus.

Nerve-supply.—By two or three subscapular branches from the back of the brachial plexus. One or more of these may arise in association with the axillary (circumflex) nerve. From the main nerves rami spread out to enter the ventral surface of the muscle near the junction of the lateral and middle thirds. The nerve fibres come from the fifth and sixth cervical nerves.

Action.—It is the chief medial rotator of the arm. It strengthens the shoulder-joint by drawing the humerus against the glenoid cavity. It is an extensor when the arm is at the side, a flexor when the arm is abducted. The upper portion of the muscle, however, acts as a flexor in both positions. The upper part acts as an abductor but when the arm is abducted the muscle is an adductor.

Relations.—Ventrally it forms the greater part of the posterior wall of the axillary fossa, and enters into relation with the serratus anterior (magnus) and the combined tendon of the coraco-brachialis and biceps. On it lie the axillary vessels, the brachial plexus, and numerous lymph-vessels and glands. At its lateral border lie the teres major, the humeral circumflex vessels, axillary (circumflex) nerve, and circumflex (dorsal) scapular vessels. Behind it lie the long head of the triceps and the teres minor muscle.

Variations.—It may be divided into several distinct segments. A fasciculus may be sent to the tendon of the latissimus dorsi and another to the brachial fascia. The **subscapularis minor** arises from the axillary border of the scapula and is inserted into the articular capsule (capsular ligament) of the shoulder-joint or into the crest of the lesser tubercle of the humerus.

BURSÆ

B. subacromialis.—A large bursa, nearly constantly found, between the acromion and coraco-acromial ligament and the insertion of the supraspinatus muscle and capsule of the joint.

Processes extend over the greater and lesser tubercles.

B. supracoracoidea.—A bursa sometimes found between the coracoid process and the clavicle and the deltoid muscle.

B. m. subscapularis.—Between the glenoid border of the scapula and the subscapularis muscle. Communicates with the joint cavity. A small portion of this bursa may be isolated adjacent to the base of the coracoid process (*b. subcoracoidea*).

B. m. infraspinati.—Between the tendon of the infraspinatus and the capsule of the joint or the great tubercle.

B. m. latissimi dorsi.—Constant between the tendons of the latissimus dorsi and the teres major.

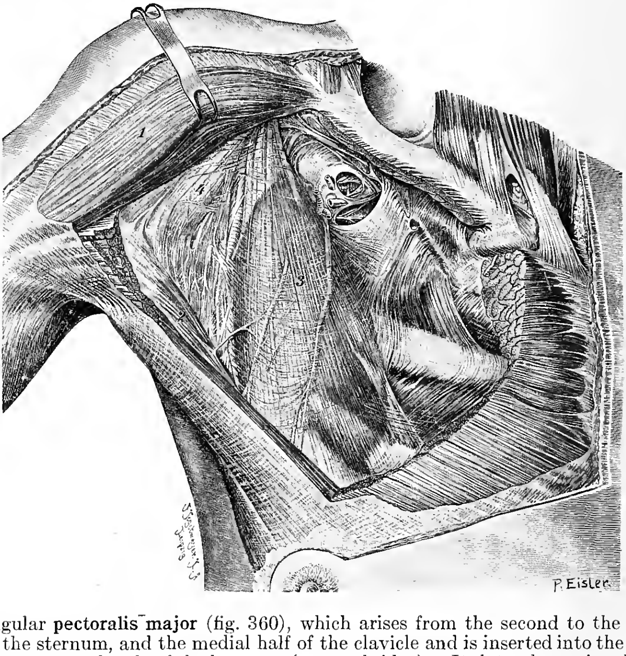
B. m. teretis majoris.—Under the insertion of the tendon of the teres major muscle.

B. PECTORAL MUSCLES AND AXILLARY FASCIA

(Figs. 357, 358, 360, 361, 388)

The muscles belonging to this group are the pectoralis major, pectoralis minor, and the subclavius. Of these, the largest and most superficial is the

Fig. 358.—Deep Fascia of the Breast. (After Eisler). The Pectoralis Major Has Been in Large Part Removed. 1, Deltoid; 2, Pectoralis Major, Abdominal Part; 3, Pectoralis Minor; 4, Coraco-Brachialis.



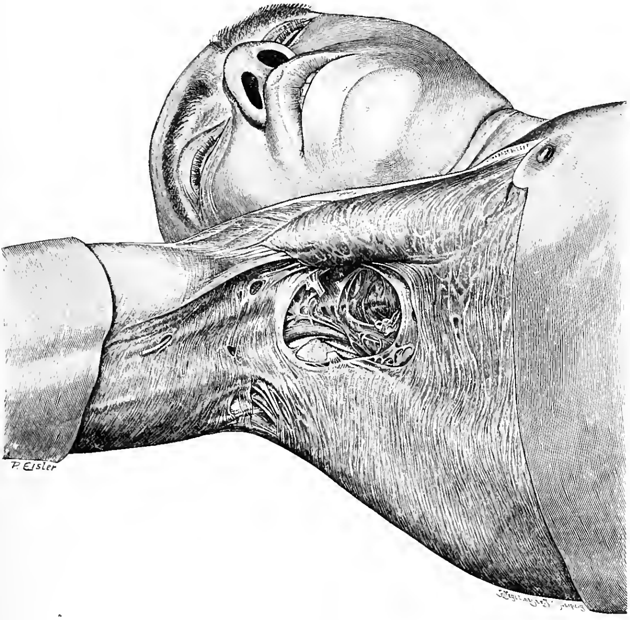
triangular **pectoralis major** (fig. 360), which arises from the second to the sixth ribs, the sternum, and the medial half of the clavicle and is inserted into the crest of the greater tubercle of the humerus (pectoral ridge). Its lateral margin adjoins the ventral margin of the deltoid. Beneath this muscle the much smaller triangular **pectoralis minor** (fig. 388) extends from near the ends of the second, third, fourth, and fifth ribs to the tip of the coracoid process, while the small **subclavius** (fig. 361) extends from the first rib upward and lateralward to the clavicle.

The pectoral muscles and the subclavius play a part in forced inspiration. The pectoralis major also serves to adduct and flex the arm and rotate it medialward.

Of the muscles included in this group, the two pectoral muscles are morphologically the most closely related. They receive a nerve-supply from the same set of nerves, the anterior thoracic With them the subclavius, which has a separate nerve of its own, is closely associated. Corresponding musculature, although variously modified in different forms, is found throughout the vertebrate series. In the lower forms it seems to be differentiated directly from the segmental trunk musculature and secondarily attached to the shoulder girdle, like the superficial and deep musculature of the shoulder girdle previously described. In man, however, the muscle mass from which these muscles arise is at all times in intimate union with the skeleton of the upper limb, and the nerves which supply it are in much more intimate union with the brachial plexus than are those of the shoulder-girdle muscles. For these reasons the three muscles are classed with the intrinsic muscles of the arm. They have no certain representatives in the lower limb, although the clavicular portion of the pectoralis major is considered by some to represent certain adductor muscles of the thigh. Possibly they correspond in their embryonic origin with the obturator internus group of the lower limb.

In many of the mammals a subcutaneous muscle arises from the pectoral muscle mass and extends over the axilla and the trunk. In man this musculature is frequently represented by abnormal slips of muscles, of which the 'axillary arch' and possibly the 'sternalis' are representatives. A list of some of the abnormal muscles which are innervated from the anterior thoracic nerves and are evidently derivatives of the pectoral muscle mass is given at the end of this section

Fig. 359.—(After Eisler). Fascia of the Axillary Fossa.



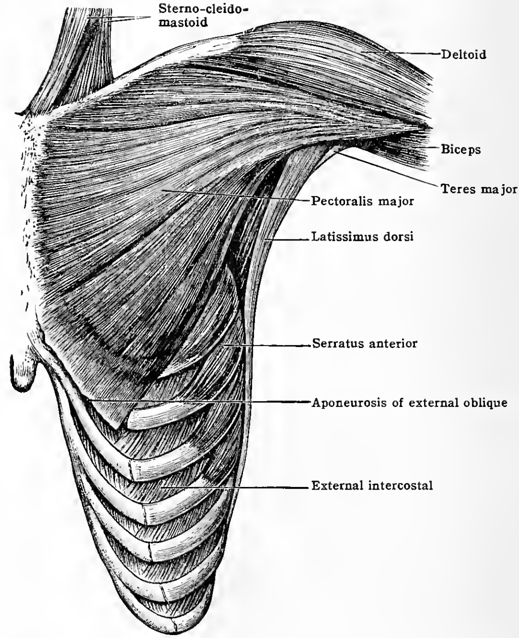
FASCIÆ

In the **tela subcutanea** of the pectoral region the mammary gland is embedded between two layers which eusheath the gland and are connected by dense fibre-bands. To a greater or less extent the platysma extends into the tela of this region from above the clavicle.

Muscle fasciæ.—The pectoralis major is invested with a thin, adherent membrane, **fascia pectoralis,** attached to the clavicle and the sternum and continued into the fascial investment of the external oblique, the serratus anterior (magnus), and the deltoid muscles, and in to the axillary fascia. More important is the **coraco-clavicular (costo-coracoid) fascia** fig. 358. This arises from two fascial sheets which invest the subclavius muscle and are attached to the clavicle. From the inferior margin of this muscle the membrane is continued to the superior margin of the pectoralis minor. Between the coracoid process and the first costal cartilage it is strengthened to form the **costo-coracoid ligament.** Between this and the pectoralis minor it is thin. At the superior margin of this muscle it again divides to form two adherent fascial sheets, which, at the axillary margin of the muscle, once more unite to form a firm membrane continued into the fascial investment of the coraco-brachialis and short head of the biceps and into the axillary fascia. Above, dorsally, the membrane is adherent to the sheath of the axillary vessels and nerves.

Axillary fascia (fig. 359).—The arm-pit, or **axillary fossa,** is a pyramidal space bounded by the pectoralis major and minor and coraco-brachialis muscles in front; by the latissimus dorsi, teres major, and subscapularis muscles behind; by the subscapularis muscle toward the joint; and by the serratus anterior (magnus) toward the thoracic wall. In the groove between the coraco-brachialis and the subscapularis and tendons of the latissimus dorsi and teres major muscles run the main nerves and vessels of the arm. These are surrounded by a considerable amount of connective tissue in which numerous blood- and lymph-vessels, lymph-nodes, nerves, and masses of fat are embedded.

Fig. 360.—The Pectoralis Major and Deltoid.



Over this connective tissue the fascia covering the musculature of the neighbouring portion of the shoulder and thorax is continued into the fascia covering the musculature of the medial side of the arm. Thus the fascia covering the pectoralis minor, the coraco-clavicular fascia, strengthened by a reflection of the fascial investment of the pectoralis major and deltoid muscles is continued across the ventral margin of the arm-pit into the fascia which covers the coraco-brachialis and biceps muscles in the arm. Similarly, dorsally, the fascia covering the latissimus dorsi and teres major is continued over the arm-pit into that covering the long head of the triceps in the arm. The ventral is connected with the dorsal fascia by a thin membrane which is adherent to the connective tissue filling the axillary space and to the subcutaneous tissue. On the trunk this membrane, the **fascia axillaris,** becomes fused below the axillary fossa with the fascia of the serratus anterior (magnus). In the arm it becomes fused with the fascia over the biceps muscle. Owing to its adherence to the skin and the connective tissue of the axillary fossa, investigators have dissected out and figured the axillary fascia in different ways.

MUSCLES

The **pectoralis major** (fig. 360).—*Origin.*—(1) From the medial half of the clavicle; (2) from the side and front of the sternum as far as the sixth costal cartilage; (3) from the front of the cartilages of the second to the sixth ribs; and (4) from the upper part of the aponeurosis of the external oblique where this extends over the rectus abdominis muscle. The costal origin may in part take place from the osseous extremities of the sixth and seventh ribs.

Insertion.—Crest of the greater tubercle (outer lip of the bicipital groove) of the humerus from the tubercle to the insertion of the deltoid (fig. 174). Some of the tendon fibres are also continued into the tendon of the deltoid and adjacent fibrous septa and into the fibrous lining of the intertubercular sulcus.

Structure.—The muscle is divisible into a series of overlapping layers spread out like a fan. Of these, the clavicular portion forms the most cranial and superficial layer, and the portion of the muscle springing from the aponeurosis of the external oblique, the most caudal and deepest layer. This last layer has a special tendon, while the other layers are inserted into a combined tendon lying ventral to this. The two tendons are continuous at their distal margins. (W. H. Lewis.)

Nerve-supply.—From the external and internal anterior thoracic nerves, branches of which enter the sterno-costal portion of the muscle about midway between the tendons of origin and insertion, and the clavicular portion in the proximal third. The nerve fibres are derived from the (fifth), sixth, seventh and eighth cervical and first thoracic nerves.

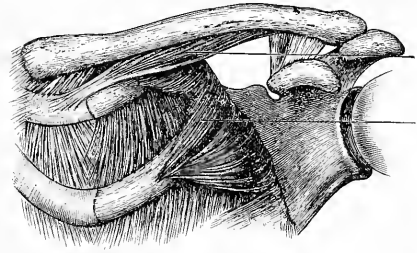
Action.—With the thorax fixed, the muscle adducts and flexes the arm and rotates it medialward. The clavicular portion draws the arm forward, upward, and medialward; the sterno-costal portion draws the arm downward, medialward, and forward. When the arm is pendent, the upper portion elevates, the lower depresses, the shoulder. With the arm fixed, the muscle draws the chest upward toward it. It is of value in forced inspiration.

Relations.—It lies over the coracoid process, the subclavius, pectoralis minor, intercostal, and serratus anterior (magnus) muscles, the coraco-clavicular (costo-coracoid) fascia, and the thoraco-acromial vessels. It forms the main part of the ventral wall of the axillary fossa, and laterally it enters into relation with the deltoid, biceps, and coraco-brachialis muscles.

Variations.—In considering variations the muscle may be looked upon as composed of four portions—a clavicular, a sternal, a costal, and an abdominal, the last being that portion which arises from the aponeurosis of the external oblique. These portions vary in the extent of their attachments and in the degree of separation which they present. The abdominal portion may extend to the umbilicus. Huntington considers this portion a derivative of the pannicular muscle of the lower mammals. On the sternum the muscles of the two sides may decussate across the middle line. The sterno-costal portions of the muscle are more frequently deficient or missing than the clavicular, but in rare cases the entire muscle is absent. The clavicular portion of the muscle may be fused with the deltoid. The sterno-costal may extend laterally to the latissimus dorsi. There may be an intimate fusion of the abdominal portion with the rectus abdominis or the external oblique. Sometimes a slip may run from the pectoralis major to the biceps, the pectoralis minor, coracoid process, capsule of the joint, or brachial fascia.

The **pectoralis minor** (fig. 388).—*Origin.*—By aponeurotic slips from the second, third, fourth, and fifth ribs near the costal cartilages.

Fig. 361.—The Subclavius and the Upper Portion of the Serratus Anterior.



Structure and insertion.—The fibre-bundles converge upward and outward to a flattened tendon which is attached to the medial border and upper surface of the coracoid process of the scapula.

Nerve-supply.—From the internal anterior thoracic nerve which enters the upper part of the middle third of the deep surface by several branches. Some of the branches extend through to the pectoralis major. The nerve fibres arise from the seventh and eighth cervical nerves.

Action.—When the thorax is fixed, the pectoralis minor pulls the scapula forward, the lateral angle of the bone downward, and the inferior angle dorsalward and upward. When the scapula is fixed, the muscle aids in forced inspiration.

Relations.—It is covered by the pectoralis major. Near its insertion the fibrous investment of the chief nerves and vessels of the arm is adherent to its enveloping fascia.

Variations.—The origin may extend to the sixth rib or may be reduced to one or two ribs. In the primates below man the insertion of the muscle takes place normally into the humerus. In man its insertion may be continued (in more than 15 per cent. of bodies—Wood) over the coracoid process to the coraco-acromial or coraco-humeral ligaments, to the tendon of the subscapularis muscle, or to the great tubercle of the humerus. It may be divided into two superimposed fasciculi. Fasciculi may extend from the muscle to the subclavius or the pectoralis major.

The **subclavius** (fig. 361).—*Origin.*—From a flat tendon attached to the first rib and its cartilage near their junction.

Structure and insertion.—The fibre-bundles arise in a penniform manner from the tendon of origin which extends for some distance along the lower border of the muscle. They are inserted in a groove which lies on the lower surface of the clavicle between the costal tuberosity and the coracoid tuberosity. The medial fibre-bundles are inserted directly, the lateral by a strong tendon.

Nerve-supply.—By a branch which arises usually from the fifth or fifth and sixth cervical nerves and enters the middle of the back part of the muscle.

Action.—When the first rib is fixed, the subclavius depresses the clavicle and the point of the shoulder. When the clavicle is fixed, the muscle aids in forced inspiration. It also serves to keep the clavicle against the sternum.

Relations.—It is concealed by the clavicle and pectoralis major muscle. Behind it lie the subclavian vessels and the brachial plexus.

Variations.—It may be replaced by a ligament or by a pectoralis minimus muscle (see below). It may be doubled or may be inserted into the coracoid process, coraco-acromial ligament, the acromion, or the humerus. The *subclavius posticus* arises near the subclavius, passes backward over the subclavian vessels and brachial plexus and is inserted into the cranial margin of the scapula near the base of the coracoid process.

Abnormal Muscles of the Pectoral Group

The following muscles are usually innervated by the anterior thoracic nerves and are probably generally abnormal derivatives of the pectoral mass. Frequently they represent muscles normally found in lower mammals.

The **sternalis.**—A flat muscle somewhat frequently seen on the surface of the pectoralis major, usually nearly parallel to the sternum. It arises from the sheath of the rectus and from some of the costal cartilages (third to seventh) and terminates on the sterno-cleido-mastoid, on the sternum, or on the fascia covering the pectoralis major. When present on both sides, the two muscles may be fused across the sternum. This muscle is found in 4 per cent. of normal individuals and 48 per cent. of anencephalic monsters. (Eisler.) Rarely, corresponding muscle slips have been found innervated by the intercostal nerves. These probably represent remains of a thoracic 'rectus' muscle.

The **pectoro-dorsalis (axillary arch).**—This muscle in its most complete form extends from the tendon of the pectoralis major over the axillary fossa to the tendon of the latissimus dorsi, to the fascia covering the latissimus dorsi, to the teres major or even more distally. It may, however, be more or less fused with either of the last two muscles mentioned, and it presents a great variety of forms. It may extend from the latissimus dorsi to the brachial fascia over the coraco-brachialis or biceps, to the long tendon of the biceps, to the axillary fascia, to the axillary margin of the pectoralis minor, or to the coracoid process, etc. It is found in about 7 per cent. of bodies. (Le Double.) When supplied from the anterior thoracic nerves, it probably represents a portion of the thoraco-humeral subcutaneous (pannicular) muscle of the lower primates. It is also sometimes supplied by the medial brachial cutaneous or the intercosto-brachial (humeral) nerve and frequently is partly or wholly supplied by the dorsal thoracic (long subscapular) nerve. The part of the muscle supplied by the dorsal thoracic nerve is probably derived from the latissimus dorsi musculature.

The **costo-coracoideus.**—A muscular slip which arises from one or more ribs or from the aponeurosis of the external oblique between the pectoralis major and latissimus dorsi muscles, and is inserted in the coracoid process.

The **chondro-humeralis** (epitrochlearis).—This is a slip which springs from one or two rib cartilages or from the thoraco-abdominal fascia beneath the pectoralis major, or from its lower border or tendon, and extends on the medial side of the arm to the intertubercular (bicipital) groove, the brachial fascia, the intermuscular septum, or the medial epicondyle. It is found in 12 to 20 per cent. of bodies (Le Double), and occurs normally in many of the lower mammals.

The **pectoralis minimus (sterno-chondro-scapularis).**—From the cartilage of the first rib and sternum to the coracoid process.

The **sterno-clavicularis.**—From the manubrium of the sternum to the clavicle between the pectoralis major and the coraco-clavicular (costo-coracoid) fascia. In 2 per cent. to 3 per cent of bodies. (Gruber.)

The **scapulo-clavicularis.**—From the coracoid process of the scapula to the outer third of the clavicle.

The **infra-clavicularis.**—From above the clavicular part of the pectoralis major to the fascia over the deltoid.

Bursæ

B. m. pectoralis majoris.—Between the tendon of insertion of the pectoralis major and the long head of the biceps. Frequent.

C. MUSCULATURE OF THE ARM

(Figs. 355, 356, 362, 363, 364, 365, 367, 370, 372)

The muscles included in this section are the triceps and anconeus, coraco-brachialis, biceps, and brachialis. The *triceps* and *anconeus* (fig. 363) constitute a mass of musculature extending along the back of the arm from the scapula and humerus to the olecranon of the ulna. The *coraco-brachialis, biceps,* and *brachialis* (figs. 364, 365) constitute a similar mass of musculature extending along the front of the arm from the scapula and the humerus to the humerus, and to the radius and ulna near the elbow. In the upper half of the arm the two groups are separated on the lateral side of the arm by the deltoid, pectoralis major, teres minor, supra- and infraspinatus muscles, and by the greater tubercle of the humerus. On the medial side they are separated the by chief nerves and blood-

vessels of the arm and by the tendons of the latissimus dorsi, teres major, and subscapularis muscles. In the distal half of the arm they are separated medially by the medial intermuscular septum (described below) and by the medial epicondyle and the ulno-volar group of muscles of the forearm. On the lateral side of the arm they are separated by the lateral intermuscular septum, by the lateral epicondyle, and by the brachio-radialis and the extensor muscles of the forearm which take origin from the lateral epicondyle.

FASCIÆ

The **fasciæ** and the general relations of the muscles of the arm are shown in the cross-sections in fig. 362.

The **tela subcutanea** of the arm is fairly well developed and contains a considerable amount of fat, especially near the shoulder. It is but loosely bound to the muscle fascia, except near the insertion of the deltoid, where the union may be more intimate.

Bursæ.—B. subcutanea epicondyli lateralis.—Between the lateral epicondyle and the skin. Rare. **B. subcutanea epicondyli medialis.**—Between the medial epicondyle and the skin. Inconstant. **B. subcutanea olecrani.**—Between the olecranon process of the ulna and the skin. Nearly constant.

The **brachial fascia** forms a cylindrical sheath about the muscles of the arm. It contains circular and longitudinal fibres, the former being the better developed. The fascia is strong over the dorsal muscles, especially near the two epicondyles of the humerus. Proximally the fascia of the arm is continued into the axillary fascia and into the fascial investment of the pectoralis major, deltoid, and latissimus dorsi muscles; distally it is continued into the fascial investment of the forearm. It is intimately bound to the epicondyles and to the dorsal surface of the olecranon. It is separated by loose areolar tissue from the bellies of the muscles which it covers. From the tendons of the deltoid, pectoralis major, teres major, and latissimus dorsi muscles, however, fibrous bundles are continued into the brachial fascia. There are a number of orifices in the fascia for the passage of nerves and blood-vessels. Of these, the largest is that for the basilic vein and two or three large branches of the medial antibrachial (internal) cutaneous nerve. This lies on the ulnar margin of the arm in the lower third. On the radial margin lie the cephalic vein in a double fold of the fascia, orifices for branches of the musculo-cutaneous nerve, and more dorsally orifices for branches of the radial. From the fascia septa descend between the muscles which it invests. Of these septa, the most important are the medial and lateral intermuscular septa, which separate the dorsal group of muscles from the ventral in the distal half of the arm. The **medial intermuscular septum** is the stronger. It is attached to the medial epicondyle and to the medial margin of the humerus proximal to this. It is continued proximally into the tendon of insertion of the coraco-brachialis and the investing fascia of this muscle. Into it longitudinal bundles of fibres descend from the tendon. It separates the brachialis and pronator teres muscles from the medial head of the triceps. The **lateral intermuscular septum** is attached to the lateral epicondyle and to the lateral margin of the humerus. It is continued proximally into the dorsal surface of the tendon of insertion of the deltoid muscle, and into the septa between the deltoid and the triceps. It separates the triceps from the brachialis in the third quarter of the arm and from the brachio-radialis and extensor carpi radialis longus in the distal quarter. The median nerve and brachial vessels lie in front of the medial septum. The ulnar nerve and the superior ulnar collateral (inferior profunda) artery are bound to its dorsal surface.

MUSCLES

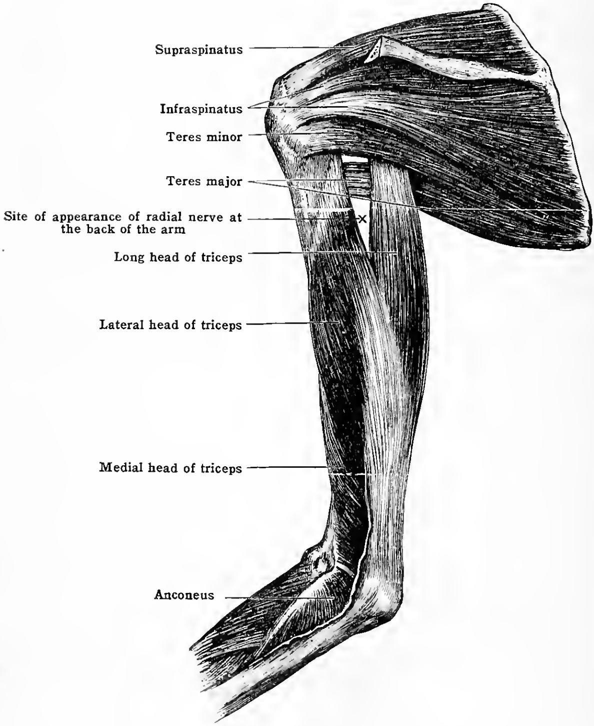
1. Dorsal or Extensor Group

Two muscles are included in this group, the triceps brachii and the anconeus. The **triceps** is a complex muscle in which proximally three heads, a long or scapular, a lateral humeral, and a medial humeral, may be distinguished. The long head arises from the infraglenoid tuberosity of the scapula, the lateral head from the humerus above and laterally to the groove for the radial nerve (musculo-spiral groove), the medial head from the lower half and medial margin of the posterior surface of the humerus. Distally these heads fuse and are inserted by a common tendon into the olecranon of the ulna. The **anconeus** lies chiefly in the forearm, but physiologically and morphologically it belongs with the triceps, and hence is described in connection with the muscles of the arm. It is a triangular muscle, which arises from the lateral epicondyle and is inserted into the olecranon and adjacent part of the shaft of the ulna. Both muscles are supplied by branches of the radial (musculo-spiral) nerve. They extend the forearm. The long head is also an adductor of the arm.

The triceps, variously modified, is found in the amphibia and all higher vertebrates. The anconeus is found in the prosimians and all higher forms. The triceps muscle is homologous with the quadriceps of the thigh. The long head is equivalent to the rectus femoris. The anconeus is not represented in the lower limb.

The **triceps brachii** (figs. 355, 356, 363).—The **long head** *arises* from the infraglenoid tuberosity of the scapula by a strong, broad tendon, some of the fibres of which are connected with the inferior portion of the capsule of the shoulder-joint. The tendon soon divides into two lamellæ, which extend distally, one a short distance on the deep surface, the other much farther

FIG. 363.—DORSAL VIEW OF THE SCAPULAR MUSCLES AND TRICEPS.



on the superficial surface of this head. The parallel fibre-bundles which arise from these lamellæ form a thick muscle-band which twists upon itself so that the ventral surface at the origin becomes dorso-medial at the insertion. At the insertion the long head becomes applied to an aponeurosis which extends upward from the main tendon of insertion of the triceps. The fibre-bundles extend for some distance on the medial side of this tendon and terminate about three-fourths of the way down the arm.

The **lateral head** has a tendinous *origin* from the superior lateral portion of the posterior surface of the humerus along a line extending from the insertion of the teres minor as far as the groove for the radial (musculo-spiral) nerve, and from the aponeurotic arch formed by the lateral intermuscular septum as it crosses this groove. The constituent fibre-bundles descend, the superior vertically, the inferior obliquely, to be inserted on the dorsal and ventral surfaces of the proximo-lateral margin of the common tendon of insertion of the triceps.

The **medial head** has a fleshy *origin* from the posterior surface of the humerus below the radial (musculo-spiral) groove and from the dorsal surfaces of the medial and lateral intermuscular septa. The greater part of the fibre-bundles arising from this extensive area are inserted into the deep surface of the common tendon, but some extend directly to the olecranon and the articular capsule of the elbow. The slip attached to the capsule is sometimes called the **subanconeus** muscle.

Insertion.—The tendon of insertion of the triceps forms a flat band covering the dorsal surface of the distal two-fifths of the muscle. It also extends proximally between the long and lateral heads and on the deep surface of the former. This tendon is inserted into the olecranon and laterally, by a prolongation over the anconeus, into the dorsal fascia of the forearm.

Nerve-supply.—From the radial (musculo-spiral) nerve. The branch to the long head arises in the arm-pit and enters that margin of the muscle which is prolonged down from the lateral edge of the tendon, but which, because of the torsion of the muscle, comes to lie on the medial side. The nerve usually enters through several rami about the middle of the free portion of the long head. Somewhat more distally the radial nerve gives off a branch that enters, by two or three branches, the proximal portion of the medial head. A similar branch is given to the lateral head and other branches are given to the lateral and medial heads from that portion of the radial (musculo-spiral) nerve lying in the radial (musculo-spiral) groove. The nerve fibres arise from the sixth, seventh, and eighth cervical nerves.

Relations.—Near the shoulder the triceps is covered by the deltoid muscle. The long head passes between the teres major and teres minor muscles. The circumflex (dorsal) scapular vessels here pass medial, the circumflex humeral vessels and the axillary (circumflex) nerve lateral, to this head. More distally the muscle lies beneath the brachial fascia. It covers the radial groove of the humerus, in which run the radial (musculo-spiral) nerve and (superior) profunda brachii artery. Ventro-lateral to the muscle lie the deltoid, brachialis, brachio-radialis, and extensor carpi radialis muscles; ventro-medial, the coraco-brachialis, biceps, and brachialis muscles.

Action.—It extends the forearm. The leverage is of such a nature that force is sacrificed for speed of movement. The long head of the triceps also serves to extend and to adduct the arm and to hold the head of the humerus in the glenoid cavity.

Variations.—The scapular attachment may extend for a considerable distance down the axillary border of the scapula. Each of the heads may be more or less fused with neighbouring muscles. Frequently a fourth head is found. This may arise from the humerus, from the axillary margin of the scapula, from the capsule of the shoulder-joint, from the coracoid process, or from the tendon of the latissimus dorsi.

The *latissimo-condyloideus* (dorso-epitrochlearis).—This muscle is found in about 5 per cent. of bodies. When well developed, it extends from the tendon of the latissimus dorsi to the brachial fascia, the triceps muscle, the shaft of the humerus, the lateral epicondyle, the olecranon, or the fascia of the forearm. It is innervated by a branch of the radial (musculo-spiral) nerve. It is a muscle normally present in some one of the forms above mentioned or in some similar form, in a large number of the inferior mammals. In the human body it is normally represented by a fascial slip from the tendon of the latissimus to the long head of the triceps or the brachial fascia.

The **anconeus.**—*Origin.*—By a short narrow tendon from the distal part of the back of the lateral epicondyle and the adjacent part of the capsular ligament of the elbow-joint.

Structure and insertion.—The tendon of origin is prolonged on the deep surface and lateral border of the muscle. From this the fibre-bundles spread, the proximal transversely, the more distal obliquely, to be inserted into the radial side of the olecranon and an adjacent impression on the shaft of the ulna. Its superior fibre-bundles are usually continuous with those of the medial head of the triceps.

Nerve-supply.—By a long branch which arises in the radial (musculo-spiral) groove from the radial (musculo-spiral) nerve, passes through the medial head of the triceps, to which it gives branches, and enters the proximal border of the anconeus. The nerve fibres arise from the seventh and eighth cervical nerves.

Action.—It aids the triceps in extending the forearm and draws the ulna laterally in pronation of the hand.

Relations.—The muscle lies immediately beneath the antibrachial fascia. It extends over the head of the supinator (brevis) and the elbow-joint and upper radio-ulnar joint.

Variations.—The extent of fusion of the muscle with the medial head of the triceps varies a good deal. It may also be fused with the extensor carpi ulnaris. It has been reported missing.

BURSÆ

B. intratendinea olecrani.—Within the tendon of the triceps near its insertion. More frequent than the following:—

B. subtendinea olecrani.—Between the tendon of the triceps and the olecranon and dorsal ligament of the elbow-joint. Inconstant.

B. epicondyli medialis dorsalis.—Between the medial epicondyle, the edge of the triceps, and the ulnar nerve. Rare.

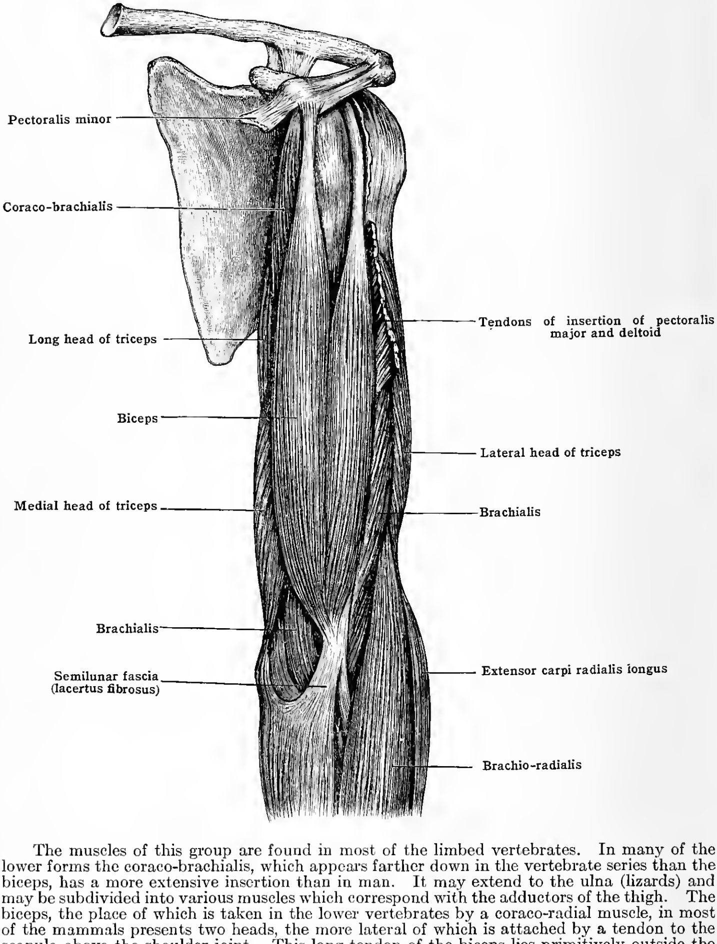
B. m. anconei.—Between the tendon of origin of the muscle and the head of the radius. Frequent.

2. Ventral or Flexor Group

(Figs. 364, 365, 370, 372)

The muscles of this group are the coraco-brachialis, the biceps, and the brachialis. The **coraco-brachialis** (fig. 365) is a band-like muscle which arises from the coracoid process and is inserted into the middle third of the shaft of the humerus. The **biceps** (fig. 364) arises by two heads: a short head, closely associated with the coraco-brachialis, from the coracoid process; a long head, by an extended tendon, from the supraglenoid tuberosity of the scapula. The fusiform belly which arises from the fusion of these two heads is inserted into the radius and into the fascia of the forearm. The **brachialis** (fig. 365) extends under cover of the biceps from the lower three-fifths of the shaft of the humerus to the coronoid process of the ulna. The muscles of this group are supplied by the musculo-cutaneous nerve. The brachialis also usually receives a branch from the radial nerve. The coraco-brachialis and short head of the biceps flex and adduct the arm at the shoulder; the biceps and brachialis flex the forearm at the elbow. The long head of the biceps abducts the arm at the shoulder.

Fig. 364.—Superficial Muscles of the Front of the Arm.



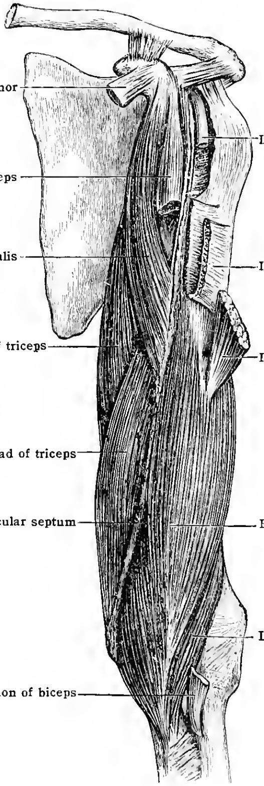
The muscles of this group are found in most of the limbed vertebrates. In many of the lower forms the coraco-brachialis, which appears farther down in the vertebrate series than the biceps, has a more extensive insertion than in man. It may extend to the ulna (lizards) and may be subdivided into various muscles which correspond with the adductors of the thigh. The biceps, the place of which is taken in the lower vertebrates by a coraco-radial muscle, in most of the mammals presents two heads, the more lateral of which is attached by a tendon to the scapula above the shoulder-joint. This long tendon of the biceps lies primitively outside the capsule of the shoulder-joint, but in some of the higher mammals has come to lie within the capsule. In the biceps four elements may be recognised:—a coraco-radial, coraco-ulnar, gleno-radial, and gleno-ulnar. (Krause.) The development of these elements varies in different mammals

The coraco-brachialis (fig. 365).—*Origin.*—(1) By a short tendon from the tip of the coracoid process of the scapula and (2) from the tendon of the short head of the biceps.

Insertion.—(1) By means of a strong tendon into the medial surface of the humerus immediately proximal to the middle of the shaft, and (2) often above this also into an aponeurotic band which extends from the tendon along the medial margin of the humerus, arches over the tendons of the latissimus dorsi and teres major, and is attached to the lesser tubercle of the humerus. When the attachment to the tubercle does not take place, the band becomes closely applied to the deep surface of the muscle.

Structure.—From the tendons of origin, which are usually closely associated, the fibre-bundles take an oblique, nearly parallel, course and are attached to the aponeurotic band above

FIG. 365.—DEEP MUSCLES OF THE FRONT OF THE ARM.



mentioned and to both surfaces of the flat tendon of insertion. This extends high into the muscle. The belly of the muscle usually shows some separation into a superficial and a deep portion, between which runs the musculo-cutaneous nerve. When this separation is well marked, the tendon of origin of the superior fasciculus may be distiuct from that of the inferior fasciculus and the short head of the biceps, and the tendon of insertion may give a separate lamina to each fasciculus.

Nerve-supply.—A branch of the musculo-cutaneous nerve, or of the brachial plexus near the origin of this nerve, enters the upper third of the medial border of the muscle, and passes across the constituent fibre-bundles about midway between their attachments. The nerve fibres arise from the sixth and seventh cervical nerves.

Action.—Adducts and flexes the arm at the shoulder and helps to keep the head of the humerus in the glenoid fossa. When the arm has been rotated lateralward, it acts as a medial rotator.

Relations.—The coraco-brachialis is largely covered by the deltoid and pectoralis major muscles. Below the inferior border of the latter it becomes superficial. Near its origin it lies between the pectoralis minor and the subscapularis muscles. More distally it lies medial to the humerus and in front of the chief brachial vessels and nerves. The musculo-cutaneous nerve usually runs through it.

Variations.—The humeral insertion of the muscle varies considerably. According to Wood, the coraco-brachialis consists primitively of three parts, which arise from the coracoid process and are inserted respectively into the upper, the middle, and the distal part of the humerus along the medial side. The superior division is most deeply, the inferior the most superficially, placed. In man the muscle is composed of parts of the middle and inferior divisions. The inferior division may be completely developed as far as the medial epicondyle. The superior division of the muscle is occasionally found. Slips from the coraco-brachialis to the brachialis have been seen. Complete absence of the muscle has been recorded.

The **biceps brachii** (figs. 364, 370).—The **short head** *arises* by a flat tendon closely associated with that of the coraco-brachialis from the coracoid process. From the dorso-medial surface of this tendon the fibre-bundles descend nearly vertically, though increasing in number, toward their attachment to the tendon of insertion. The fibre-bundles which arise highest on the tendon of origin are inserted highest on the tendon of insertion, while those which have the lowest origin have the lowest insertion.

The **long head** *arises* from the supraglenoid tuberosity and from the glenoid ligament by a long tendon (9 cm.) bifurcated at its origin. The tendon at first passes over the head of the humerus within the capsule of the joint, and then passes into the intertubercular (bicipital) groove, which is covered by the capsule of the joint and an expansion from the tendon of the pectoralis major. To this point the tendon is surrounded by the synovial membrane of the joint. After emerging from this the tendon slowly expands and from its dorsal concave surface arise fibre-bundles which, increasing in number, extend, somewhat obliquely, toward the tendon of insertion. As in case of the short head, here also the fibre-bundles which arise highest on the tendon of origin have the highest insertion.

Insertion.—The tendon of insertion begins usually in the distal quarter of the arm as a vertical septum between the two heads of the muscle. More distally this broadens out on each side into a flattened aponeurosis. The fibre-bundles are inserted into the sides of the septum and on each surface of the aponeurosis—those of the long head chiefly on the deep surface, those of the short head chiefly on the superficial surface. The aponeurosis is continued into a strong, flattened tendon which descends between the brachio-radialis and pronator teres muscles to be inserted on the dorsal half of the bicipital tuberosity of the radius. From the medial border of the tendon an aponeurotic expansion, the **lacertus fibrosus** (semilunar fascia), is continued into the fascia of the ulnar side of the forearm.

Nerve-supply.—By a branch from the musculo-cutaneous nerve for each head. These branches may be bound in a common trunk for some distance. They enter the deep surface of the muscle in the proximal part of the middle third of each belly often by several rami. Usually there is a distinct intramuscular fissure for the reception of the branches to each head and the blood-vessels which accompany them. The nerve fibres come from the fifth and sixth cervical nerves.

Action.—It is a chief flexor of the arm at the elbow and is also a supinator of the forearm. This last action is most marked when the forearm is flexed and pronated. Both heads are flexors and medial rotators of the arm at the shoulder. The long head is an abductor and so also is the short head when the arm is greatly abducted, otherwise the short head is an adductor.

Relations.—The tendons of origin are concealed by the pectoralis major and deltoid muscles. Beyond this the muscle is covered by the fascia brachii. In the lower part of the arm it lies upon the brachialis muscle. Upon the medial margin lie the coraco-brachialis muscle, the brachial vessels. and the median nerve.

Variations.—Variations are frequent. The whole muscle or either head may be missing, but such cases are rare. The long head may extend only to the bicipital groove. Frequently the muscle is partially divided into the four primitive portions mentioned above. The two heads may be separate from origin to insertion. There may be an accessory head (1 in 10 subjects—Le Double) which arises from the coracoid process, the capsule of the joint, the tendon of the pectoralis major, or the shaft of the humerus near the insertion of the coraco-brachialis. In most instances the origin takes place above the origin of the brachialis from the humerus. Sometimes several accessory heads are seen. Marked variation of insertion is less frequent, but occasionally a supernumerary slip may go to the medial intermuscular septum or the medial epicondyle. The fusion of the biceps with neighbouring muscles (pectoralis major and minor, coraco-brachialis, brachialis, palmaris longus, pronator teres, brachio-radialis) by means of tendinous or muscular slips has been frequently reported.

The **brachialis** (fig. 365).—*Origin.*—(1) From the distal three-fifths of the front of the humerus, (2) from the medial intermuscular septum, and (3) from the lateral intermuscular septum proximal to the heads of the brachio-radialis and extensor carpi radialis longus. Proximally it sends up a pointed process on the lateral side of the insertion of the deltoid and another between the insertions of the deltoid and the coraco-brachialis. Distally the area of origin stops a little above the capitulum and the trochlea.

Structure and Insertion.—The fibre-bundles arise directly from this area of origin, except near the insertion of the deltoid and on the medial margin, where tendinous bands are developed. The fibre-bundles descend, the middle vertically, the medial obliquely lateralward, the lateral still more obliquely medialward. The tendon of insertion appears on the dorsal side of the lateral edge of the muscle in its lower fourth. Continuous with this stronger lateral portion of the tendon more distally a thinner band appears upon the ventral surface of the muscle above the joint. The tendon becomes thick as it passes distally, is closely united to the capsule of the elbow-joint, and is attached to the ulnar tuberosity. In addition to the main tendon, some of the deeper fibre-bundles of the muscle and some of those coming from the lateral intermuscular septum are attached by short tendinous bands to the coronoid process.

Nerve-supply.—From the musculo-cutaneous nerve by a branch which enters the ventral surface of the muscle near the junction of the upper and middle thirds of the medial border. In addition the radial (musculo-spiral) nerve usually sends a small branch into the distal lateral portion of the muscle. A branch from the median nerve frequently supplies the medial side of the muscle near the elbow-joint (Frohse).

Action.—To flex the forearm.

Relations.—It lies behind the biceps, on each side of which it projects. The distal lateral portion of the muscle is grooved by the brachio-radialis, which here is closely applied to it. The radial (musculo-spiral) nerve runs between these two muscles. On the medial side run the brachial vessels and median nerve.

Variations.—It may be divided into two distinct heads continuous with the projections on each side of the deltoid tuberosity. A great number of supernumerary slips have been recorded. These may be attached to the radius, ulna, fascia of the forearm, capsule of the joint, brachio-radialis, and extensor carpi radialis muscles. It may be partially fused with neighbouring muscles. It has also been reported absent.

Bursæ

B. m. coraco-brachialis.—Between the subscapularis muscle, the tendon of the coraco-brachialis, and the coracoid process. Frequent.

B. bicipito-radialis.—Between the ventral half of the radial tuberosity and the tendon of the biceps. Constant.

B. cubitalis interossea.—Between the tendon of the biceps and the ulna and the neighbouring muscles. Frequent.

D. MUSCULATURE OF THE FOREARM AND HAND

(Figs. 366–379)

The muscles of the forearm arise in part from the humerus, in part from the radius and ulna. Their bellies lie chiefly in the proximal half of the forearm. They are divisible into two groups:—a radio-dorsal, composed of extensors of the hand and fingers and supinators of the forearm; and an ulno-volar, composed of flexors of the hand and fingers and pronators of the forearm. The brachio-radialis, which belongs morphologically with the former group, is physiologically a flexor of the forearm.

The two groups are separated on the medial side of the back of the forearm by the dorsal margin of the ulna (figs. 366, 369). Ventrally they are separated by the insertions of the biceps and brachialis and by an intermuscular septum (figs. 366, 370).

In the **hand,** in addition to the tendons of the muscles of the forearm mentioned above (fig. 376), there are several sets of intrinsic muscles. About the metacarpal of the thumb (figs. 375, 376, 377) is grouped a set of muscles which arise from the carpus and metacarpus and are inserted into the metacarpal and first phalanx of the thumb. A similar set of muscles is grouped about the metacarpal of the little finger (figs. 375, 376). These sets of muscles give rise respectively to the thenar and hypothenar eminences. Between the metacarpals lies a series of dorsal and palmar interosseous muscles (figs. 377, 378, 379) which are inserted into the first row of phalanges and into the extensor tendons. From the tendons of the deep flexor of the fingers a series of lumbrical muscles passes to the radial side of the extensor tendons (figs. 373, 375). These various muscles abduct, adduct, flex, and extend the digits. In addition to these deeper skeletal muscles of the hand there is a subcutaneous muscle over the hypothenar eminence (fig. 375). Of the muscles of the hand, all are supplied by the ulnar nerve except most of those of the thumb and the two more radial lumbricals, which are supplied by the median nerve.

An arrangement of the muscles of the forearm in which the dorsal extensor-supinator musculture extends proximally on the radial side of the arm to the distal extremity of the humerus, and the volar flexor-pronator musculature similarly on the ulnar side, is characteristic of all limbed vertebrates and is associated with the pronate position of the forelimb characteristic of quadrupeds. In amphibia and reptiles the musculature terminates distally on the carpus and in the aponeuroses of the hand. In the higher forms special tendons are differentiated for those muscles of the forearm which act on the fingers. On the back of the hand in many vertebrates short extensor muscles are found running from the carpus to the phalanges. On the volar surface a complex musculature is found in all forms which have freely movable fingers. In animals which walk on the ends of the fingers, especially in the hoofed animals, the intrinsic musculature of the hand is greatly reduced. The phylogenetic development of the muscles of the forearm and hand is too complex a subject to be briefly summarised. The phylogeny of the forearm flexors and the palmar musculature has been studied by McMurrich. In his papers a summary of the literature on the subject may be found.

FASCIÆ

The fasciæ and the general relations of the musculature of the forearm and hand may be followed in the cross-sections fig. 366.

The **tela subcutanea** contains a moderate amount of fat in the upper part of the forearm. This grows less in amount as the wrist is approached. On the back of the hand it contains little fat. In the palm and on the volar surface of the fingers a moderate amount of fat is embedded between dense vertical bundles of fibres which unite the skin to the fascia. Except on the volar surface of the hand and on the backs of the terminal phalanges, the tela is but loosely united to the underlying fascia.

The **bursa subcutanea olecrani** lies over the dorsal surface of the olecranon. Subcutaneous bursæ are also frequently found over the knuckles (**b. subcutaneæ metacarpophalangeæ dorsales**) and the proximal joints of the fingers (**b. subcutaneæ digitorum dorsales**).

The **antibrachial fascia** encloses the muscles of the forearm in a cylindrical sheath, composed in the main of circular fibre-bundles, but strengthened by longitudinal and oblique bundles extending in from the epicondyles of the humerus, the olecranon, the lacertus fibrosus of the biceps, and the tendon of the triceps. The fascia of the forearm is attached to the dorsal surface of the olecranon and to the subcutaneous margin of the ulna. Above, it is continued into the fascia of the arm; below, into the fascia of the hand. From the antibrachial fascia in the upper half of the forearm a fibrous septum extends between the radio-dorsal and the ulno-volar muscle group to the radius. In the radial septum below the elbow a branch of communication extends between the superficial and deep veins of the arm. That part of the fascia overlying the radio-dorsal group of muscles is much denser than that covering the volar group, except where the latter is strengthened by the lacertus fibrosus. In addition to the main radial septum other septa descend between the underlying muscles from the antibrachial fascia. These septa are best marked near the attachment of the muscles to the humerus. Here the fascia is firmly fused to the muscles.

Dorsally the antibrachial fascia is strengthened at the wrist by transverse fibres which extend from the radius to the styloid process of the ulna, the triquetrum (cuneiform), and pisiform, and give rise to the **dorsal ligament of the carpus** (posterior annular ligament). From this ligament septa descend to the radius and ulna and convert the grooves in these bones into osteo-fibrous canals which lodge the tendons of the various muscles extending to the wrist and hand.

On the **back of the hand** there is spread a fascia composed of two thin fascial sheets between which the extensor tendons are contained. Between the tendons these sheets are more or less fused. On the backs of the fingers the fascia blends with the extensor tendons and the associated aponeurotic expansions from the interosseous and lumbrical muscles. Between the fingers it is continued into the transverse fasciculi of the palmar aponeurosis. At the sides of the hand the fascia is continued into the thenar and hypothenar fasciæ. Each dorsal interosseous muscle is covered by a special fascial membrane which is separated by loose tissue from the fascia investing the extensor tendons.

FIG. 366, A–H.—TRANSVERSE SECTIONS THROUGH THE LEFT FOREARM AND HAND.

H. Transverse section through the first phalanx of the middle finger, diagrammatic, with the cavity of the synovial sheath of the flexor tendons distended.

The regions through which these sections pass are indicated in the diagram. *c* and *d* in the diagram show the regions through which pass sections C and D, fig. 362 (p. 375).

On the **volar side of the forearm** for some distance above the wrist the tendons of the flexor carpi radialis, the palmaris longus, and the flexor carpi ulnaris run between two layers of the fascia. The fascia is much strengthened at the wrist by transverse fibres which give rise to the **volar ligament of the carpus.** Beneath it lies the **transverse ligament of the carpus** (anterior annular ligament). This dense band is broader than the volar ligament but like it extends from the pisiform bone and the hamulus of the hamatum (unciform) to the tuberosity of the navicular and the tuberosity of the greater multangular (trapezium). It serves to complete an osteo-fibrous canal through which pass the flexor tendons of the fingers. Between the two ligaments which are partially fused with one another run the ulnar artery and nerve.

On the **palm of the hand** the ensheathing fascia presents three distinct areas—a central, a lateral, and a medial.

The central portion, the **palmar aponeurosis,** is composed chiefly of bundles of fibrous tissue which radiate superficially toward the fingers from the tendon of the palmaris longus or from a corresponding region of the forearm fascia when this muscle is absent. Between these bundles are others which arise from the transverse ligament. The deep surface of the fascia is composed of a thin incomplete layer of transverse fibres which continue the transverse fibres of the forearm fascia. Near the capitula of the metacarpals this layer becomes much stronger and constitutes a ligamentous band (**superficial transverse ligament** of Poirier). Near the bases of the digits bundles of transverse fibres (**fasciculi transversi**) lie in the webs of the fingers and constitute an incomplete transverse ligament separated by a distinct interval from the superficial transverse ligament.

From the palmar aponeurosis processes are sent in toward the deeper structures. Of these, the most important are those continued into a fibrous sheath which surrounds the space containing the long flexor tendons and the lumbrical muscles. This dense fibrous sheath is united by fibrous processes to the third, fourth, and fifth metacarpals. As the flexor tendons diverge and the ends of the metacarpals are approached, numerous processes descend from the palmar aponeurosis to the transverse capitular ligament. These hold the tendons in place. On the volar surface of the fingers the fascia serves to complete osteo-fibrous canals for the long flexor tendons. The ventral surface of the first and second phalanges of each finger is slightly grooved. The fascia is firmly united on each side to the margin of the groove, and over the groove forms a semicylindrical, strong, fibrous sheath, the **vaginal ligament** of the finger. This sheath is strengthened by transverse bands over the bases of the first and second phalanges (**annular ligaments**) and by cruciate bands over the shafts of the phalanges (**cruciate ligaments**). Over the interphalangeal joints the sheath is thin, but is strengthened by crucial bands which permit of freedom of motion.

The **thenar fascia** is a thin membrane covering the short muscles of the thumb. It is continued above into the fascia of the forearm, medially is fused with the tendon of the palmaris longus and the palmar aponeurosis, and extends as a septum to be attached to the third metacarpal. Laterally it is attached to the first metacarpal and is continued into the dorsal fascia of the hand. It is fused with an aponeurosis from the tendon of the abductor pollicis longus. Distally it is continued into the vaginal ligament of the long flexor of the thumb. Superficially it is closely adherent to the skin.

The **hypothenar fascia** invests the palmar muscles of the little finger. It is continued from the ulnar margin of the fifth metacarpal over the muscles of the little finger to the palmar aponeurosis, and, by means of a septum, to the radial side of the fifth metacarpal. Proximally, it is attached to the hamatum (unciform) and extends into the fascia of the forearm, distally, it extends into the vaginal ligament of the tendon of the fifth digit.

A deeply seated suprametacarpal fascial layer, or **deep palmar fascia,** covers the interosseous muscles and is attached to the volar surface of the metacarpal bones.

In addition to the fasciæ mentioned, intermuscular septa serve to separate more or less completely the various intrinsic muscles of the hand.

MUSCLES

1. Radio-Dorsal Division

The muscles of this group lie in two chief layers, a superficial and a deep.

a. Superficial Layer

(Figs. 367, 370, 371)

The muscles of this layer, closely associated at their origins, extend from the radial side of the distal end of the humerus to the distal extremity of the radius, the carpus, and the fingers. They are divisible into a radial, an intermediate, and an ulnar set.

Radial set.—To this belong three muscles, the brachio-radialis, extensor carpi radialis longus and brevis. The **brachio-radialis** (fig. 370), a forearm flexor, is a superficial fusiform muscle which arises from the lateral epicondylar ridge of the humerus and is inserted into the base of the styloid process of the radius. The **extensor carpi radialis longus** (fig. 371) is a narrow, fusiform muscle which extends along the radial margin of the forearm, partly under cover of the brachio-radialis. It arises from the lateral epicondylar ridge of the humerus, and is inserted into the second metacarpal bone. The **extensor carpi radialis brevis** (fig. 367) is a band-like muscle more dorsally placed than the last at the radial side of the arm. It arises from the lateral epicondyle and is inserted into the bases of the second and third metacarpals. These muscles are supplied by branches of the radial nerve which arise proximal to the passage of the deep radial (posterior interosseous) through the supinator muscle. Distally this set of muscles is separated from the intermediate set by the long abductor and the extensors of the thumb, which pass from an origin under the latter set over the tendons of the radial extensors to the thumb.

The **intermediate set.**—This consists of the thick, flattened **extensor digitorum communis** and the slender **extensor digiti quinti proprius** (fig. 367). They arise from the lateral epicondyle, and are inserted into the backs of the fingers.

The **ulnar set** consists of one muscle, the fusiform **extensor carpi ulnaris,** which arises from the lateral epicondyle of the humerus and is inserted into the back of the base of the fifth metacarpal.

The intermediate and ulnar sets of muscles are supplied by branches from the ramus profundus of the radial nerve after this has passed through the supinator muscle.

In the leg the lateral set of the superficial layer is represented by the tibialis anterior. The intermediate set is represented by the long extensors of the toes. The single muscle which constitutes the medial set is represented by the peroneal muscles.

The brachio-radialis (supinator radii longus) (figs. 367, 370).—*Origin.*—From the upper two-thirds of the lateral epicondylar ridge of the humerus and from the front of the lateral intermuscular septum.

Insertion.—Into the lateral side of the base of the styloid process of the radius.

Structure.—The constituent fibre-bundles arise directly from the septum and by short tendinous bands from the epicondylar ridge, extend downward and ventrally, and terminate in a penniform manner on a tendon which extends high on the deep surface of the muscle. This tendon becomes free about the middle of the forearm as a broad, flat band. This becomes narrow as the tendon winds about the radius from the volar to the lateral surface. Before its insertion it expands laterally and is connected with neighbouring ligaments. The free surface of the muscle faces laterally at its origin, but, owing to the torsion, ventrally in the forearm. The tendon, however, is turned again so that at the insertion it faces laterally once more.

Nerve-supply.—From a branch of the radial nerve (musculo-spiral) which enters the proximal third of the muscle on its deep surface. The nerve fibres arise from the fifth and sixth cervical nerves.

Action.—To flex the forearm. This action is strongest when the forearm is pronated. It acts as a supinator only when the arm is extended and pronated. It then serves to put the arm in a state of semi-pronation. When the forearm is flexed, it acts as a pronator.

Relations.—The muscle is superficially placed on the ventro-lateral surface of the forearm. Its tendon of insertion, however, is covered by the long abductor and the short extensor of the thumb. Near its origin (fig. 367) it lies lateral to the brachialis. In the intervening tissue run the radial nerve and the terminal branch of the profunda brachii artery. Dorsally and laterally lies the medial head of the triceps. More distally the muscle overlies the extensor carpi radialis longus. It crosses the supinator, pronator teres, and flexor pollicis longus muscles. Beneath its medial edge lie the radial vessels and nerve.

Variations.—The humeral origin may extend half-way up the shaft. The radial insertion may be as high as the middle of the shaft or descend to the lesser multangular, navicular, or third metacarpal. In about 7 per cent. of bodies (Le Double) the tendon of insertion divides into two or three slips which are inserted on the styloid process of the radius. Occasionally the radial nerve passes between these slips. An accessory slip may pass to the fascia of the forearm. The muscle may be doubled throughout its length and it may be missing. It may be connected by accessory slips with neighbouring muscles, the deltoid, brachialis, long abductor of the thumb, or long radial carpal extensor. The slip most frequently found goes to the brachialis.

The extensor carpi radialis longus (figs. 367, 368, 371.)—*Origin.*—From the lower third of the lateral epicondylar ridge, the lateral intermuscular septum, and from the front of the tendons of the extensor carpi radialis brevis and the extensor communis digitorum which arise from the lateral epicondyle.

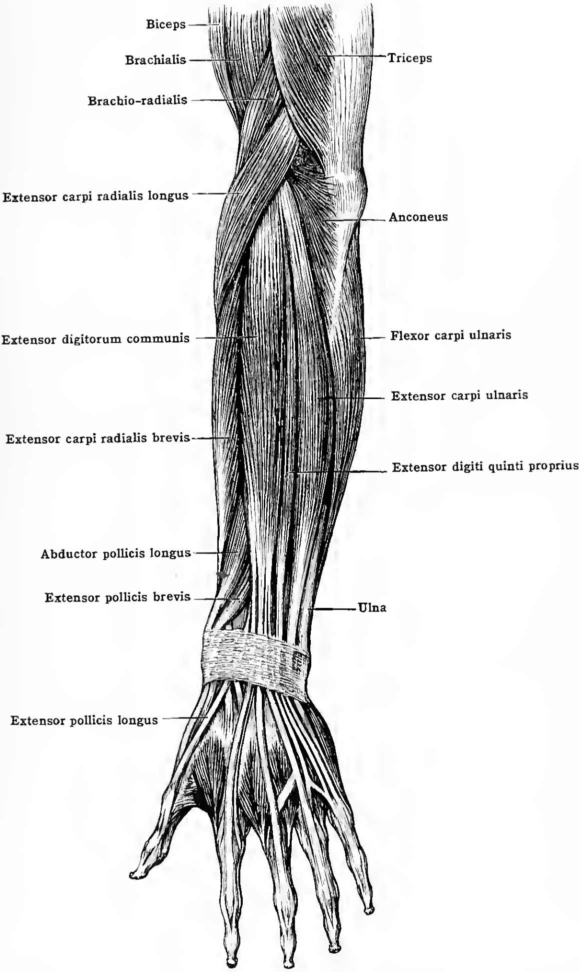
Structure and insertion.—The fibre-bundles are inserted in a penniform manner on both surfaces of a tendon which first appears on the lateral border of the deep surface of the muscle, becomes free above the middle of the forearm, and descends, closely applied to the tendon of the short radial carpal extensor, to the second compartment beneath the dorsal carpal ligament, through which it passes to its insertion into the base of the second metacarpal near the radial border. The outer surface of the muscle faces at first laterally, then ventrally.

Nerve-supply.—By one or two branches which arise from the radial (musculo-spiral) nerve as it passes between the brachialis and brachio-radialis. The nerve enters the deep surface of the muscle in the proximal third. The nerve fibres arise from the (fifth), sixth and seventh cervical nerves.

Action.—To extend and abduct the hand. It steadies the wrist when the flexors act on the fingers. It is a flexor of the forearm; a supinator when the forearm is extended, a pronator when it is flexed.

Relations.—It is covered by the brachio-radialis near the elbow. Below it becomes superficial except where crossed by the tendons of the muscles of the thumb. (For the relations to the short radial carpal extensor see below.)

Fig. 367.—Muscles of the Radial Side and the Back of the Forearm.

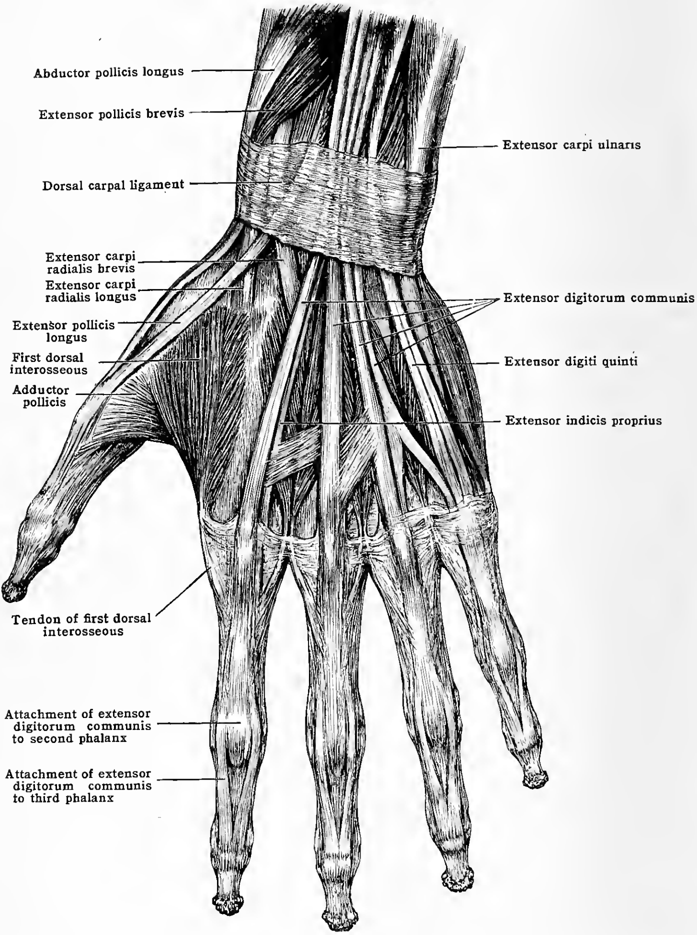


Variations.—The humeral attachment may be more extensive than that indicated above. The tendon of insertion may send a band to the third or to the fourth metacarpal or to the multangulum majus (trapezium). The muscle may be fused, partly or completely, with the short radial extensor. It may send a slip to the abductor pollicis longus or to some of the interossei.

The extensor carpi radialis brevis (figs. 367, 368).—*Origin.*—From a band which descends on its deep surface from the common extensor tendon attached to the lateral epicondyle, from the intermuscular septa surrounding its head, and from the radial collateral ligament of the elbow-joint.

Structure and insertion.—The fibre-bundles converge obliquely toward a tendon which appears high up on the dorso-lateral surface of the muscle. Toward the lower third of the forearm this tendon becomes a free, strong band closely applied to the under surface of the tendon of the long radial extensor, and with this passes through the second compartment beneath the dorsal ligament of the carpus, diverging as it does so toward its insertion into the back of the bases of the second and third metacarpal bones.

FIG. 368.—TENDONS UPON THE DORSUM OF THE HAND.



Nerve-supply.—A branch is supplied to the muscle from the deep radial (posterior interosseous) nerve before this enters the supinator (brevis). The branch enters the middle third of the medial margin of the muscle by several rami. The nerve fibres arise from the (fifth), sixth and seventh cervical nerves.

Action.—To extend the hand and, to a slight extent, to flex the forearm.

Relations.—In its proximal portion the muscle is placed with a medial surface toward the common extensor, a deep toward the supinator (brevis) and pronator teres, and a dorsolateral toward the long radial extensor. More distally the muscle and its tendon become flattened about the radius and partly covered by the long radial extensor and its tendon.

In the distal quarter of the forearm the tendons of these two muscles are crossed by the long abductor and the short extensor of the thumb. Beneath the dorsal carpal ligament the tendon of the short radial extensor is crossed by the tendon of the long extensor of the thumb.

Variations.—The tendon often sends no slip to the second metacarpal. Fusion of the two radial extensors is frequent. The fused muscle may have from one to four tendons. The **extensor carpi radialis intermedius** of Wood is a muscle which arises, rarely directly from the humerus, but not infrequently as a slip from one or both radial extensors. It is inserted into the second or third metacarpal bone or into both. The **extensor carpi radialis accessorius** is a muscle which has an origin like the extensor intermedius, but which terminates on the base of the metacarpal or first phalanx of the thumb, the short abductor of the thumb, or some neighbouring structure.

The extensor digitorum communis (figs. 367, 368).—*Origin.*—From a tendon attached to the lateral epicondyle, and from intermuscular septa which lie between the head of the muscle and the short radial extensor, the extensor of the little finger, and the supinator muscle.

Insertion.—By four tendons into the bases of the phalanges of the fingers.

Structure.—The fibre-bundles arise from the interior of the pyramidal case formed by the tendon, the fascia, and intermuscular septa, and pass distally to converge on four tendons which begin in the middle of the forearm, become free a little above the wrist, pass under the dorsal carpal ligament in a groove common to them and the tendon of the extensor indicis proprius, and diverge to the backs of the fingers. Opposite the metacarpo-phalangeal joint each tendon gives rise on its under surface to a band which becomes attached to the base of the first phalanx of its respective digit. The tendon is also closely bound to the joint by fibrous bands connected with the palmar fascia. On the dorsum of the first phalanx the tendon expands and is bound to an aponeurotic extension from the interosseous and lumbrical muscles. The tendon divides into three bands. The middle band passes to the base of the second phalanx, the lateral bands pass laterally around the joint to be inserted into the back of the base of the third phalanx. The lateral bands are bound to the second joint by a thin layer of transverse and oblique fibres.

An obliquely transverse band usually passes from the tendon of the index to that of the middle finger above the heads of the metacarpals. The tendon to the index finger is united to the tendon of the extensor indicis proprius opposite the metacarpo-phalangeal articulation. The tendon to the ring finger usually sends a slip to join the tendon of the middle finger. The fourth tendon lies near that of the ring finger and divides into two slips, one of which joins the tendon of the ring finger and one goes to the little finger to join the tendon of the extensor digiti quinti proprius.

Nerve-supply.—From a branch which arises from the deep radial (posterior interosseous) nerve as it emerges from the supinator (brevis) muscle. From this several twigs enter the deep surface of the middle third of the belly. Often the nerve is bound up with the nerve to the extensor of the little finger and the ulnar extensor. On the other hand, there may be several separate branches to the muscle. The nerve fibres arise from the sixth, seventh, and eighth cervical nerves.

Action.—The muscle extends the two terminal phalanges on the basal, the basal on the metacarpus, and the hand at the wrist. The extensor action is strongest on the first phalanx. The cross-bands between the tendons hinder the independent extension of the middle and ring fingers, while the special extensors of the index and little fingers makes the movements of these fingers freer. When the hand is abducted toward the radial side, the extensor muscles tend to draw the fingers ulnarward. When the hand is abducted toward the ulnar side, the muscles tend to draw the fingers toward the thumb. When the hand is in the mid-position the ring finger and little finger are abducted and the index-finger is adducted. (Frohse.)

Relations.—It is superficially placed. Under it lie the deep muscles of the back of the forearm, the interosseous vessels, and the deep radial (posterior interosseous) nerve. It lies between the short radial carpal extensor and the extensor of the little finger.

Variations.—There is considerable variation in the extent of isolation of the parts going to the various fingers. That to the index-finger is the one most frequently isolated. At times the tendon to the index or little finger may be wanting. More frequently one or more of the tendons subdivides to be attached to two or more fingers or to the thumb. The connections between the tendons on the back of the hand vary greatly.

The extensor digiti quinti proprius (extensor minimi digiti) (figs. 367, 368).—*Origin.*—Chiefly from the septum between it and the common extensor, but also in part from the septum between it and the extensor ulnaris and from the overlying fascia.

Structure and insertion.—The fibre-bundles descend in a narrow band which begins near the neck of the radius. They are inserted into the side of a tendon which begins high on the ulnar margin of the muscle. The most distal fibre-bundles extend nearly to the wrist-joint. The tendon passes through the fifth compartment beneath the dorsal carpal ligament, and extends on the back of the fifth metacarpal to the base of the first phalanx of the little finger, where it is joined by a slip from the fourth tendon of the common extensor. The insertion of the tendon is like that of the tendons of the common extensor.

Nerve-supply.—By a branch or branches from the deep radial (posterior interosseous) nerve. The nerve filaments enter the middle third of the fleshy portion of the muscle on its deep surface. The innervation of this muscle is intimately related to that of the preceding.

Action.—It acts as a portion of the common extensor, but, owing to its separation, independent movement of the little finger is possible.

Relations.—It lies between the common extensor and the ulnar extensor and upon the deep muscles of the back of the forearm.

Variations.—Absence is not very frequent; blending with the common extensor is frequent. Its tendon often divides into two or more slips. The belly may also be doubled. It may have a supplementary origin from the ulna. A tendon slip to the ring-finger is frequently found.

The extensor carpi ulnaris (figs. 367, 368).—*Origin.*—By two heads: one from the inferior dorsal portion of the epicondyle by an aponeurotic band attached below the tendon of the common extensor, from the enveloping fascia, and from the septa between it and the extensor digiti quinti, anconeus, and supinator (brevis); the other from the proximal three-fourths of the dorsal border of the ulna.

Structure and insertion.—The fibre-bundles descend in an osteo-fascial compartment bounded by the dorsal surface of the ulna, the fascia of the forearm, the dense fascia overlying the ulnar origin of the muscles of the thumb, and the origin of the extensor indicis. The tendon commences high in the muscle and appears on the radial border of the middle third of the back of its belly. The fibre-bundles are inserted in a penniform manner on the ulnar border and deep surface of the tendon as far as the wrist. Here the tendon enters the sixth osteo-fibrous canal beneath the dorsal carpal ligament in a special groove on the outer side of the styloid process of the ulna. It is inserted into the base of the fifth metacarpal.

Nerve-supply.—By a branch which arises from the deep radial (posterior interosseous) nerve as this emerges from the supinator (brevis) muscle. Several filaments enter the deep surface of the muscle in the middle third. The nerve fibres arise from the sixth, seventh and eighth cervical nerves.

Action.—To extend and abduct the hand ulnarward.

Rèlations.—It occupies a superficial position on the ulnar side of the extensors of the forearm. Beneath it lie the deep muscles of the back of the forearm and the posterior surface of the ulna.

Variations.—It may receive a slip from the triceps or be fused with the anconeus or with the extensor of the little finger. More frequently it is doubled, partially or completely. An accessory tendon may go to the first phalanx of the little finger, to the head of the fifth metacarpal, to the fourth metacarpal, to the extensor tendon of the little finger, or to the fascia over the opponens digiti quinti. The muscle may be reduced to a fibrous band. The **ulnaris digiti quinti** is a rare muscle arising from the dorsal surface of the ulna and inserted into the base of the first phalanx of the little finger. It may be represented by a fasciculus or an extra tendon from the ulnar extensor.

b. Deep Layer

(Fig. 369)

The muscles of this group extend from the ulna to the radius, thumb, and index-finger. They are the supinator, abductor pollicis longus, extensor pollicis longus and brevis, and extensor indicis proprius. The **supinator** is a rhomboid muscle which arises from the lateral epicondyle of the humerus and the supinator crest of the ulna winds laterally around the radius and is inserted into its volar surface. The **abductor pollicis longus** is a fusiform muscle which arises from the middle third of the ulna, the interosseous membrane, and the radius, and is inserted into the base of the first metacarpal. The **extensor pollicis brevis** arises from the radius distal to the preceding muscle, and is inserted into the base of the first phalanx of the thumb. The **extensor pollicis longus** is a narrow muscle which arises from the middle third of the dorsal surface of the ulna and is inserted into the base of the second phalanx of the thumb. The **extensor indicis proprius** is a narrow, fusiform muscle arising from the shaft of the ulna and inserted into the dorsal aponeurosis of the index-finger. These muscles are supplied from branches of the deep radial (posterior interosseous) nerve while this is passing through or after its exit from the supinator.

The extensor pollicis longus is represented by the extensor hallucis longus of the leg. The abductor pollicis longus and extensor pollicis brevis are represented by the abnormal abductor hallucis longus and extensor primi internodii hallucis muscles, the rudiments of which are perhaps normally present in the tibialis anterior. The supinator and the extensor indicis muscles are not represented in the leg. On the other hand, the extensor digitorum brevis, normal in the foot, is only occasionally found on the back of the hand.

The supinator (brevis) (figs. 366, 369, 372).—*Origin.*—From (1) the inferior dorsal portion of the lateral epicondyle by a tendinous band which is adherent to the deep surface of the tendons of origin of the radial and common extensors and to the radial collateral ligament of the joint; and (2) the ulna by a superficial aponeurosis and by fibre-bundles attached directly to the depression below the radial notch and to the supinator crest.

Insertion.—The lateral and volar surfaces of the radius from the tuberosity to the attachment of the pronator teres.

Structure.—From their origin the fibre-bundles descend spirally in a muscular sheet which enwraps the radius (fig. 366). The attachment extends to the oblique line. The muscle is divided into a superficial and a deep plane by a septum in which the deep radial (posterior interosseous) nerve runs. The radial attachments of these two portions are separated by an osseous area into which no fibre-bundles are inserted. The fibre-bundles of the superficial layer have a much more vertical course and are longer than those of the deep layer.

Nerve-supply.—By branches which arise from the deep radial (posterior interosseous) nerve before it passes between the two layers of the supinator muscle. The nerve fibres arise from the fifth, sixth, and seventh cervical nerves.

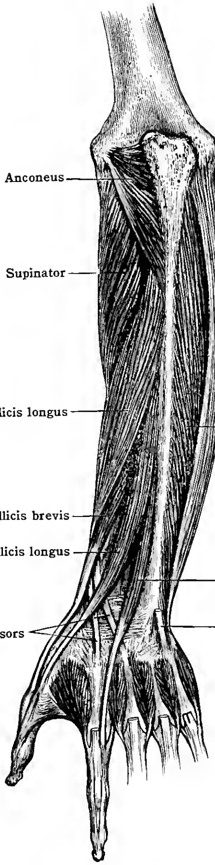
Action.—To supinate the forearm.

Relations.—The supinator is covered by the superficial group of extensor muscles above described and by the anconeus.

[1] *Variations.*—The extent of separation of the muscles into two portions varies. Accessory fasciculi of origin are not uncommon. These may spring from the annular ligament, **tensor ligamenti annularis anterior** (5 per cent. or more of bodies—Le Double), the lateral epicondyle, the tendon of the biceps, the tuberosity of the radius, etc. A sesamoid bone may lie in the tendon of origin. The **tensor ligamenti annularis posterior** is a slip generally present and often independent of the supinator. It runs from the ulna behind the radial notch to the annular ligament of the radio-ulnar joint.

The abductor pollicis longus (extensor ossis metacarpi pollicis) (fig. 369).—*Origin.*—From (1) the lateral margin of the dorsal surface of the ulna in the proximal portion of the middle third,

Fig. 369.—The Deep Muscles of the Back of the Forearm.



and the adjacent interosseous membrane, (2) the dorsal surface of the radius distal and medial to the attachment of the supinator, and (3) at times, from the septa lying between it and the supinator, extensor carpi ulnaris, and extensor pollicis longus.

Structure and insertion.—The fibre-bundles from this extensive area of origin converge in a bipenniform manner upon a tendon which appears as an aponeurosis on the deep surface of the muscle about the middle of the forearm. The tendon as it descends becomes rounded. The insertion of fibre-bundles continues nearly to the wrist. Here, together with the tendon of the short extensor, it enters the first osteo-fibrous canal beneath the dorsal carpal ligament upon the lateral surface of the distal extremity of the radius. Upon leaving this canal the tendon extends to be inserted on the radial side of the base of the first metacarpal bone.

Nerve-supply.—By one or more branches from the deep radial (posterior interosseous) nerve after it has emerged from the supinator. The branches enter the muscle on the superficial surface in the proximal third. The nerve fibres come from the sixth, seventh (and eighth) cervical nerves.

Action.—It carries the first metacarpal radialward and forward. At the height of its contraction it flexes and abducts the hand at the wrist.

Relations.—Near its origin the muscle is covered by the superficial extensors of the forearm. More distally, accompanied by the short extensor, it passes radially, becomes superficial, and crosses the tendons of the two radial carpal extensors.

Variations.—The muscle or its tendon may be doubled. An accessory tendon may be applied to the multangulum majus (trapezium), the transverse ligament of the carpus, the superficial muscles of the thenar eminence, or the first metacarpal. Of these, the attachment to the short abductor and short flexor is the most frequent (7 out of 36 bodies—Wood). There may be three or more tendons. The muscle may be fused with the short extensor.

The extensor pollicis brevis (fig. 369).—*Origin.*—From the distal part of the middle third of the medial portion of the dorsal surface of the radius and from the neighbouring portion of the interosseous membrane. Rarely its origin extends to the ulna.

Structure and insertion.—The fibre-bundles converge on a tendon which appears on the radial border. The fibres are inserted as far as the dorsal carpal (posterior annular) ligament. The tendon lies parallel to the ulnar side of that of the abductor pollicis longus, and, in close connection with it, passes through the first compartment beneath the dorsal carpal ligament, and crosses the metacarpo-phalangeal joint on the radial side of the long extensor tendon. It is inserted on the base of the first phalanx of the thumb or into the capsule of the metacarpo-phalangeal joint.

Nerve-supply.—From a branch derived from the deep radial (posterior interosseous) nerve. This branch is usually given off in common with or near the nerve to the abductor pollicis longus, and many traverse that muscle to reach the extensor pollicis brevis, which it enters in the proximal third of its radial border. The nerve fibres come from the sixth, seventh (and eighth) cervical nerves.

Action.—To extend the thumb at the metacarpo-phalangeal joint and to abduct the first metacarpal. It likewise acts as a weak supinator of the forearm.

Relations.—It lies between the abductor pollicis longus and the extensor pollicis longus, by which its origin is partly overlapped. In company with the former muscle it passes medially from beneath the common extensor of the fingers and over the tendons of the radial carpal extensors to reach its osteo-fibrous canal under the dorsal carpal ligament.

Variations.—The head of the muscle may be fused with the long abductor. Its tendon of insertion may give rise to a slip inserted on the first metacarpal (in 2 out of 85 bodies—Le Double) or into the terminal phalanx. Its tendon is often united with that of the long extensor. It may be fused with the long abductor of the thumb and has been found missing. It may be doubled.

The extensor pollicis longus (fig. 369).—*Origin.*—From the middle third of the lateral part of the dorsal surface of the ulna; from the neighbouring part of the interosseous membrane; and from the septa between it and the extensor indicis proprius, and the extensor carpi ulnaris.

Structure and insertion.—The fibre-bundles converge in a bipenniform manner on the two sides of a tendon which appears high on the dorsal surface of the muscle. They extend as far as the dorsal carpal (posterior annular) ligament. The fusiform body of the muscle descends somewhat obliquely on the dorsal surface of the forearm. The tendon enters the third osteo-fibrous canal beneath the dorsal carpal (posterior annular) ligament. On emerging from the canal it passes very obliquely across the dorsal surface of the carpus, over the tendons of the radial extensors, to the ulnar side of the first metacarpal. It passes along this and on the dorsal surface of the first phalanx, expands to be inserted into the base of the second phalanx. The aponeurosis of insertion receives tendinous slips from the short muscles of the volar surface of the thumb.

Nerve-supply.—By a twig from the deep radial (posterior interosseous) nerve. The branch gives rise to twigs which enter the proximal third of the radial border of the muscle. The fibres arise from the sixth, seventh, and eighth cervical nerves.

Action.—To extend the second phalanx on the first, and this on the metacarpal. It also draws the whole thumb when extended toward the second metacarpal. It may have a slight supinator action on the forearm.

Relations.—The head of the muscle is partly overlapped by the long abductor of the thumb. It lies between this and the extensor pollicis brevis on one side, and the extensor indicis proprius on the other. Over it lie the extensors of the fingers and the ulnar carpal extensor.

Variations.—The tendon may give a slip to the base of the first phalanx of the thumb, to the dorsal carpal ligament, or to the index finger. It may receive an accessory slip from the common extensor of the fingers or the short extensor of the thumb. It is frequently doubled. An additional extensor is found in about 6 per cent. of bodies between the extensor of the index finger and that of the thumb. It has a double tendon and insertion into both digits (**extensor communis pollicis et indicis**).

The extensor indicis proprius (fig. 369).—*Origin.*—From the proximal part of the distal third of the posterior surface of the ulna, medial and distal to that of the preceding muscle, from the adjacent interosseous membrane, and from the septum between it and the extensor pollicis longus.

Structure and insertion.—The fibre-bundles are inserted on a tendon which first appears on the radial border of the muscle. The insertion of fibre-bundles extends nearly to the dorsal carpal (posterior annular) ligament. Here the tendon passes beneath that of the extensor of the little finger and enters the fourth osteo-fibrous canal beneath the lateral tendons of the common extensor. It passes across the wrist beneath the tendon from the extensor communis to the index finger, and is inserted on the ulnar side of this into the dorsal aponeurosis of the index finger opposite the base of the first phalanx.

Nerve-supply.—By a twig from the deep radial (posterior interosseous) nerve. This twig enters the proximal third of the radial border of the muscle. It frequently arises from a branch to the extensor pollicis longus. The nerve fibres come from the sixth, seventh, eighth cervical nerves.

Action.—To extend the first phalanx on the metacarpal. Like the common extensor it has a limited action on the two terminal phalanges. It also adducts the index finger and is a weak supinator of the forearm.

Relations.—It is covered by the superficial extensor group.

Variations.—These are frequent. It may be absent. There may be two heads, or the muscle may be completely doubled. It may receive an accessory slip from the ulna or the carpus. The tendon may give accessory slips to the middle finger, the ring finger, or the thumb. The accessory tendon to the middle finger is the most frequent. The tendon to the index finger may be inserted on the metacarpus.

Abnormal Muscles of the Back of the Wrist and Hand

The **extensor medii digiti** is a small muscle which arises from the ulna beneath the extensor of the index finger, with which it is more or less fused. It sends a tendon to the extensor aponeurosis of the middle finger or slips both to this finger and the index finger. It is present in about 10 per cent. of bodies (Le Double).

The **extensor digiti annularis** is a muscle similar to the extensor medii digiti, but much rarer.

The **extensor digitorum brevis,** which resembles the muscle of corresponding name on the dorsum of the foot, may have from one to four fasciculi, but most frequently one. The most common fasciculus is one which sends a tendon to the extensor tendon of the index finger. One for the middle finger is nearly as frequent. Others are rare. A fasciculus for the thumb has not been reported. (Le Double.) The fasciculi usually arise from the bones of the ulnar half of the carpus—lunatum (semilunar), triquetrum (cuneiform), hamatum (unciform), and capitatum (magnum), and from the dorsal ligaments uniting these bones. The tendons are inserted either into the corresponding extensor tendons or into the metacarpals. The muscle is found in about 10 per cent. of bodies (Wood).

Bursæ

B. m. extensoris carpi radialis brevis.—Between the tendon and the base of the third metacarpal.

B. m. abductoris pollicis longi.—Between the tendons of the long and short radial extensors and the tendons of the abductor pollicis longus and extensor pollicis brevis. Another bursa lies beneath the tendon of insertion of the abductor.

B. intermetacarpo-phalangeæ.—Between the lateral surfaces of the heads of the metacarpal bones of neighbouring fingers dorsal to the transverse capitular ligament.

B. tendinum m. extensoris digitorum communis.—Small bursæ are sometimes found beneath the tendons to the index and little fingers near where they begin to diverge from the common tendon.

B. m. extensoris carpi ulnaris.—A small bursa may be found under the tendon of origin of this muscle.

B. m. supinatoris.—Between the supinator and the tendon of the extensor muscles.

B. m. extensoris pollicis longi.—Between the tendon and the first metacarpal.

Synovial Tendon-sheaths

Vagina tendinum mm. extensorum carpi radialium.—Synovial sheaths cover the tendons of the two radial carpal extensors as they pass beneath the dorsal carpal (posterior annular) ligament. In the adult these sheaths usually are more or less fused and communicate with the sheath of the extensor pollicis longus where this crosses them.

Vagina tendinum mm. extensoris digitorum communis et extensoris indicis.—A synovial sheath surrounds the tendons of these muscles as they pass beneath the dorsal carpal (posterior annular) ligament. This sheath extends for some distance on the tendons as they diverge.

Vagina tendinis m. extensoris digiti quinti.—A synovial sheath extends on the tendon of this muscle from above the dorsal carpal (posterior annular) ligament to the base of the metacarpal.

Vagina tendinis m. extensoris carpi ulnaris.—This sheath commences above the carpal (posterior annular) ligament and extends to the insertion of the tendon.

Vagina tendinum mm. abductoris pollicis longi et extensoris pollicis brevis.—The sheaths which surround these two tendons beneath the dorsal carpal (posterior annular) ligament usually communicate freely.

Vagina tendinis m. extensoris pollicis longi.—A long synovial sheath surrounds this tendon. Where it crosses the tendons of the radial extensors, a communication is found with the sheath of the latter.

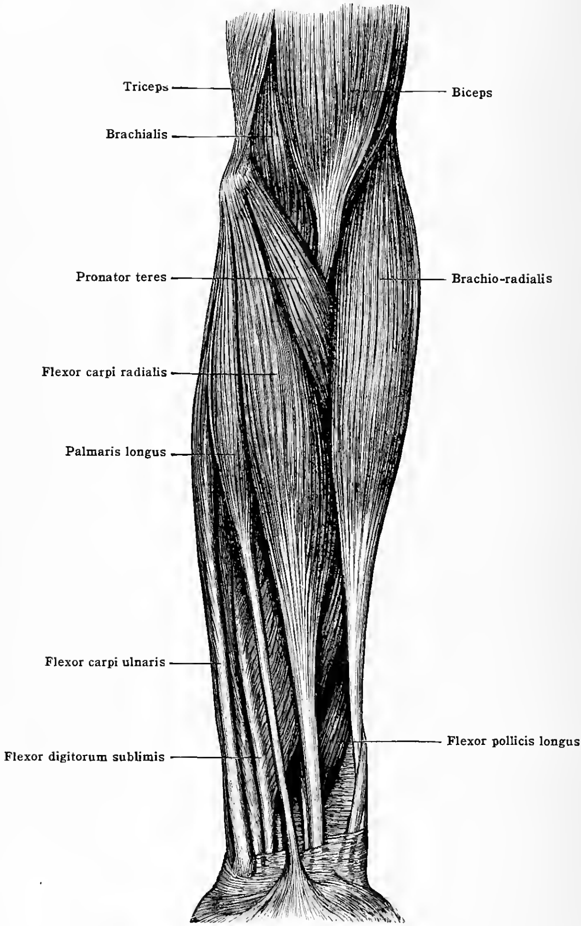
2. Ulno-Volar Division

The muscles on the volar side of the forearm lie in four layers.

a. First Layer
(Fig. 370)

Of the four muscles of associated ulnar epicondylar origin which constitute this layer the **pronator teres** is a strong, band-like muscle which is inserted into the lateral surface of the middle third of the shaft of the radius; the fusiform **flexor carpi radialis** sends a tendon to the base of the second metacarpal; the slender **palmaris longus** is inserted into the palmar fascia; and the medially situated, fusiform **flexor carpi ulnaris** into the pisiform bone and the palmar fascia. The pronator teres is the most powerful pronator of the forearm. When

FIG. 370.—FRONT OF THE FOREARM: FIRST LAYER OF MUSCLES.



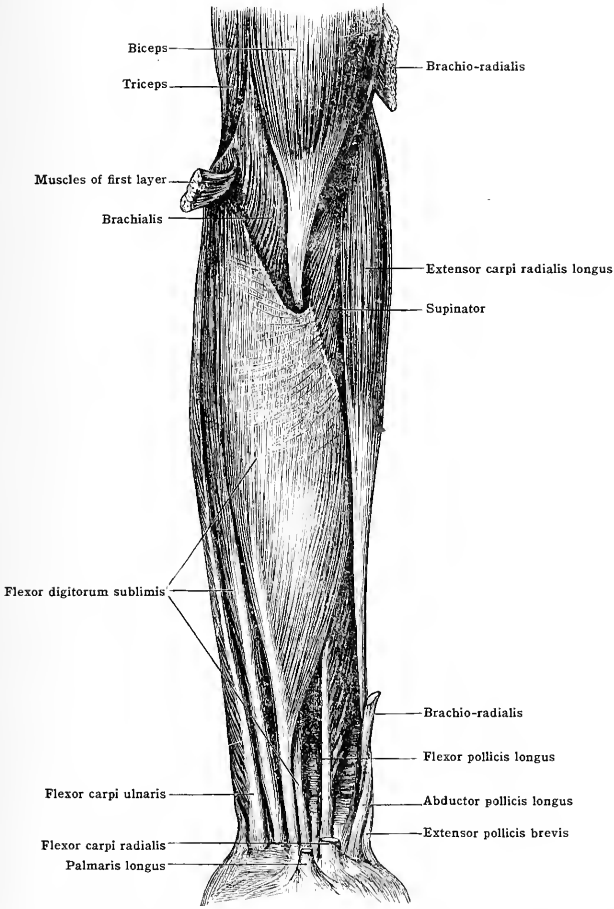
the hand is slightly flexed the ulnar carpal flexor abducts ulnarward. When the hand is greatly flexed lateral movement is difficult. The ulnar flexor is supplied by the ulnar nerve, the other muscles by the median.

The pronator teres probably corresponds with the popliteus of the leg. The flexor carpi radialis and flexor carpi ulnaris probably represent in the main the two heads of the gastrocnemius; and the palmaris longus, the plantaris.

The pronator teres (fig. 370).—*Origin.*—By two heads:—(1) The *humeral* or chief head arises by a tendon from the superior half of the ventral surface of the medial epicondyle and directly from the overlying fascia and from the intermuscular septa between it and the medial head of the triceps and the flexor carpi radialis. (2) The *ulnar*, deep or accessory, head arises by an aponeurotic band attached to the inner border of the coronoid process medial to the tendon of the brachialis. Between the humeral and ulnar heads is a fibrous arch beneath which the median nerve passes.

Structure and insertion.—The fibre-bundles of the humeral head are inserted in a penniform manner on a tendon which begins near the middle of the belly of the muscle on the superficial

Fig. 371.—Front of the Forearm: Second Layer of Muscles.



surface along the radial border. The tendon gradually becomes broader, winds about the volar surface of the radius, and is inserted into the middle third of its lateral surface. The attachment of fibre-bundles continues nearly to this insertion. The fibre-bundles of the ulnar head form a slender fasciculus which is inserted into the radial side of the deep surface of the humeral head.

Nerve-supply.—By a branch derived from the median nerve before it passes between the two heads of the muscle. The nerve enters the proximal part of the middle third of the main belly of the muscle on its deep surface near the radial border. The branch to the ulnar head usually enters this portion of the muscle somewhat proximal to its fusion with the humeral head. The nerve fibres arise from the sixth and seventh cervical nerves.

Action.—To pronate and flex the forearm.

Relations.—The muscle is superficially placed. Near its origin it is covered by the lacertus fibrosus of the biceps, and near its insertion by the radial vessels and nerve and the brachioradialis and radial extensor muscles. It is the most radial of the group of muscles under consideration. The radial border helps to bound an angular space, the cubital fossa, in which lie the brachial vessels, median nerve, and the tendon of the biceps. The median nerve passes between its humeral and ulnar heads. The muscle overlies the supinator, the brachialis, and the radial origin of the flexor digitorum sublimis muscles and the ulnar artery.

Variotions.—Supplementary fasciculi may arise from the humerus, the medial intermuscular septum of the arm, the flexor carpi radialis, the flexor sublimis, or the brachialis muscles. The two portions of the muscle may be distinct from origin to insertion. Either part of the muscle may be doubled. The ulnar head may be absent. The radial insertion may be extensive. Fasciculi may extend to the long flexor of the thumb. There may be a sesamoid bone in the tendon of origin from the humerus.

The flexor carpi radialis (fig. 370).—*Origin.*—From (1) the common tendon attached to the medial epicondyle; and (2) the septa between its head and the pronator teres, the flexor sublimis, and the palmaris longus.

Structure and insertion.—The fibre-bundles descend to converge upon a tendon at first intramuscular, but which in the middle of the arm appears on the volar surface of the muscle and soon becomes free from the attachment of fibre-bundles. The fibre-bundles from the epicondyle descend nearly vertically to the front and sides of the tendon, while those from the intermuscular septa take an oblique course to the deep surface of the tendon. The tendon is at first flat, but soon becomes cylindrical, bound to the superficial muscle fascia, and enters the hand through a special osteo-fibrous canal formed mainly by the groove in the os multangulum majus (trapezium) and the transverse carpal (anterior annular) ligament. It is inserted into the base of the second metacarpal. It usually also sends a tendon slip to the third.

Nerve-supply.—By a branch from the median nerve which divides into several twigs that enter the muscle near the junction of its proximal and middle thirds on the deep surface. The nerve usually arises near the elbow. The nerve fibres arise from the sixth, seventh (and eighth) cervical nerves.

Action.—To flex the hand at the wrist. To a slight extent it may also act as a pronator of the forearm and a flexor of the forearm on the arm.

Relations.—It is superficial except near its insertion. The belly of the muscle lies between the pronator teres and the palmaris longus and upon the flexor digitorum sublimis. The tendon of the muscle passes over the flexor pollicis longus, and near the wrist is a guide to the radial artery, which here lies lateral to it. In the hand the tendon lies beneath the thenar muscles and is crossed by the tendon of the long flexor of the thumb.

Variations.—It may receive a fasciculus from the brachialis or biceps muscles or from the radius or ulna. It may send tendon slips to the multangulum majus (trapezium), navicular, the transverse carpal (anterior annular) ligament, or the fourth metacarpal. The insertion may take place variously into these structures.

The palmaris longus (fig. 370).—*Origin.*—From the common tendon attached to the medial epicondyle and from the surrounding intermuscular septa.

Structure and insertion.—The fibre-bundles take a nearly parallel course to a tendon which appears high in the middle third of the forearm on the volar surface of the muscle. In the middle of the forearm the attachment of fibre-bundles usually ceases, the tendon becomes bound to the overlying fascia, and descends parallel with that of the radial flexor. Near the proximal border of the transverse carpal (anterior annular) ligament the tendon expands into radiating bundles of fibres of which the medial and lateral are attached to the fascia over the intrinsic muscles of the thumb and little finger, while the middle, much more developed, constitute the chief portion of the palmar aponeurosis.

Nerve-supply.—From a branch which usually arises in company with the nerve to the proximal part of the flexor sublimis. It frequently traverses the superficial fibres of the flexor sublimis. The nerve enters the middle third of the muscle.

Action.—To flex the hand. It is also a weak flexor and pronator of the forearm.

Relations.—It is placed between the radial and ulnar flexors over the flexor sublimis. In the distal part of the forearm the tendon lies over the median nerve.

Variations.—It is absent in 11.2 per cent. of instances (Le Double). It may be highly developed or reduced to a tendinous band. The belly of the muscle may lie in the distal instead of in the proximal part of the forearm. It may be digastric. It may be fused with neighbouring muscles. It may arise from the medial intermuscular septum of the arm or from the lacertus fibrosus, from the radius, from the coronoid process, from the radial or ulnar flexor, or from the flexor sublimis muscles. The tendon may terminate in the fascia of the forearm, the thenar eminence, the carpus, or the abductor of the thumb. The muscle may be partly or wholly doubled.

The flexor carpi ulnaris (fig. 370).—*Origin.*—By two heads:—(1) the **humeral head** arises from the common flexor tendon attached to the lower ventral part of the medial epicondyle Fibre-bundles of this head are also attached to the surrounding intermuscular septa and the deep fascia of the forearm. (2) The **ulnar head** arises by short tendinous fibres from the medial side of the olecranon and by an aponeurotic band common to it and the flexor digitorum profundus from the upper two-thirds of the dorsal border of the ulna. Proximally the two heads of the muscle are united by a fibrous arch extending from the olecranon to the medial epicondyle. Beneath this band pass the ulnar nerve and the dorsal recurrent ulnar artery. (See Epitrochleo-olecranonis, p. 402.)

Structure and insertion.—The fibre-bundles of the humeral head descend nearly vertically, those of the ulnar head obliquely distally in a radial direction. They are inserted in a penniform manner on a tendon which appears in the proximal part of the middle third of the belly of the muscle on the radial margin of the deep surface, and in the distal third of the forearm forms the radial border of the muscle. On the ulnar side the insertion of fibre-bundles continues nearly to the pisiform bone. The insertion of the tendon takes place chiefly into the pisiform bone, but from it tendinous bundles extend to the palmar aponeurosis, volar ligament of the carpus, to the pisohamate ligament (pisi-unciform), and to the bases of the fifth, fourth, and third metacarpals.

Nerve-supply.—From two or three branches of the ulnar nerve, the most proximal of which arises near the elbow-joint. These branches, which may arise by a single trunk, enter the deep surface of the proximal third of the muscle and send long twigs distally across the middle third of the constituent fibre-bundles. The nerve fibres arise from the seventh and eighth cervical and first thoracic nerves.

Action.—To flex the hand and to abduct the hand ulnarward.

Relations.—It is superficially placed. Its aponeurotic origin is adherent to the fascia of the forearm. It lies medial to the palmaris longus and flexor sublimis and upon the flexor profundus. Beneath the muscle lies the ulnar nerve. The ulnar artery extends along the radial border of the tendon near the wrist.

Variations.—These are rare. Slips from the tendon may pass to the metacarpo-phalangeal articulation of the little finger. (See, however, Abnormal Muscles, p. 402.)

b. Second Layer

This is composed of one muscle, the **flexor digitorum sublimis,** which, although in part covered by the muscles of the preceding layer, is in part superficial. It arises from the medial epicondyle of the humerus, and from the radius and the ulna, and sends tendons to the second row of phalanges of the fingers. It corresponds probably with the soleus and the tendons of the flexor digitorum brevis in the leg and foot.

The flexor digitorum sublimis (figs. 371, 373, 375).—*Origin.*—By two heads: the **ulnar or chief head** arises (1) by the tendon common to it and the superficial group of muscles from the medial epicondyle, and by short tendinous bands from the ventral surface of the epicondyle; (2) from the ulnar collateral ligament of the elbow, the ulnar tuberosity, the medial border of the coronoid process, and the inferior extremity of the tendon of the brachialis; and (3) from the intermuscular septum between the flexor sublimis and the overlying muscles. The **radial head** arises from an oblique line on the volar surface of the radius, and from the middle third of the anterior border.

Insertion.—Into the sides of the volar surface of the shafts of the second row of phalanges of the fingers.

Structure.—The fibre-bundles of the ulnar head and the upper part of the radial head converge, the ulnar fibre-bundles nearly vertically, the radial obliquely, to form a common belly the deep surface of which on the ulnar side is backed by a dense tendinous band. On the radial side of this a less dense membrane covers over an oval canal which passes distally along the line of junction of the two heads and lodges the ulnar artery and the median nerve.

The fibre-bundles of the ulnar head form a superficial and a deep group. The superficial portion near the middle of the forearm divides into a lateral and a medial division, the former being inserted on a tendon that goes to the middle and the latter on one that goes to the ring finger. The fibre-bundles of the radial head join with the lateral division of the superficial layer of the ulnar head and are inserted on the tendon of the middle finger nearly as far as the wrist. A small muscle fasciculus of the superficial portion of the ulnar head is usually united by a tendon to the long flexor of the thumb.

The deep portion of the ulnar head about the middle of the forearm terminates in large part on the volar surface of the dense tendinous band above mentioned. From this in turn two muscle bellies arise. One of these is inserted in a bipenniform manner on a tendon going to the index finger, the other on a tendon going to the little finger. A muscle fasciculus also usually passes from the region of the tendon band to that portion of the superficial fasciculus which terminates on the tendon of the ring finger.

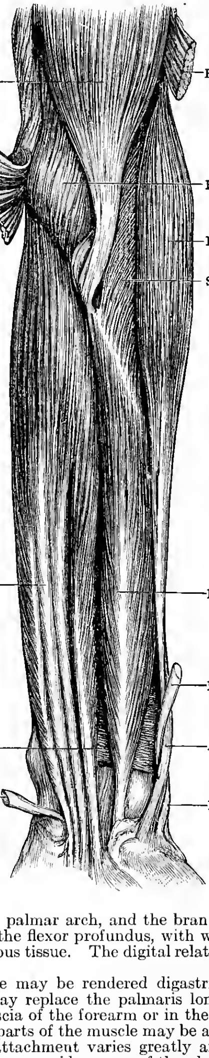
The four tendons pass together through the carpal canal under the transverse carpal (anterior annular) ligament, those to the middle and ring fingers lying at first superficial to the other two. The tendons then diverge, and each tendon, together with and above a tendon of the flexor profundus, passes over the metacarpo-phalangeal joint into an osteo-fibrous canal on the palmar surface of the first phalanx of the finger for which it is destined. Here the tendon becomes flattened about the round tendon of the flexor profundus. Opposite the middle of the phalanx the tendon divides into two slips, between which the tendon of the flexor profundus passes. The divided halves of the sublimis tendon fold about the profundus tendon so that their lateral edges come to meet in the mid-line beneath this tendon opposite the phalangeal joint (figs. 375, 376). They then again separate, extend distally, and are attached one on each side into a ridge at the middle of the lateral border of the second phalanx. The tendons are also attached by **vincula tendinum, a ligamentum breve,** between the tendon and the head of the first phalanx and the joint, and a **ligamentum longum,** between the tendon and the volar surface of the first phalanx.

Nerve-supply.—Before the median nerve passes between the two heads of the pronator teres a branch arises which accompanies the nerve through the pronator and sends several branches into the proximal third of the ulnar head of the muscle. As the median nerve passes beneath the muscle, one or more branches are given to the radial head, and a long branch is given to the fasciculus of the second and from this one to that of the fifth digit. Occasionally, the median nerve in the distal third of the forearm gives rise to branches for these fasciculi. The nerve fibres arise from the seventh and eighth cervical and first thoracic nerves.

Action.—Chiefly to flex the second phalanx of each finger on the first; secondarily, to flex the fingers on the hand and the hand on the forearm.

Relations.—The belly of the muscle is covered by the pronator teres, flexor carpi radialis, and palmaris longus, but is superficial along a narrow strip between the flexor carpi ulnaris and the palmaris longus, and on each side of the tendon of the flexor carpi radialis. The muscle rests on the flexor pollicis longus and flexor digitorum profundus, the median nerve (see description given above) and ulnar vessels. The median nerve emerges from beneath the radial border of the muscle in the lower third of the forearm. In the palm the tendons lie beneath the

FIG. 372.—FRONT OF THE FOREARM: THIRD LAYER OF MUSCLES.



palmar aponeurosis, the superficial palmar arch, and the branches of the median nerve, while they lie in front of the tendons of the flexor profundus, with which they are closely associated into a common bundle by loose fibrous tissue. The digital relations of the tendons are described above.

Variations.—The whole muscle may be rendered digastric by a transverse tendon. A fasciculus of the flexor sublimis may replace the palmaris longus or the two may coexist. A fasciculus may terminate in the fascia of the forearm or in the transverse carpal ligament, the palmar aponeurosis, etc. Various parts of the muscle may be absent or more independent than usual. The extent of the radial attachment varies greatly and may be missing. A special fasciculus may be received from the coronoid process of the ulna. A fasciculus may be sent to the flexor profundus or to other muscles. There may be some fusion with neighbouring muscles.

c. Third Layer

(Figs. 372–376)

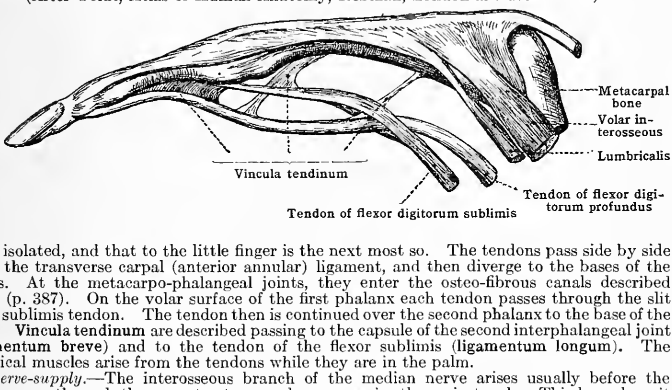
The two muscles which constitute this layer may be looked upon as differentiated from a single deep flexor muscle. The **flexor digitorum profundus** is a strong, broad muscle which arises from the upper three-fourths of the volar surface of the ulna and gives rise to tendons which are inserted into the bases of the third row of phalanges of the fingers. The **flexor pollicis longus,** likewise broad and flat, arises from the volar surface of the radius and is inserted into the base of the second phalanx of the thumb. Both muscles are supplied by the median nerve and the flexor profundus is also supplied by the ulnar nerve.

These muscles correspond to the flexor digitorum longus and the flexor hallucis longus of the leg.

The flexor digitorum profundus (figs. 372–376).—*Origin.*—(1) Through an aponeurotic septum between it and the flexor carpi ulnaris from the dorsal border of the ulna; (2) directly from the proximal two-thirds of the medial surface and the proximal three-fourths of the volar surface of the ulna and from the adjacent interosseous membrane; and (3) inconstantly, from a small area on the radius below the bicipital tuberosity.

Structure and insertion.—The fibre-bundles descend nearly vertically and give rise to a common belly which soon divides into four portions, each of which is attached about midway down the forearm in a semipenniform manner to the dorsal surface of a tendon. The attachment of fibre-bundles continues nearly to the wrist. The digital divisions of the muscle vary in the height to which they extend. That belonging to the index finger is usually the one most exten-

Fig. 373.—Insertions of the Tendons of the Muscles which act on the Finger. (After Toldt, Atlas of Human Anatomy, Rebman, London and New York.)



sively isolated, and that to the little finger is the next most so. The tendons pass side by side under the transverse carpal (anterior annular) ligament, and then diverge to the bases of the fingers. At the metacarpo-phalangeal joints, they enter the osteo-fibrous canals described above (p. 387). On the volar surface of the first phalanx each tendon passes through the slit in the sublimis tendon. The tendon then is continued over the second phalanx to the base of the third. **Vincula tendinum** are described passing to the capsule of the second interphalangeal joint (**ligamentum breve**) and to the tendon of the flexor sublimis (**ligamentum longum**). The lumbrical muscles arise from the tendons while they are in the palm.

Nerve-supply.—The interosseous branch of the median nerve arises usually before the nerve passes through the pronator teres and accompanies the main trunk. This branch as it passes beneath the flexor sublimis gives off a branch (or two) from which several twigs spring. These twigs enter the muscle near the radial border and pass in across the middle third of the constituent fibre-bundles of the fasciculi to the index and middle fingers. The ulnar nerve near the elbow gives rise to a branch which enters the volar surface of the muscle near the junction of the proximal and middle thirds of that portion of the belly, giving tendons to the ring and little fingers. There is some variation in the extent of the innervation by the branches of the ulnar and those of the median nerve. To a greater or less extent through anastomosis their territories overlap. The nerve fibres arise from the seventh and eighth cervical and first thoracic nerves.

Action.—To flex the terminal phalanx of each finger on the second and the second on the first, while that of the superficial flexor is to flex the second phalanx on the first. The action of the two flexors on the first phalanx is somewhat more limited. The interosseous muscles, aided by the lumbricals, are the chief flexors of the first row of phalanges. The flexor profundus acts, though not powerfully, as a flexor of the wrist.

Relations.—The flexor profundus muscle lies beneath the flexor sublimis and the flexor carpi ulnaris muscles, the median nerve, and the ulnar vessels and nerve. Under the muscle lie the ulna, the interosseous membrane, and the pronator quadratus muscle. Under the transverse carpal (anterior annular) ligament the tendons lie beneath those of the flexor sublimis in the same synovial sac. In the palm the tendons with the associated lumbrical muscles lie upon the interosseous muscles, the adductor of the thumb, and the deep palmar arch, and beneath the flexor sublimis tendons. For the relations to the synovial bursæ see p. 403.

Variations.—There is considerable variation in the extent of the radial origin and in the extent of the independence and fusion of the different fasciculi. In the prosimians a common tendon extends as far as the hand. The division in the higher forms is associated with refinement of movements of the fingers. One or more special fasciculi not infrequently join the muscle from the flexor sublimis, the flexor pollicis longus, the medial epicondyle, or the ulna. The **accessorius ad flexorem digitorum profundum** is a fasciculus which arises from the coronoid process of the ulna and sends a tendon to join the tendon of one of the fingers, most frequently the middle or index. It is found in 20 per cent. of bodies.

The flexor pollicis longus (fig. 372).—*Origin.*—The attachment extends along the oblique line and the ventral border of the radius from slightly below the bicipital tuberosity to within 5 cm. of the wrist. Medially it is continued into the interosseous membrane. Proximally the tendon frequently extends to the distal radial margin of the coronoid process of the ulna and gives rise to fibre-bundles connected with the muscle, as well as to a fasciculus of the flexor profundus.

Structure and insertion.—The fibre-bundles descend obliquely to be inserted in a penniform manner on a tendon which begins high up on the volar surface near the ulnar border of the muscle, and descends as a broad band which near the wrist becomes cylindroid. The insertion of fibres continues nearly to the point where the tendon passes under the transverse carpal ligament. Here the tendon enters the carpal canal radial to the tendons of the flexor profundus, and passes beneath the superficial head of the short flexor of the thumb, then between the thumb sesamoids into the osteo-fibrous canal of the thumb, in which it is continued to the base of the terminal phalanx.

Nerve-supply.—Usually from two branches of the volar interosseous ramus of the median nerve. These enter the proximal half of the ulnar margin of the muscle. The nerve fibres arise from the sixth, seventh (and eighth) cervical nerves.

Action.—It is a strong flexor of the second phalanx on the first and has less powerful action on the metacarpo-phalangeal joint and on the wrist.

Relations.—It lies beneath the flexor sublimis, the flexor carpi radialis and brachio-radialis muscles, and the radial artery. Near the wrist it crosses over the insertion of the pronator quadratus. In the hand the tendon runs beneath the opponens pollicis and the superficial head of the flexor brevis, and across the deep head of the latter.

Variations.—It may be fused or united by fasciculi with the flexor profundus, the flexor sublimis, or the pronator teres. It may be partially doubled, giving rise to an accessory tendon which extends to the index finger. The origin may extend to the medial epicondyle of the humerus (epitrochlear bundle).

d. Fourth Layer

This layer consists of a single quadrilateral muscle which passes transversely across the lower part of the forearm from the ulna to the radius. In the leg there is no corresponding muscle.

The pronator quadratus (fig. 377).—*Origin.*—Medial side of the volar surface of the lower fourth of the ulna.

Structure and insertion.—From the ulna a strong aponeurosis extends a third of the way across the volar surface of the muscle. From this membrane and from the bone fibre-bundles extend transversely to be inserted on the distal quarter of the volar surface of the radius and on the triangular area above the ulnar notch. The deeper fibre-bundles which arise directly from the ulna are inserted into the radius by means of an aponeurosis. The superficial and deep portions of the muscle are often separated. The muscle is thicker distally than proximally.

Nerve-supply.—The volar interosseous nerve descends along the interosseous membrane, passes behind the middle of the proximal margin of the muscle, and sends branches into its deep surface. The nerve fibres arise from the (sixth), seventh and eighth cervical and first thoracic nerves.

Action.—To pronate the forearm.

Relations.—The muscle lies immediately beneath the muscles of the third layer and upon the radius and ulna, the interosseous membrane, and radio-ulnar joint. The radial artery and ulnar nerve pass in front of it, the volar interosseous artery behind it.

Variations.—It may be missing or may extend further up the forearm than usual or down upon the carpus. It may be triangular or divided into parts the fibre-bundles of which take different directions. It may send fasciculi to the carpus or metacarpus or be fused with the flexor carpi radialis brevis (see below).

Abnormal Muscles of the Volar Side of the Forearm and Wrist

The epitrochleo-olecranonis (anconeus internus).—A muscle fasciculus, distinct from the distal margin of the triceps, which runs from the medial epicondyle to the olecranon over the groove for the ulnar nerve, by a branch of which it is supplied. It takes the place of the fibrous arch normally extending between the epicondylar and ulnar heads of the flexor carpi ulnaris. It occurs in about 25 per cent. of bodies (Testut), and represents an adductor of the olecranon of the lower mammals. Occasionally the medial head of the triceps may descend over the ulnar groove, but this forms another type of muscle variation.

The flexor carpi ulnaris brevis (ulno-carpeus).—An abnormal muscle which arises from the distal quarter of the volar surface of the ulna and is inserted into the hamatum (unciform), the pisiform, the abductor of the little finger, or the superior extremity of the fifth metacarpal.

The unci-pisiformis.—A short, thick band of muscle which runs from the pisiform to the tip of the hamulus of the os hamatum (unciform) parallel with the pisohamate (pisi-unciform) ligament. It is innervated by the ulnar nerve.

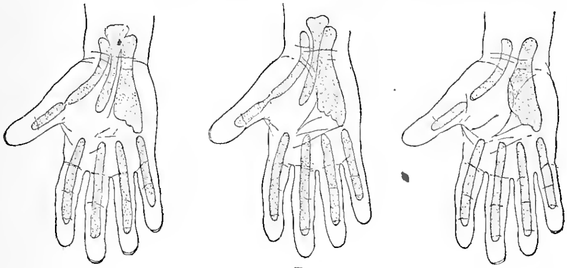
The flexor carpi radialis brevis (radio-carpeus).—An abnormal muscle found in about 5 per cent. of bodies (Le Double). It arises from the lateral or the volar surface of the distal half of the radius. Some of the fibre-bundles may spring from the pronator quadratus, the fascia of the forearm, or the ulna. It is inserted into the carpus or metacarpus, and occasionally even into the first phalanx of the index finger, etc. It is supplied by a branch of the volar interosseous nerve. It serves to flex the wrist. It is said to represent the tibialis posterior of the leg.

Bursæ

B. m. flexoris carpi ulnaris.—Between the tendon of this muscle and the pisiform bone.

B. m. flexoris carpi radialis.—Between the tendon of this muscle and the tubercle of the navicular bone.

Fig. 374.—Synovial Sheaths of the Tendons of the Long Flexors of the Fingers
A. Frequent type; B. normal type; C. fœtal type. (After Poirier and Charpy.)



A bursa is often found between the tendon of the deep flexor of the index finger and the carpus. This bursa is frequently in communication with the radial and ulnar tendon sheaths.

A bursa is also often found between the deep and superficial tendons of the index finger.

Synovial Tendon Sheaths

(Figs. 366 and 374)

Vagina tendinis m. flexoris carpi radialis.—About the tendon as it passes beneath the transverse carpal ligament.

Vaginæ tendinum mm. flexorum digitorum.—The osteo-fibrous canals of the digits are lined by a synovial membrane which is reflected by means of a fold (cul-de-sac) to the tendons at each end and over the vincula tendinum, in which blood-vessels and nerves for the tendons are contained. The synovial cavity of the first and usually that of the fifth digit communicate with those of the palm.

In the wrist and palm two large synovial sacs may usually be recognized, although the number may be raised to five or reduced to one.

The radial sac, **vagina tendinis m. flexoris pollicis longi,** surrounds the long flexor tendon of the thumb in the wrist and palm and usually communicates with that of the thumb. In the palm a well-marked mesotendon usually extends to the deep ulnar side of the tendon from the parietal layer of the sheath.

The ulnar sac, **vagina tendinum mm. flexorum communium,** surrounds the tendons of the long flexors of the fingers. It begins proximal to the transverse carpal ligament and extends nearly or quite to the synovial sheath of the little finger on the ulnar side and on the radial side to the centre of the palm.

3. Musculature of the Hand

(Figs. 366, 368, 375–379)

The intrinsic muscles of the hand are taken up in the following groups:—

a The subcutaneous muscle of the palm.
b The muscles of the little finger.
c The muscles of the thumb.
d The lumbrical muscles.
e The interosseous muscles.

The ulnar nerve supplies the muscles of the little finger, the interossei, the medial lumbrical muscles, and two of the muscles of the thumb; the median nerve supplies most of the muscles of the thenar region and the lateral lumbrical muscles.

(a) *Subcutaneous Muscle*

(Fig. 375)

The **palmaris brevis** is a small, trapezoid sheet situated between the hypothenar fascia and the skin. It arises at the lateral edge of the palmar aponeurosis from tendinous slips which may be traced through the aponeurosis to the navicular and greater multangular. It is composed of nearly parallel fibre-bundles, and extends into the deep surface of the skin along the ulnar border of the palm. It is generally taken to be a subcutaneous muscle like the superficial muscles of the head and neck. It has, however, been suggested that it represents the remnants of a short flexor of the digits corresponding with the flexor digitorum brevis of the foot.

Nerve-supply.—The superficial branch of the palmar division of the ulnar nerve gives rise to a twig which enters the deep surface of the muscle. The fibres come from the (seventh and) eighth cervical and first thoracic nerves.

Action.—The action of the muscle is to draw the skin of the ulnar side of the hand toward the centre of the palm. It is said that it thus helps to form a cup-shaped hollow when the hand conveys fluid to the mouth. The contraction of the muscle by raising a ridge over the ulnar nerve and artery when an object is grasped hard serves, according to Henle, to protect these structures.

Variations.—It varies in size. In about 2 per cent. of bodies it is absent (Le Double). It may send tendinous slips to the pisiform bone. (For a thenar subcutaneous muscle, see variations of the abductor pollicis brevis.)

(b) *Muscles of the Little Finger*

(Figs. 375, 376, 377)

In the hypothenar eminence are three muscles, the abductor, the flexor brevis, and the opponens digiti quinti. The **abductor digiti quinti** is a flat, fusiform muscle which arises from the pisiform and is inserted into the ulnar border of the first phalanx and into the dorsal aponeurosis through which it helps to flex the first and extend the second and third phalanges of the little finger. The fusiform **flexor brevis** arises from the hamatum (unciform) and adjacent part of the transverse carpal (anterior annular) ligament and is *inserted into* the ulnar side of the base of the first phalanx. The triangular **opponens** likewise arises from the hamatum (unciform) and the transverse (anterior annular) ligament. It is inserted into the ulnar border and the head of the fifth metacarpal.

The abductor of the little finger corresponds with that of the little toe. A part of the opponens beneath the ulnar nerve corresponds with that of the little toe, while the more superficial portion is unrepresented in the foot. The flexor brevis of the little toe corresponds with a part of the deep portion of the opponens of the little finger. The flexor brevis of the little finger is unrepresented in the foot. (Cunningham.)

The abductor digiti quinti (figs. 375, 376).—*Origin.*—From the distal half of the pisiform, the ligaments between this and the hamatum, the tendon of the flexor carpi ulnaris, and often from the transverse carpal (anterior annular) ligament.

Structure and insertion.—The fibre-bundles descend vertically, at first increasing in number and then concentrated, toward two short tendons one of which is inserted into the ulnar border of the first phalanx of the little finger and the other into the aponeurosis of the extensor tendon of the little finger.

Nerve-supply.—From the deep palmar division of the ulnar nerve before it passes through the opponens, or from the superficial palmar branch, arise one or more twigs which enter the radial side of the muscle on its deep surface in the proximal third. The nerve fibres arise from the (seventh and) eighth cervical and first thoracic nerves.

Action.—To abduct the little finger, flex the first phalanx, and extend the last two.

Relations.—It overlies the opponens and flexor brevis. Superficially it is covered by fascia and the palmaris brevis muscle. Along the proximal part of its radial margin run the deep palmar branches of the ulnar artery and nerve.

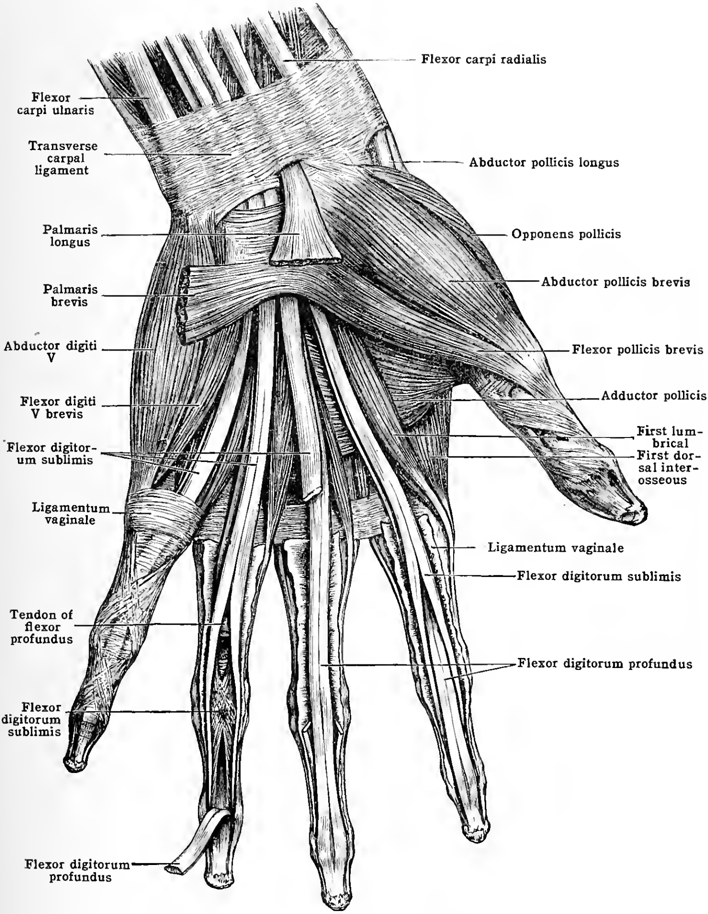
Variations.—It may be missing or doubled. It may be fused with the short flexor or receive fasciculi from the palmaris longus, the ulnar flexor, the fascia of the forearm, etc.

The flexor digiti quinti brevis (figs. 376, 377).—*Origin.*—By a short tendon from the hook of the hamatum (unciform) and from the adjacent parts of the transverse carpal (anterior annular) ligament.

Structure and insertion.—The fibre-bundles take a nearly parallel course and are inserted by a short tendon which is fused with that of the abductor and is inserted into the ulnar side of the base of the first phalanx of the little finger. A sesamoid bone may lie in the tendon.

Nerve-supply.—A branch from the superficial or deep palmar division of the ulnar nerve enters the deep surface of the muscle in its proximal half. The nerves to the abductor and flexor may arise in common from the ulnar. The nerve fibres arise from the (seventh and) eighth cervical and first thoracic nerves.

FIG. 375.—THE SUPERFICIAL MUSCLES OF THE PALM OF THE HAND.



Action.—To flex the first phalanx of the little finger. When it sends a tendon slip to the aponeurosis of the extensor of the finger it helps to extend the two terminal phalanges.

Relations.—The muscle closely adjoins and is partly covered by the abductor. The palmaris brevis and the lateral volar digital artery to the fifth finger lie superficial to it. Under it lies the opponens.

Variations.—The muscle may be wanting or may be closely fused with the abductor or the opponens. It may receive an accessory slip from the forearm fascia. It may give a tendon slip to the extensor aponeurosis or to the head of the fifth metacarpal.

The opponens digiti quinti (fig. 377).—*Origin.*—Partly tendinous, from the distal ulnar border of the hook of the hamatum (unciform) and from the adjacent transverse carpal (anterior annular) ligament.

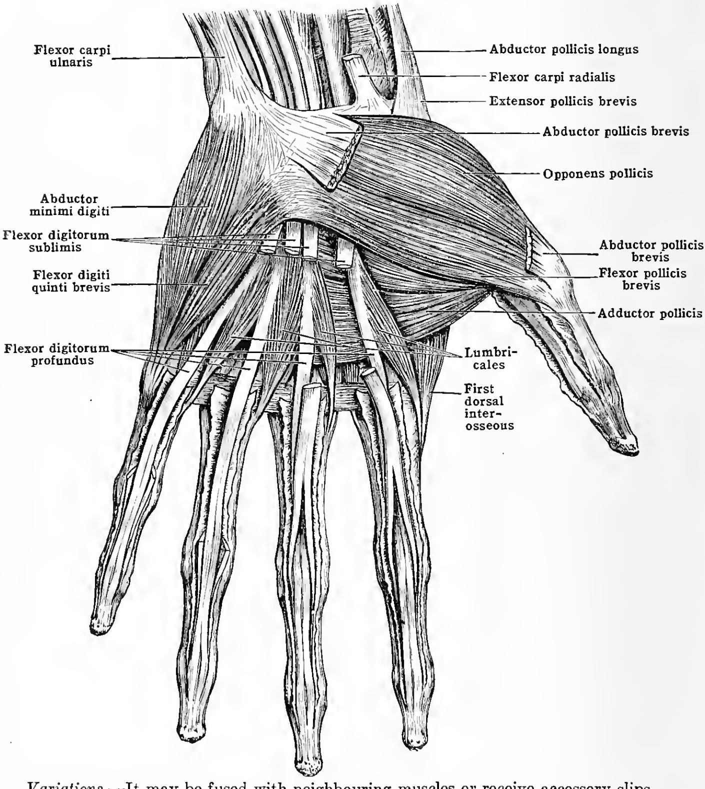
Structure and insertion.—The fibre-bundles diverge, the proximal short and horizontal, the distal long and oblique, and are inserted on the whole of the ulnar border and on a part of the head of the fifth metacarpal. Often the muscle is divisible into two portions between which the ulnar nerve runs.

Nerve-supply.—Before the deep palmar branch passes through the muscle it gives rise to a twig which enters its volar surface in the middle third near the ulnar margin. The nerve fibres arise from the (seventh and) eighth cervical and first thoracic nerves.

Action.—To flex, adduct, and slightly rotate the fifth metacarpal; as, for example, in 'cupping' the hand to drink from it.

Relations.—The opponens lies beneath the abductor and flexor brevis muscles. The deep branches of the ulnar nerve and artery pass through the opponens near its carpal origin and then under it extend into the palm.

Fig. 376.—The Deeper Muscles of the Palm of the Hand.



Variations.—It may be fused with neighbouring muscles or receive accessory slips.

The tensor capsularis articulationis metacarpo-phalangei digiti quinti is a slender muscle which arises from the ligaments which unite the pisiform to the hamatum, and is inserted into the volar surface of the metacarpo-phalangeal joint of the little finger.

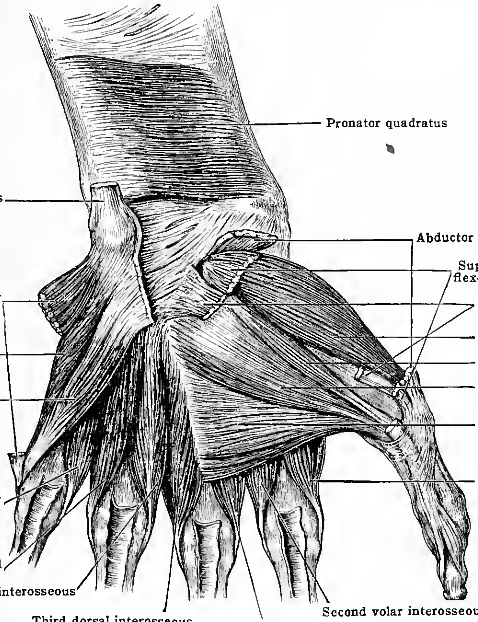
(c) *Muscles of the Thumb*

(Figs. 375, 376, 377)

In the thenar region there are four muscles. Of these, the abductor pollicis brevis is the most superficial. Then come the opponens pollicis and the short flexor, and beneath the last the adductor pollicis. All are triangular in form. The **abductor pollicis brevis** arises from the radial side of the volar surface of the carpus and is inserted into the radial side of the base of the first phalanx of the thumb. The **opponens** is a thick muscle extending from the transverse carpal (anterior annular) ligament to the radial side of the first metacarpal. The **flexor pollicis brevis** arises by two heads, a "deep" and a "superficial" from the carpus and is inserted into the radial side of the base of the first phalanx. The **adductor pollicis** arises from the carpus and the second and third metacarpals and is inserted into the ulnar side of the first phalanx of the thumb. From the tendons of insertion of the abductor and flexor brevis slips are continued into the dorsal aponeurosis of the thumb so that they aid in extending the second phalanx.

In the foot an opponens hallucis occurs as an abnormal muscle. The abductor, flexor brevis and adductor of the thumb are represented by the corresponding muscles of the big toe, although

Fig. 377.—The Pronator Quadratus and Deep Muscles of the Palm.



the last two muscles are not perfectly homologous in the hand and foot.

The abductor pollicis brevis (fig. 375).—*Origin.*—From the volar surface of the transverse carpal (anterior annular) ligament, and from the greater multangular bone (trapezium). Also often from the navicular bone and from a tendon slip of the long abductor.

Structure and insertion.—The fibre-bundles converge upon a flat tendon with two lamellæ, the deeper of which is inserted into the radial side of the base of the first phalanx of the thumb and the superficial into the aponeurosis of the extensor pollicis longus.

Nerve-supply.—By a branch of the first volar digital ramus of the median nerve. This branch passes over or through the flexor brevis and enters the muscle on the volar surface in the middle third near its ulnar border.

Action.—To abduct the thumb, flex the first phalanx, and extend the terminal phalanx.

Relations.—It lies beneath the thenar fascia lateral to the superficial head of the flexor brevis and over the opponens. The superficial volar artery usually perforates the muscle.

Variations.—It may be wanting or may be divided into two divisions. The origin may extend to the fascia of the forearm or styloid process of the radius. It may receive an accessory slip from the long radial extensor, the opponens, or the short extensor of the thumb. A *thenar subcutaneous muscle* is occasionally present. It is narrow, is closely associated with the short abductor of the thumb, and extends from the radial side of the base of the first metacarpal into the skin of the thenar eminence.

The opponens pollicis (fig. 377).—*Origin.*—From the volar surface of the transverse carpa (anterior annular) ligament and from the tubercle of the greater multangular bone (trapezium).

Structure and Insertion.—The fibre-bundles extend obliquely in a nearly parallel direction to their insertion along the whole lateral border of the volar surface of the shaft and the head of the first metacarpal.

Nerve-supply.—By a branch of the first volar digital ramus of the median nerve. This branch passes over or through the superficial division of the flexor brevis near the origin of the muscle. One or two twigs enter the deep surface of the proximal third of the opponens near its ulnar border. The nerve fibres arise from the sixth and seventh cervical nerves.

Action.—To flex, adduct, and rotate medialward the first metacarpal bone. The volar surface of the thumb is thus brought to face the volar surface of the other digits.

Relations.—It lies beneath the thenar fascia and the abductor brevis. The flexor brevis overlies its ulnar border.

Variations.—It may be absent or it may be divided into two heads. It is usually more or less fused with the short flexor.

The flexor pollicis brevis (figs. 376, 377).—The muscle is divided by the tendon of the long flexor into a superficial and a deep portion. The **superficial head** arises from the greater multangular bone (trapezium), the adjacent part of the transverse carpal (anterior annular) ligament, and the tendon sheath of the flexor carpi radialis. The fibre-bundles descend closely applied to the opponens, and terminate by a tendon which is attached to the lateral side of the front of the base of the first phalanx. Over the joint a sesamoid bone lies in the tendon. The **deep head** has a tendinous origin from the os multangulum minus (trapezoid) and the os capitatum (magnum). The fibre-bundles take an oblique course, to be inserted into the tendon of the superficial part. A muscle fasciculus which arises from the ulnar side of the base of the first metacarpal and the neighbouring carpal ligaments and is inserted on the ulnar side of the base of the first phalanx, is sometimes considered to be the deep head of the flexor brevis. It is closely bound up with the carpal head of the adductor pollicis and they have a common tendon. Some fibres of the medial division of the tendon may be traced into the aponeurosis of the extensor tendon. It is probable that this portion of the muscle represents a first volar interosseous, and it is so described later with the interosseous muscles. There is much dispute as to what fasciculi should be included in the flexor brevis.

Nerve-supply.—The muscle is usually supplied by twigs derived from a branch from the first volar digital ramus of the median nerve as this branch passes through its substance, and by twigs from the deep branch of the ulnar. Brookes found this supply in 19 out of 29 instances, in 5 by the median alone, and in 5 by the ulnar alone. The nerve fibres come from the sixth and seventh cervical nerves.

Action.—To flex, adduct, and rotate medialward the metacarpal of the thumb; flex the first phalanx; and extend the second phalanx.

Relations.—Proximally the short flexor is grooved for the tendon of the long flexor, beneath which more distally the deep head of the muscle passes laterally. The superficial portion of the muscle lies beneath the skin. The ulnar border of the deep head is fused proximally with the adductor.

Variations.—The deep head may be absent. Either or both heads may be double. The superficial head may be fused with the abductor brevis, and is usually more or less fused with the opponens.

The adductor pollicis (fig. 377).—*Origin.*—By two heads. The **carpal or oblique head** arises from the deep carpal ligaments, the capitatum and the bases of the second and third metacarpals; the **metacarpal or transverse head,** from the crest of the third metacarpal, from the suprametacarpal fascia of the third interspace, and sometimes also from that of the fourth interspace and from the capsules of the second, third, and fourth metacarpo-phalangeal articulations.

Structure and insertion.—The fibre-bundles converge toward a tendon which is inserted into the ulnar side of the front of the base of the first phalanx of the thumb. A sesamoid bone lies in the tendon over the joint.

Nerve-supply.—One or more twigs from the deep palmar branch of the ulnar enter the middle third of the muscle on its deep surface. There may also be an anastomosing branch from the median nerve. The nerve fibres come from the sixth, seventh and eighth cervical and first thoracic nerves.

Action.—To adduct and flex the first metacarpal and flex the first phalanx of the thumb. When the thumb is in an extreme position of apposition, it acts as an abductor.

Relations.—Superficial to the muscle lie some of the tendons of the deep flexor of the fingers and the first two lumbrical muscles. It extends over the two more lateral intermetacarpal spaces, and is in part subcutaneous on the dorsal surface. The deep palmar arch extends between the two heads and beneath the oblique head. The oblique head of the muscle is closely united to the first volar interosseous, so that the latter by some is considered a part of the adductor.

Variations.—The extent of the attachments of origin of the muscle vary considerably. The two heads of the muscle may be more or less completely separated from one another. Each may be divided into separate fasciculi.

(*d*) *Lumbrical Muscles*

From the deep flexor tendons in the palm of the hand arise the lumbrical muscles, four in number, which are attached by small tendons to the radial side of the extensor tendons (figs. 373, 375). These lumbrical muscles have homologues in the sole of the foot.

The **lumbricales** (figs. 375, 376).—*Origin.*—The two lateral arise from the radial side of the volar aspect of the first and second tendons of the flexor digitorum profundus; the two medial arise from the adjacent sides of the second and third and third and fourth tendons.

Structure and insertion.—The fibre-bundles of each muscle arise directly from the flexor tendons near the distal border of the transverse carpal (anterior annular) ligament. They converge as far as the metacarpo-phalangeal joint, upon a small tendon which begins about the middle of the muscle. The tendon passes out between the palmar aponeurosis and the transverse capitular ligament, winds about the metacarpo-phalangeal joint, expands, and is attached along the side of the first phalanx to the radial border of the tendon of the extensor digitorum communis.

Nerve-supply.—Branches from the median nerve enter the middle third of the radial border of the first two or three lumbrical muscles. The last one or two are supplied by branches from the deep volar branch of the ulnar nerve, which enter the middle third of the deep surface. The third lumbrical and sometimes one or more of the others may receive a branch from both nerves. The nerve fibres come from the eighth cervical and first thoracic nerves.

Action.—Together with the interosseous muscles they flex the basal phalanges on the metacarpal bones and extend the terminal and middle phalanges. They also adduct the fingers toward the thumb.

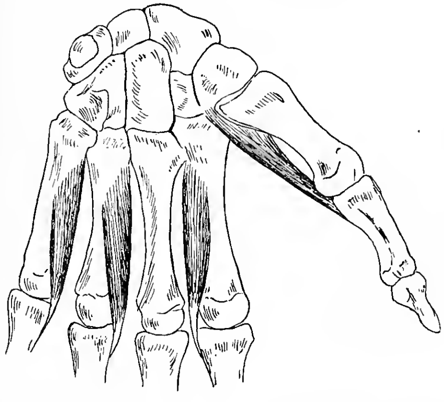
Relations.—The muscles run between the tendons of the flexor profundus and beneath the palmar aponeurosis. They lie upon the fascia covering the interosseous muscles, the capitular ligaments, and the septum over the adductor and deep head of the flexor pollicis brevis.

Variations.—These are very frequent, especially in case of the third and fourth. Each may be doubled or missing. They may arise from the tendons of the flexor sublimis or from the belly of the deep flexor. The first lumbrical may come from the tendon of the long flexor, from the opponens, or the metacarpal of the thumb. The tendon of insertion may go to the ulnar side of the base of the digit opposite that to which the tendon is usually attached, or the tendon may divide and go to the adjacent sides of two fingers. Kopsch has found that in 110 bodies all four lumbricals were inserted on the radial side of their respective digits in 39 per cent. In 35 per cent. the first, second, and fourth were so inserted, while the third sent slips to the adjacent sides of the middle and ring fingers. An accessory fasciculus has been found to arise from the tendon of the flexor pollicis longus and go to the base of the index finger.

(*e*) *Interosseous Muscles* (figs. 377, 378, 379)

These muscles lie between the metacarpal bones and are covered dorsally and ventrally by fasciæ attached to the metacarpals. In each interspace are two muscles, a dorsal and a palmar. The volar interossei are inserted into all the fingers

FIG. 378.—THE VOLAR INTEROSSEI.



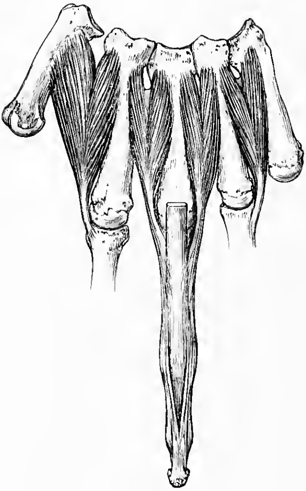
except the middle finger, and are adductors toward an axis passing through the middle finger; the dorsal interossei are inserted into both sides of the middle finger and into the radial side of the second and the ulnar side of the fourth finger, and are abductors. All also serve as flexors of the first row of phalanges and extensors of the second and third. In the foot the axis to and from which the interosseous muscles adduct and abduct the toes passes through the second toe.

The **interossei volares** arise from the sides toward the middle finger and the front of the shafts of the first, second, fourth, and fifth metacarpals. The first arises from near the base, the others from three-fourths of the shaft. The fibre-bundles of each muscle converge in a penniform manner upon a tendon which is inserted into the aponeurosis of the digital extensor tendon and the base of the first phalanx on the middle finger side of the corresponding digit (see fig. 373). The first volar interosseous is often described as a division of the flexor pollicis brevis or of the adductor pollicis.

The **interossei dorsales** arise from the adjacent sides of the metacarpal bones in each interspace. On the sides nearest the middle finger they cover three-fourths of the bone, on the opposite sides much less. The fibre-bundles converge in a bipenniform manner upon a tendon which begins high in the muscle and is inserted into the aponeurosis of the extensor muscles and the base of the first phalanx on each side of the middle finger, on the thumb side of the index finger, and the ulnar side of the ring finger. The interosseous muscle in the first interspace is thick and strong and forms with the adductor pollicis the fleshy web between the base of the thumb and the palm.

Nerve-supply.—By branches of the deep palmar division of the ulnar nerve. As a rule, a branch to each volar interosseous enters the proximal third of the muscle. To each dorsal interosseous a branch is given which enters between the two heads. These branches may be variously combined before entering the interosseous muscles. The nerve fibres arise from the eighth cervical and first thoracic nerves.

Fig. 379.—The Dorsal Interossei.



Action,—To move the fingers toward the radial and ulnar sides, to flex the first phalanx and extend the second and third. The volar interossei move the fingers toward the median axis, the dorsal from it.

Relations.—The volar interossei lie volarward from the dorsal interossei. The two sets of muscles are bound in place by the dorsal and volar metacarpal fasciæ. The tendons pass out on the dorsal side of the transverse capitular ligament and are closely applied to the metacarpophalangeal joints. The muscles of the first two interspaces lie immediately dorsal to the adductor of the thumb; the others dorsal to the flexor tendons.

Variations.—The tendon slip from an interosseous muscle to the base of the first phalanx of a digit may be missing. This is more frequent in case of the volar than in that of the dorsal interossei, and in the medial than the lateral muscles. Either a volar or a dorsal interosseous muscle may be double or missing. Rarely the insertions of the interosseous muscles characteristic of the foot (see p. 499) may be found in the hand.

III. SPINAL MUSCULATURE

(Figs. 380, 381, 382, 383)

The spinal (vertebral) column is of special interest as the segmented longitudinal axial support of the body which has given rise to the term "vertebrates" as applied to the class of animals of which man is the highest form. The segmentation in fishes permits the lateral movements of the body which are their chief means of propulsion. In the land vertebrates, with the exception of snakes, the limbs are developed as the chief organs of propulsion but flexibility of the column is retained for the sake of freedom of movement. In man the spinal column, with the exception of the sacral region, may be readily extended (bent backward) and flexed (bent forward), abducted (bent to the side) and rotated. Freedom of movement is greatest in the cervical and lumbar regions and is restricted by the thorax in the thoracic region. The cervical region allows considerable flexion, extension and rotation, but a more limited abduction. In the thoracic region rotation and abduction are freer than flexion and extension. The lumbar region is that in which the chief flexion and extension of the trunk takes place, but abduction and rotation are limited, especially the latter. In the isolated articulated spinal column freedom of movement of the various parts depends chiefly upon the thickness and elasticity of the intervertebral discs, upon the conformation of the articular processes, and upon the elasticity or arrangement of the various ligaments uniting the vertebræ. In the living body freedom of movement is further restricted by the musculature and skeletal apparatus attached to the column. There is much individual variation in the flexibility of the vertebral column.

The various movements of the column are produced partly by muscles which act directly on it and partly by muscles which act on it through the head, thorax or pelvis. Most of the muscles which act on it directly belong to the intrinsic dorsal musculature; that is, to musculature which is derived from the dorsal divisions of the myotomes and is innervated by the dorsal divisions of the spinal nerves. This musculature extends from the sacrum to the skull and is closely applied on each side of the mid-dorsal line of the body to the backs of the vertebræ and the back of the thorax (fig. 381). Its chief function is to extend the spinal column and head, hence the old term applied to the superficial portion of this musculature "erector spinæ." During the development of the body, muscles belonging to the ventro-lateral thoracic musculature and to the upper extremity come to overlie in part the intrinsic dorsal musculature. The trapezius and rhomboid muscles which cover it in the cervical and thoracic regions, and the latissimus dorsi which covers it in the thoracic and lumbar regions belong to the shoulder girdle and arm and have already been described, p. 360. The serratus posterior superior, which overlaps it in the upper thoracic region, and the serratus posterior inferior, which overlaps it at the junction of the thoracic and lumbar regions, are derived from the intercostal musculature which is described below, p. 422 (fig. 380). All of these muscles are innervated by the ventro-lateral divisions of the spinal nerves. The levatores costarum (fig. 380), which extend from the transverse process of the thoracic vertebræ to the ribs, and which, in spite of their name, act chiefly on the spinal column, are derived from the external intercostal musculature and are innervated by the intercostal nerves.

Ventral to the spinal column and closely applied to it there are a few muscles, the chief function of which is to flex the column. All are supplied by branches from the ventro-lateral divisions of the spinal nerves. Of these the *longissimus colli* and *longissimus capitis* and *scalene* muscles have been described in connection with the muscles of the neck, p. 353. In the thoracic region there are no muscles of this type. In the lumbar region there are four muscles on each side, the pillars of the *diaphragm*, fig. 391, the *psoas minor*, fig. 391, the *psoas major*, fig. 391, and the *quadratus lumborum*, fig. 391. All of these muscles are flexors of the spine, except the quadratus, which is an extensor. The psoas major muscle is also a flexor of the thigh. Even more powerful flexors of the column than those above mentioned are some of those which work indirectly upon it through the leverage offered by the skull (sterno-cleido-mastoid described above, p. 347), and the thorax (the ventro-lateral abdominal musculature).

Abduction and rotation of the spine are produced by contraction of muscles on one side while the corresponding muscles on the other side are relaxed. See Table, p. 502.

In the present section we shall confine our attention to the intrinsic dorsal musculature, leaving for consideration elsewhere the other musculature which acts on the vertebral column.

The intrinsic dorsal musculature is attached to the sacrum, to the ilium, to the spines, transverse, and articular processes and laminæ of the lumbar, thoracic, and cervical vertebræ, to the backs of the ribs and to the base of the skull. Two great longitudinal subdivisions may be recognised, a lateral, supplied by lateral branches of the posterior divisions of the spinal nerves, and a medial, supplied by medial branches. The lateral portion is further divisible into a superficial division, consisting chiefly of systems of muscles extending laterally from the spines of the vertebræ upward toward the transverse processes of the vertebræ, the ribs, and the mastoid process of the skull; and a deep division, consisting of muscles which extend between successive transverse processes. The medial portion likewise consists of two parts; a superficial medial composed of fasciculi extendiug from inferior to superior spines, best developed in the dorsal region, and a deep portion consisting mainly of muscle fasciculi which pass from the transverse processes upward toward the spines of vertebræ situated more cranially. In the neck the more superficial extend to the base of the skull. Between the base of the skull and the first two vertebræ there are several specialised muscles. There is also frequently present the rudimentary *sacro-coccygeus posterior* described on p. 448, which represents an extension into the caudal region of the intrinsic dorsal musculature.

The **superficial lateral dorsal musculature** consists of the splenius and the sacro-spinalis. The **splenius** (fig. 380) is a flat, somewhat triangular muscle, which extends from the cervical and upper thoracic spines to the upper cervical transverse processes and to the mastoid process of the temporal bone and the neighbouring part of the occipital. The **sacro-spinalis** (erector spinæ) (fig. 381) is the name given to a mass of musculature which takes its origin from the ilium, the sacrum, and the lumbar spines. In the lumbar region this muscle divides into its two chief portions, the ilio-costalis and the longissimus. The *ilio-costalis* (fig. 382) is attached to the lumbar transverse processes and to the ribs near the angles, and is continued upward by accessory fasciculi along the back of the thorax to the transverse processes of the cervical vertebræ. The *longissimus* (fig. 382) extends upward between the ilio-costalis and the spines of the lumbar and thoracic vertebræ. It is attached to the transverse processes of the lumbar and thoracic vertebræ and to the ribs lateral to the transverse processes. It is continued to the transverse processes of the cervical vertebræ and to the skull by accessory muscle slips.

The **deep lateral dorsal musculature** consists of the **dorsal intertransverse** muscles. The intertransverse muscles are best developed in the cervical and lumbar regions. In the cervical region intertransverse muscles belonging to the dorsal musculature extend between the successive dorsal tubercles, while intertransverse muscles belonging to the ventral musculature extend between the ventral tubercles. The latter, as well as the rectus capitis anterior and rectus capitis lateralis, which belong in the series, have been described above (p. 356). In the lumbar region there are also two sets of intertransverse muscles, one belonging to the ventral and one to the dorsal musculature.

The **superficial medial dorsal musculature** consists of the spinalis dorsi and cervicis. The *spinalis dorsi* (fig. 381) is intimately fused with the longissimus. It extends from the lower to the upper thoracic spines, and is derived from the medial dorsal musculature. The inconstant *spinalis cervicis*, which extends from the upper thoracic to the lower cervical spines, is likewise derived from the medial dorsal musculature, but is less intimately related to the longissimus.

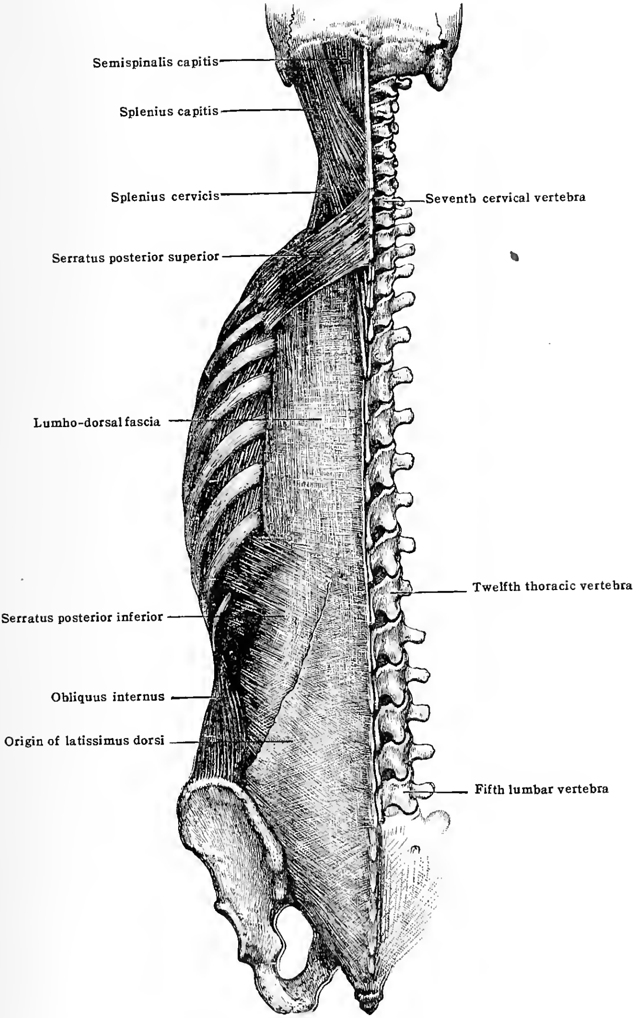
The **deep medial dorsal musculature** (fig. 383) lies in the groove between the transverse processes and the spines of the sacral, lumbar, thoracic, and cervical vertebræ. It extends from the sacrum to the skull, and is best developed in the lumbar and cervical regions. It is subdivided into a vertebro-occipital muscle (semispinalis capitis), a transverso-spinal group, and the interspinal muscles. The *semispinalis capitis* (complexus) (fig. 381) arises from the transverse processes of the third cervical to the sixth thoracic vertebræ and from the spines of the upper thoracic vertebræ and is inserted into the base of the skull. The *transverso-spinal* group (fig. 383) extends from the sacrum to the second cervical vertebra. It is more or less artificially divisible into several layers. In the superficial layer, the *semispinalis dorsi et cervicis*, which extends from the twelfth thoracic to the second cervical vertebra, the constituent fasciculi extend from the transverse process of one vertebra to the spine of a vertebra four to six segments above. In the middle layer, the *multifidus*, the fasciculi extend over from two to four vertebræ. In the deepest layer, the *rotatores*, the fasciculi extend to the next vertebra (short rotators) or to the second vertebra above (long rotators). The *interspinal* muscles extend between successive spines.

The muscles which pass from the first two vertebræ to the base of the skull behind, or *suboccipital muscles* (fig. 382), consist of the *rectus capitis posterior minor*, from the spine of the atlas to beneath the inferior nuchal line of the occipital and *rectus capitis posterior major*, from the spine of the epistropheus (axis) to beneath the inferior nuchal line, lateral to the preceding; of the *obliquus capitis inferior*, from the spine of the epistropheus (axis) to the transverse process of the atlas, and the *obliquus capitis superior*, from the transverse process of the atlas to the base of the lateral part of the inferior nuchal line of the occipital above the *rectus major*.

The primitive condition of the dorsal musculature is one of metameric segmentation. This is characteristic of fishes, many amphibia, and of the embryos of all higher vertebrates. In the tailless amphibia, however, a partial differentiation of the dorsal musculature takes place during embryonic development, and in all higher forms a differentiation takes place which corresponds in many ways to that described above for man. According to Favaro, the splenius is differentiatied from the medial dorsal system, but its innervation should place it with the lateral system. In the human embryo the dorsal segmental musculature extends into the tail region, but afterward here undergoes retrograde metamorphosis.

The intrinsic musculature of the back serves to extend, bend from side to side, and to rotate the spinal column and head. The muscles attached to the ribs depress the thorax.

Fig. 380.—The Third and Fourth Layers of the Muscles of the Back. (Intrinsic Dorsal Musculature)



FASCIÆ

The **fasciæ** and the general relations of the muscles of the back may be followed in the cross-sections shown in figs. 347, 351, 357, 384, and 407.

The **tela subcutanea** of the upper dorsal region has been described in connection with the muscles of the shoulder girdle (p. 347). It is thick, fibrous, and adherent. In the lower dorsal region it is somewhat less compact, but is thicker and contains more fat. It is usually divisible into two layers, of which the deeper is adherent to the lumbodorsal fascia.

The splenius (fig. 380) is enveloped in a thin, adherent fascial covering. The sacro-spinalis is covered by a fascia, the **fascia lumbo-dorsalis** (fig. 380), which inferiorly is attached to the iliac crest, the distal and lateral margins of the sacrum, and the sacral spines. In the lumbar and thoracic regions it is attached medially to the vertebral spines. Laterally, in the lumbar region, it is reflected around the muscle to its ventral surface, where a 'ventral' or 'deep' layer forms an intermuscular septum (fig. 384) between the quadratus lumborum and the sacro-spinalis. This intermuscular septum (fig. 383) extends from the twelfth rib to the iliac crest and the ilio-lumbar ligament, and is attached medially to the transverse processes of the lumbar vertebræ, from which fibre-bands extend laterally into it. It is strengthened above by fibre-bundles which pass from the first and second lumbar vertebræ to the twelfth rib (lumbo-costal ligament). (For the relation of the abdominal muscles to this fascia see p. 328.)

In the thoracic region (fig. 384) the lumbo-dorsal fascia is attached to the ribs lateral to the ilio-costal muscle. In the cervical region (fig. 351) the fascia is continued into the intermuscular septa which surround the muscles of this group in the neck.

The *transverso-spinal muscles* are covered throughout their extent by a fascial membrane which serves to separate them from the longissimus in the sacral, lumbar, and thoracic regions.

In the dorsal region of the neck (figs. 347, 351, 357) the muscles are covered on each surface by adherent fascial sheets, **fascia nuchæ**, and are arranged in several concentric layers, each of which is separated from its neighbours by dense fatty areolar tissue. The deepest of the layers is formed by the muscles of the transverso-spinal group. This is covered by a dense membrane, and is separated from the semispinalis capitis (complexus) by a thick layer of areolar tissue containing the chief blood-vessels and nerves of the neck. The semispinalis capitis (complexus) is covered on each surface by a more delicate adherent membrane, and is separated from the splenius by loose tissue. The splenius has a somewhat denser adherent fascial covering into which the fascia of the levator scapulæ is continued. Separated from this by areolar tissue lies the trapezius. The cervical and thoracic portions of the semispinalis are separated by delicate membranous septa from the semispinalis capitis (complexus), the levator scapulæ, and the splenius. The muscles of each side are separated in the dorsal median plane by the dense **ligamentum nuchæ**, into which the various cervical septa and fasciæ extend. The sub-occipital muscles are covered by fascial sheaths which are so fused as to constitute a special fascia for these muscles. Distally this is continued into the fascia of the transversospinal muscles.

MUSCLES

A. Superficial Lateral Dorsal System

The splenius (fig. 380).—The two parts of which this muscle is composed may be separately considered.

The splenius cervicis.—*Origin.*—By a narrow aponeurotic band from the spinous processes and the supraspinous ligament of the third to the sixth thoracic vertebræ.

Structure and insertion.—The fibre-bundles extend upward and laterally and give rise to a flat muscle sheet from which fasciculi arise that are inserted by short tendinous processes on the posterior tubercles of the transverse processes of the first two or three cervical vertebræ. The processes are often united with those of the levator scapulæ and the longissimus cervicis.

The splenius capitis.—*Origin.*—From the ligamentum nuchæ in the region of the third to the seventh cervical vertebræ and from the spinous processes and the supraspinous ligament of the first two to five thoracic vertebræ.

Structure and insertion.—The fibre-bundles form a sheet which continues cranialward that of the splenius cervicis. The fibre-bundles converge somewhat and are inserted by a short, broad, thick tendon into—(1) the back, the side, and the tip of the mastoid process below the sterno-cleido-mastoid muscle, and (2) into the neighbouring part of the occipital bone.

Relations.—The splenius lies dorsal to the semispinalis capitis (complexus) and to the cervical (transversalis cervicis) and the cranial (trachelo-mastoid) portions of the longissimus and the cervical portion (cervicalis ascendens) of the ilio-costalis and to the levator scapulæ, and is partly covered by the trapezius, sterno-cleido-mastoid, serratus posterior superior, and the rhomboids. In the triangle bounded by the trapezius, sterno-cleido-mastoid, and the levator scapulæ it is subcutaneous.

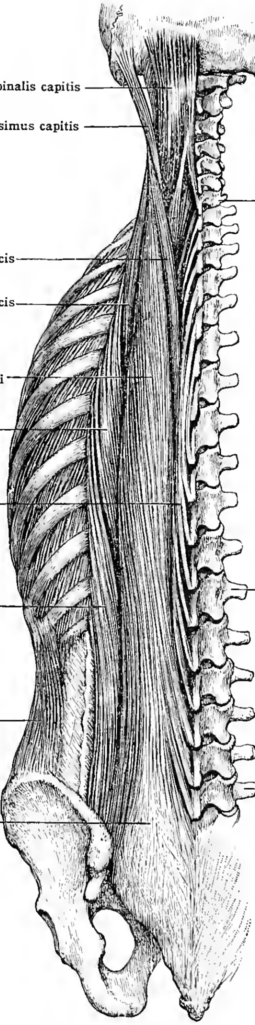
Nerve-supply.—The lateral branches of the posterior divisions of the second, third and fourth (sometimes also of the first, the fifth and the sixth) cervical nerves give off rami which enter the deep surface of the muscle.

Action.—To incline and rotate the head and neck toward the side on which the muscle is placed. When both muscles act, the head and neck are extended.

Variations.—The extent of separation and of fusion of the two muscles varies. Absence of either muscle is rare. The splenius capitis may be divided into mastoid and occipital portions. The attachment of the muscle also varies somewhat. Occasionally the spinal origin of the splenius may extend to the cranial end of the ligamentum nuchæ. The origin may extend laterally over the fascia covering the deeper dorsal muscles. An accessory slip, the **splenius cervicis accessorius**, separated from the main muscle by the tendon of the serratus posterior superior, is frequently (8 per cent. of instances, LeDouble) found to run from the lower cervical or upper thoracic vertebræ to the transverse process of the atlas.

The sacro-spinalis (erector spinæ).—*Origin.*—(1) From a strong aponeurosis attached to the spines of the lumbar, and the sacral vertebræ, to the ligament passing from the sacrum to the coccyx, to the lateral sacral crest, the sacro-tuberous ligament, the long posterior sacro-iliac ligament, and to the dorsal fifth of the iliac crest; (2) directly from the iliac crest in front of and lateral to the attachment of the aponeurosis; and (3) from the short posterior sacro-iliac ligaments. The aponeurosis covers the muscles of the sacral region and is there united to the overlying fascia by more or less dense areolar tissue. Opposite the iliac crest fibre-bundles begin to take origin from the lateral margin of the dorsal surface as well as from the deep or

FIG. 381.—THE FIFTH LAYER OF THE MUSCLES OF THE BACK.



ventral surface of the aponeurosis of origin, and gradually the line of dorsal attachment extends medially until, in the lower thoracic region, the tendon becomes completely embedded in the muscle-fasciculi which take their origin from it. The aponeurosis, which is the strongest in the lower lumbar region, is composed chiefly of fibres which take a direction upward and somewhat lateralward.

In the lower lumbar region the sacro-spinalis (erector spinæ) muscle begins to show a distinct division into its two chief component parts, the ilio-costalis and the longissimus. The parts of which the ilio-costalis and longissimus are composed will be taken up separately.

The ilio-costalis lumborum (figs. 381, 382).—*Origin.*—(1) Chiefly from the back of the sacrospinal aponeurosis, medial to and cranialward from the iliac crest, and (2) from the iliac crest directly. The deep medial surface of the muscle is closely united in the lumbar region to the longissimus.

Structure and insertion.—From the mass of fibre-bundles which compose the muscle, fasciculi are given off which are attached chiefly by tendinous slips to—(1)the tips of the transverce processes of the lumbar vertebræ; (2) the fibrous processes which extend lateralward from the tips of the transverse processes of the upper lumbar vertebræ into the anterior layer of the lumbo-dorsal fascia; (3) the inferior margin of the last six or seven ribs near the angles. The insertions into the lumbo-dorsal fascia and the twelfth rib are usually fleshy. The portions attached to the lumbar vertebræ are by some considered to belong to the longissimus (Eisler).

Relations.—The muscle lies on the lateral margin of the longissimus and upon the ribs and the external intercostal and levatores costarum muscles, and under the axio-appendicular muscles described above.

The ilio-costalis dorsi (accessorius).—*Origin.*—By fleshy fasciculi from the superior borders of the lower seven ribs medial to the angles.

Structure and insertion.—The slips of origin lie beneath the preceding portion of the muscle, pass medial to and partly fuse with it, and give rise to a belly from which tendinous slips extend to be inserted into the upper seven ribs near their angles and to the transverse process of the seventh cervical vertebra.

Relations.—The muscle lies upon the ribs and the external intercostal muscles lateral to the longissimus.

The ilio-costalis cervicis (cervicalis ascendens).—*Origin.*—By fleshy slips from the upper borders near the angles of the seventh to the third (sometimes to the second or first) ribs.

Structure and insertion.—The slips of origin are covered by the slips of insertion of the dorsal portion (accessorius). They emerge medial to them and give rise to a fleshy belly from which tendons pass to the backs of the transverse processes of the sixth to the fourth cervical vertebræ.

Relations.—The scalenus posterior lies in front, the levator scapulæ at the side, and the splenius and longissimus (transversalis) cervicis medial to this muscle.

A *bursa* is frequently found between the muscle and the tubercle of the first rib.

The longissimus dorsi (figs. 381, 382).—*Origin.*—(1) From the deep surface of the sacrospinal aponeurosis; (2) from the short posterior sacro-iliac ligaments; and (3) through accessory slips which arise from the transverse processes of the first two lumbar and the last five or six thoracic vertebræ. In the lumbar region it is fused dorso-laterally with the ilio-costalis.

Structure and insertion.—From the muscle mass arise fasciculi which are inserted partly directly, partly by means of tendons, into—(1) the lower border of the back of the transverse processes of the lumbar vertebræ and the inferior margins of the ribs lateral to the tubercles; and (2) the accessory tubercles of the lumbar and the tips and inferior margins of the transverse processes of the thoracic vertebræ. The attachment to the first rib is usually wanting. The attachment to the first five ribs may fail. The medial attachments seldom extend to the first vertebra.

Relations.—The lateral margin of the muscle is covered by the ilio-costalis. Medially it overlies the transverso-spinal muscles. The lateral branches of the dorsal veins, arteries, and nerves pass mainly in the fibrous tissue which separates the longissimus from the ilio-costalis, the medial branches chiefly between the longissimus and the transverso-spinal muscles. The relations to the axio-appendicular muscles and to the dorsal fascia have been pointed out above. Ventrally it lies upon the intertransverse muscles, the external intercostals, and the levatores costarum.

The longissimus cervicis (transversalis cervicis).—*Origin.*—By tendinous slips from the transverse processes of the first four to six thoracic vertebræ.

Structure and insertion.—The fasciculi which arise from these slips give rise to a muscle belly from which tendons of insertion extend to the posterior tubercles of the transverse processes of the mid-cervical (second to sixth) vertebræ.

Relations.—This muscle lies between the longissimus dorsi and capitis with which it is to some extent fused and the ilio-costalis dorsi (accessorius) and cervicis (cervicalis ascendens) muscles.

The longissimus capitis (trachelo-mastoid).—*Origin.*—By tendinous slips from the transverse processes of the first three or four thoracic vertebræ and the articular processes of the last four cervical.

Structure and insertion.—The muscle fasciculi arising from these tendons form a belly which is united to the mastoid process by a short tendon. A tendinous inscription often crosses the muscle.

Relations.—It lies ventral to the splenius capitis, lateral to the semispinalis capitis (complexus) and medial to the longissimus cervicis (cervicalis ascendens).

Nerve-supply of the sacro-spinalis.—From the lateral branches of the posterior divisions of the spinal nerves. The exact distribution of these branches is too complex to be treated here. The nerves for the ilio-costalis arise from the eighth cervical to the first lumbar, those for the longissimus from the first cervical to the fifth lumbar.

Action of the sacro-spinalis.—The sacro-spinalis serves, when acting on one side, to bend the spinal column toward that side, and when acting on both sides, to extend the spinal column. The cranial portions of the muscle serve to incline the head toward the same side, and when both muscles act they serve to extend the head. The ilio-costalis muscle has the greatest power for producing lateral inclination. The ilio-costalis lumborum depresses the ribs, while the ilio-costalis cervicis (cervicalis ascendens) may aid in elevating them. The spinalis muscle serves merely as an extensor.

Variations of the sacro-spinalis.—The slips of origin and insertion of the various parts of this muscle and the extent of fusion of the various parts vary greatly. Statistical data from which the most frequent conditions might be determined are wanting. Tendinous inscriptions may extend across the longissimus cervicis and other parts of the sacro-spinalis.

B. Deep Lateral Dorsal System

The intertransversarii.—These are vertical bands composed of short bundles which pass between the transverse processes of the cervical, lumbar, and the lower thoracic vertebræ.

(a) *Cervical* (fig. 349).—Ventral, lateral and dorsal muscles are found in the cervical region. The ventral and lateral muscles run between the ventral tubercles and tips of the transverse processes of the vertebræ, are homologous with the intercostal muscles, are supplied by branches from the anterior divisions of the corresponding spinal nerves, and have been described above (p. 356). The dorsal muscles run between the dorsal tubercles and belong to the intrinsic dorsal musculature. They are supplied by the lateral branches of the posterior divisions of the cervical nerves.* The three sets of muscles are, however, more or less fused. The first pair of muscles extends between the atlas and axis, the lowest passes to the transverse process of the first thoracic vertebra, or to the first rib close to this. The *obliquus capitis superior* (described later) belongs, however, to the posterior set of muscles, the *rectus capitis lateralis* (p. 356) to the lateral set. The vertebral artery runs vertically between each pair of muscles above the sixth, and the anterior division of each cervical nerve passes laterally between the artery and the dorsal muscle in each space, and then out between the ventral and lateral muscles. The posterior division of each cervical nerve passes medial to each dorsal muscle.

(b) *Thoracic.*—Small muscle fasciculi may extend between the transverse processes of the thoracic vertebræ and between the last thoracic and first lumbar. They are most frequent in the upper and lower thoracic regions. Often they are replaced by tendinous bands. In the second interspace the insertion may extend to the rib near the transverse process. The innervation is from the lateral branches of the posterior divisions of the spinal nerves.

(c) *Lumbar* (fig. 383).—In the lumbar region there is a lateral set of muscles connecting the adjacent margins of the transverse processes and a medial connecting the mammary tubercle of one vertebra to the mammary or the accessory tubercle of the vertebra next above. They extend between each two of the five lumbar vertebræ and sometimes also to the first sacral. They lie between the sacrospinalis and psoas muscles. The medial muscles are supplied by the lateral branches of the posterior divisions of the spinal nerves. The lateral muscles are supplied by branches from the junction between the two divisions of the corresponding spinal nerves. These branches probably belong to the anterior divisions.

Action.—The intertransverse muscles bend the spinal column laterally, and when acting on both sides, make it rigid.

Variations.—The number of intertransverse spaces occupied by the muscles varies, especially in the thoracic region. They may be doubled or extend over more than one interspace.

C. Superficial Medial Dorsal System

The spinalis dorsi.—*Origin.*—By tendinous bands from the tips of the two upper lumbar and the last two thoracic spines.

Structure and insertion.—From the deep surface of the tendinous bands there arises a long slender muscle belly which is fused laterally with the longissimus dorsi. It is attached by tendinous processes to the spines of the upper thoracic vertebræ, usually the second or third to the ninth.

Nerve-supply.—From the medial divisions of the sixth to ninth thoracic nerves.

The spinalis cervicis.—A muscle of inconstant development which arises from the spines of the two upper thoracic and two lower cervical vertebræ and extends to the spines of the second to the fourth cervical vertebræ. The nerve supply is from the dorsal divisions of the lower cervical nerves.

Action.—To extend the vertebral column.

Variation.—There is great variation in the development of the spinalis muscles. Similar fasciculi are sometimes found in the lumbar region and in the cervical region sometimes extend to the skull.

D. Deep Medial Dorsal System

1. *Vertebro-occipital Muscle*

The semispinalis capitis (complexus) (fig. 381).—This muscle is usually separated from the semispinalis muscles of the back and neck by a well-marked septum and has a distinctive structure.

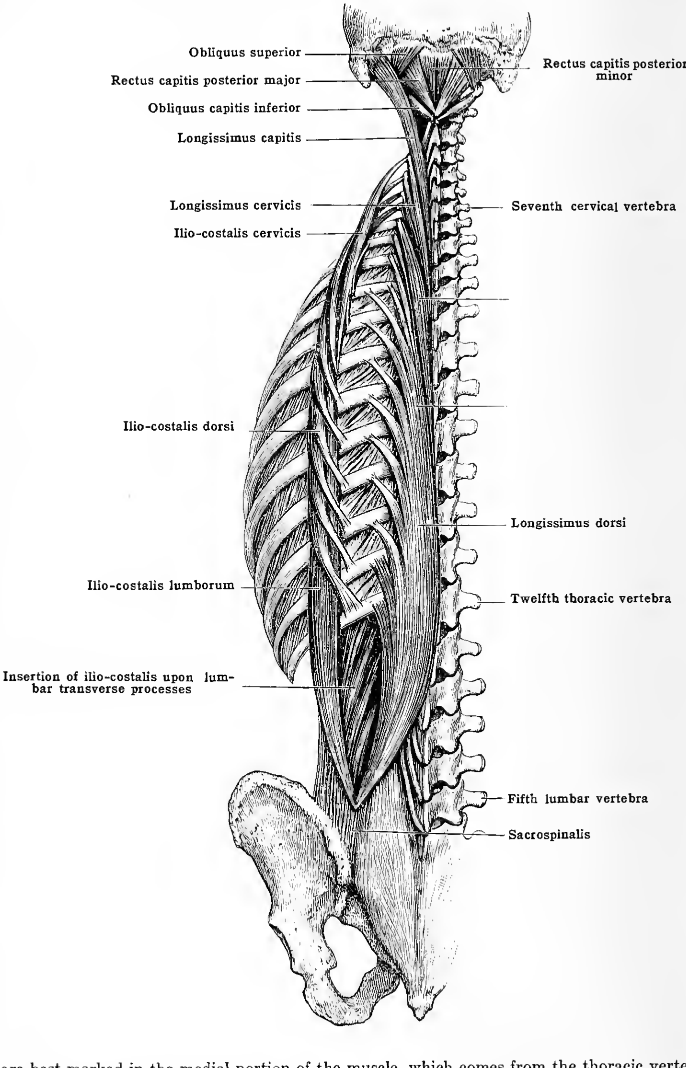
Origin.—(1) By long tendinous fasciculi from the tips of the transverse processes of the upper five or six thoracic vertebræ and of the seventh cervical vertebra; (2) by short fleshy processes from the articular processes and bases of the transverse processes of the third to the sixth cervical vertebræ; and (3) by delicate fleshy fasciculi from the spinous processes of the upper thoracic vertebræ.

Structure and insertion.—The slightly diverging fibre-bundles form a long, flat belly which is inserted, partly by means of an aponeurosis which covers the muscle laterally, into the lower

* According to Lickley, both sets of cervical intertransverse muscles are supplied by the anterior divisions of the spinal nerves.

surface of the squamous portion of the occipital, between the superior and inferior nuchal lines. There is often a transverse tendinous inscription across the muscle opposite the sixth cervical vertebra, and less frequently one between the upper and middle thirds of the muscle. These

FIG. 382.—THE FIFTH LAYER OF THE MUSCLES OF THE BACK, AFTER SEPARATING THE LONGISSIMUS AND ILIO-COSTALIS DIVISIONS.



are best marked in the medial portion of the muscle, which comes from the thoracic vertebræ and is sometimes separately designated as the *spinalis capitis* (*biventer cervicis*).

Nerve-supply.—It is supplied chiefly by the medial branches of the posterior divisions of the first four or five cervical nerves. The muscle also gets some twigs from the lateral branches.

Relations.—It lies dorso-lateral to the suboccipital muscles and to the semispinalis cervicis. From this latter it is separated by a septum containing the descending branch of the occipital artery, the deep cervical artery, and the medial dorsal branches of the cervical nerves. It is covered laterally by the longissimus capitis (trachelo-mastoid), and dorsally by the splenius, and above the upper margin of the splenius by the trapezius.

Action.—To extend the head and to incline it slightly toward the same side.

Variations.—The origin of the muscle may extend to the eighth thoracic vertebra or merely to the first thoracic. It may be fused with the longissimus (transversalis) cervicis. A special fasciculus may run beneath the muscle from the upper thoracic vertebræ to the head. The origin from the spinous processes of the thoracic vertebræ is not constant. The part of the muscle arising from this origin may be looked upon as a spinalis capitis.

2. *Transverso-spinal Muscles*

The semispinalis dorsi et cervicis (fig. 383).—This superficial transverso-spinal muscle sheet extends from the twelfth thoracic to the second cervical vertebra. The fasciculi which compose it arise by short tendons from the backs of the transverse processes, and are inserted by short tendons into the spines.

The semispinalis dorsi.—*Origin.*—From the sixth to the tenth or twelfth thoracic vertebræ.

Insertion.—The upper four to six thoracic and the last two cervical vertebræ. The fasciculi extend over four to six vertebræ.

Nerve-supply.—Third to sixth thoracic.

The semispinalis cervicis.—*Origin.*—From the upper five or six thoracic vertebræ.

Insertion.—Into the fifth to the second cervical vertebræ. The fasciculi extend over four to five vertebræ.

Nerve-supply.—Third to sixth cervical.

Relations.—This muscle lies beneath the longissimus dorsi and the semispinalis capitis (complexus) and over the following musculature.

Variations.—A semispinalis lumborum is a muscle rarely found extending from the lumbar to the lower thoracic vertebræ.

The multifidus (fig. 383).—This second layer of transverso-spinal musculature extends from the sacrum to the second cervical vertebra. It is best developed in the lumbar region and least so in the thoracic.

Origin.—(1) From the groove on the back of the sacrum between the spines and the articular elevations, from the dorsal sacro-iliac ligaments, from the dorsal end of the iliac crest, and from the deep surface of the aponeurosis of the sacrospinal muscle; (2) from the mammary and accessory processes of the lumbar vertebræ; (3) from the backs of the transverse processes of the thoracic vertebræ; and (4) from the articular processes of the fourth to the seventh cervical vertebræ and the back of the transverse process of the seventh.

Insertion.—Spinous processes of the lumbar, thoracic, and lower six cervical vertebræ.

Structure.—The more superficial fasciculi arise by short tendinous processes, the deeper ones directly. The more superficial fasciculi extend to the fourth or fifth vertebra above, the middle to the third, and the deepest to the second above.

The rotatores.—These, the third layer of transverso-spinal muscles, extend from the sacrum to the second cervical vertebra. They are composed of short fleshy fasciculi which extend to the second vertebra above (*rotatores longi*) and to the first above (*rotatores breves*). The fasciculi arise from the back and upper borders of the transverse processes or their homologues, and are inserted into the laminæ of the preceding vertebræ. They are best developed in the thoracic region. Some authors consider the rotatores breves confined to the thoracic region. In the cervical region the fasciculi usually run from articular processes to the bases of the spines, in the lumbar region from the mammary processes to the caudal margin of the laminæ of the arches.

3. *The Interspinal Muscles*

The interspinales consist of short fasciculi which extend from the upper surface of the spine of each vertebra near its tip to the lower surface of the spine of the vertebra above. In the neck the muscles lie in pairs between the bifid extremities of the vertebræ. In the lumbar region they form broad bands attached to the whole length of the spinous processes and are separated by the interspinous ligaments. In the thoracic region they usually are undeveloped.

Nerve-supply of medial dorsal muscles.—These are all supplied by the medial branches of the posterior divisions of the spinal nerves.

Action of medial dorsal muscles.—These muscles extend the spinal column when acting on both sides. When acting on one side, they produce a movement of rotation toward the opposite side.

E. Suboccipital Muscles

(Figs. 382, 383)

The rectus capitis posterior major.—*Origin.*—From the upper surface of the spine of the epistropheus.

Structure and insertion.—The muscle-fibres diverge to form a broad triangular band which is inserted into the lateral half of the inferior nuchal line of the occipital bone and the area below it. Its insertion is immediately below that of the obliquus superior.

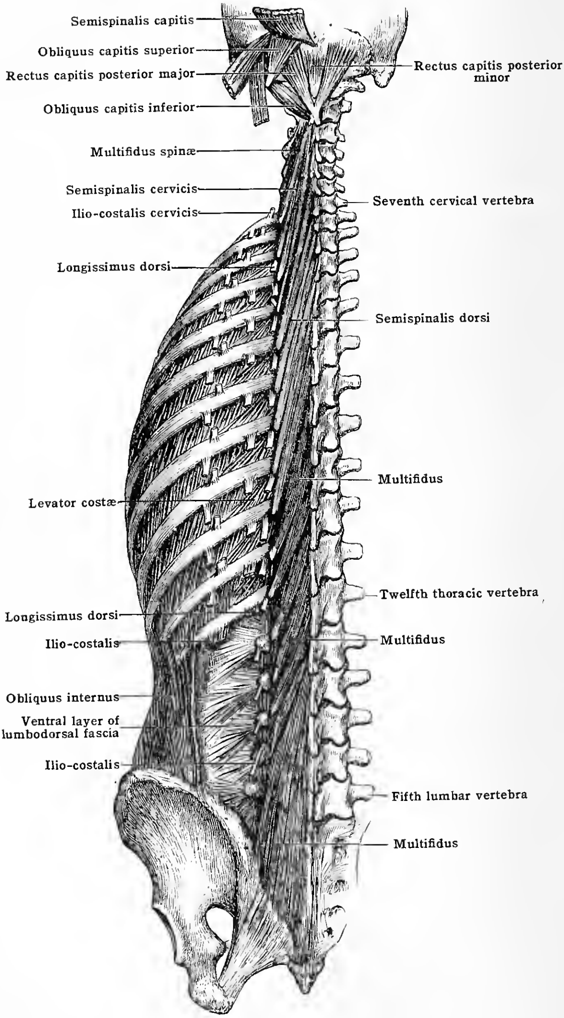
The rectus capitis posterior minor.—*Origin.*—From the upper part of the side of the posterior tubercle of the atlas.

Structure and insertion.—The fibre-bundles diverge to form a flat, triangular sheet inserted below the medial third of the inferior nuchal line of the occipital bone on the inferior surface of the squama occipitalis.

The obliquus capitis inferior.—*Origin.*—From the upper part of the side of the spine of the epistropheus (axis).

Structure and insertion.—The fibre-bundles form a fusiform belly which is inserted by a short tendon into the lower part of the tip of the transverse process of the atlas.

FIG. 383.—THE TRANSVERSO-SPINALIS.



The obliquus capitis superior.—*Origin.*—From the back of the upper part of the transverse process of the atlas.

Structure and insertion.—The fibre-bundles diverge to form a flat, triangular muscle, inserted into the lateral third of the inferior nuchal line of the occipital bone, and above the lateral part of the insertion of the rectus capitis posterior major.

Fig. 384, A and B.—Sections through the Left Side of the Trunk in the Regions shown in the Diagram.

The muscles of the body wall have been slightly pulled apart in order to reveal the relations of muscles, fasciæ, and aponeuroses. *a* and *b* in the diagram indicate sections A and B, fig. 351 (p. 352); a^2 and b^2, sections A and B, fig. 357 (p. 366); $a^{2'}$ and b^2, sections A and B, fig. 407 (p. 458):

Vert. thoracalis X.

Nerve-supply.—These muscles are all supplied by the posterior branch of the suboccipital (first cervical) nerve. The branch to the two rectus muscles passes across the dorsal surface of the major rectus and supplies branches to the middle of the dorsal surface of each muscle. The branch to the superior oblique muscle enters the middle of the medial margin, that to the inferior oblique about the middle of its superior margin. The inferior oblique and major rectus muscles usually, the other muscles occasionally, receive branches from the second cervical nerve.

Relations.—The two oblique muscles with the rectus major serve to bound a small triangular space, the suboccipital triangle, through which pass the dorsal division of the suboccipital nerve and the vertebral artery. The two minor recti lie on the atlanto-occipital membrane in the upper part of the space bounded by the major recti. The muscles are covered medially by the semispinalis capitis (complexus), laterally by the longissimus and splenius capitis. In front of the two oblique muscles and the major rectus runs the vertebral artery. The great occipital nerve runs between the semispinalis capitis (complexus) and the inferior oblique and the two recti in a dense fatty connective tissue containing the extensive suboccipital venous plexus.

Action.—The rectus muscles and the superior oblique draw the head backward. The rectus major and the inferior oblique, when acting on one side, rotate the face toward that side.

Variations.—Each of these muscles may be doubled by longitudinal division. Accessory slips may connect the two recti with the semispinalis capitis. The **atlanto-mastoid** is a small muscle frequently found. It passes from the transverse process of the atlas to the mastoid process.

IV. THE THORACIC–ABDOMINAL MUSCULATURE

The thoracic and abdominal viscera are contained within cavities, the ventro-lateral walls of which may be contracted and expanded by muscular action. The skeletal support for the intrinsic musculature of these walls consists of the ribs, the sternum and the vertebral column and the pelvis. The intrinsic musculature in the thoracic walls is situated chiefly between the ribs (*intercostal muscles,* figs. 385, 386) while in the region of the abdomen it extends in broad sheets from the lower part of the thorax to the pelvis (the *quadratus lumborum* and the *external* and *internal oblique, transverse,* and *rectus* muscles, figs. 387, 388, 390, 406). Between the two cavities, attached to the lower part of the thorax and to the lumbar vertebræ lies the dome-shaped diaphragm (fig. 391). The thoracic cavity extends on each side slightly above the first rib. The abdominal cavity extends downward and backward into the pelvis, as the pelvic cavity.

The function of the intercostal muscles is to expand and contract the thoracic cavity for the sake of respiration. The shape of the ribs and their articulations with the vertebræ are such that a slight rotation of the neck of each rib will cause the shaft to swing outward and upward or in the reverse direction. The costal cartilages are elastic enough to permit this movement, and at the same time are strong enough to make the thorax an effective skeletal apparatus. Ninety joints are called into play in the movements of the thorax (24 between the heads of the ribs and the vertebræ, 20 between the tuberosities and the transverse processes of the vertebræ, 24 between the ribs and costal cartilages, 14 between the costal cartilages and the sternum, 6 between the costal cartilages and 2 intrasternal). When the shafts of ribs are swung outward and upward the thorax is enlarged in the antero-posterior and transverse axes. In the adult when standing the sternum may be raised nearly 3 cm., and protruded 1 cm. The cartilages of the lower ribs may be raised 4 to 5 cm. The side of the thorax at the level of the second rib may be protruded 3 cm., and at the level of the eighth rib nearly as far. This extent of movement, however, is found only in forced respiration. In ordinary quiet respiration it is far less, the sternum being raised merely 3 or 4 mm. and protruded 2 mm., and the thorax is enlarged at the side merely 5 mm. (R. Fick). The chief muscles used in quiet inspiration are the external intercostals and the intercartilaginous parts of the internal intercostals.

During inspiration the diaphragm contracts so that the thoracic cavity is further enlarged perpendicularly. The extent of movement of the upper part of the diaphragm is estimated by R. Fick at from $1\frac{1}{2}$–3 cm.

The ventro-lateral abdominal muscles contract the thoracic cavity by depressing the thorax and by pushing the diaphragm upward. They directly contract the abdominal cavity. Contraction of the abdominal cavity is of aid in defecation and parturition. The abdominal muscles are also of value in flexion, abduction, and rotation of the vertebral column and pelvis.

The thorax, with its intrinsic musculature, is in large part covered by the musculature which extends from the trunk to the shoulder girdle and arm; dorsally by the trapezius and rhomboids, ventrally by the pectoral muscles, and laterally by the serratus anterior and the latissimus dorsi, as well as by the scapula and the muscles which pass from it to the humerus. The upper extremity on each side is largely supported from the spine by the trapezius, rhomboid and levator scapulæ muscles but it none the less exerts some pressure on the thorax and interferes to some extent with respiration. If the girdle and arm are fixed or raised the muscles which pass from them to the thorax are an aid in forced inspiration. Advantage of this is taken when in artificial respiration the arms are raised so as to lift the ribs through traction by the latissimus dorsi, the pectoralis muscles and the subclavius. Some of the muscles of the neck, especially the scalene muscles and the sterno-cleido-mastoid, are likewise of value in forced inspiration.

Expiration is produced not only by the part ofthe internal intercostals which lie between the bony ribs, and by the abdominal muscles, but also by the lumbar ilio-costales and by the quadratus lumborum.

The intrinsic muscles of the thorax and abdomen are derived from the twelve thoracic myotomes and the first one or two lumbar and are innervated by the corresponding nerves, while the musculature of the shoulder girdle and arm which covers the intrinsic muscles of the thorax is of cervical origin and is innervated by cervical nerves. The diaphragm is likewise of cervical origin and is innervated by the phrenic nerve from the cervical plexus.

The intrinsic muscles of the back extend over the thoracic musculature (external intercostals and levators of the ribs, fig. 383) and in turn are in part covered by muscles which extend dorsally from the thoracic region (posterior serrate muscles, fig. 380).

The intrinsic thoracic-abdominal muscles are composed laterally of three layers of sheet-like muscles.

In the **external layer** the fibre bundles run downward and ventralward. This layer is represented in the thoracic region by the external intercostal muscles, the levators of the ribs and the posterior serrate muscles. The fibre-bundles of the **external intercostals** (fig. 385), extend between each pair of ribs but between the costal cartilages are replaced by fibrous tissue, the *external intercostal ligaments.* The **levatores costarum** (fig. 383), extend from the transverse process of one vertebra to the rib which articulates with the next vertebra below and in some instances the fibre bundles are continued to the second rib below.

The **serratus posterior superior and inferior** (fig. 380), are derivatives of the external oblique which during development wander in part over the intrinsic dorsal musculature. The *superior serrate* arises from the spines of the last two cervical and first two thoracic vertebræ and is inserted into the second to the fifth ribs. The *inferior serrate* muscle arises from the spines of the last two thoracic and first two lumbar spines and is inserted into the last four ribs. The fibre-bundles of this muscles therefore take a direction opposite to that of the other muscles of the group. The muscles aid in inspiration. In the abdominal region the external layer is represented by the **external oblique** muscle (fig. 387). This arises by digitations from the last seven ribs and is inserted into the crest of the ilium and by means of a broad flat aponeurosis into the linea alba in the mid-ventral line and into the inguinal ligament below. The external intercostal, levatores costarum, and posterior serrate muscles are innervated from branches which arise near the tubercles of the ribs. The external oblique muscles are innervated by branches which in large part arise in conjunction with or from the lateral branches of the anterior divisions of the last seven thoracic nerves and frequently also by branches from the ilio-hypogastric.

The **middle layer** of the lateral thoraco-abdominal musculature is composed of fibre-bundles which run downward and backward obliquely across the fibre-bundles of the external layer. In the thoracic region it is represented by the internal intercostal and subcostal muscles. The **internal intercostal** (fig. 385) muscles lie between the costal cartilages and between the ribs as far dorsalward as the angles, beyond which they are replaced by membranous tissue and by the **subcostal muscles.** The latter, instead of extending from one rib to the next rib below, extend to the second or third rib below. They are best developed in the lower part of the thoracic cavity. In the abdominal region the middle layer is represented by the **internal oblique muscle** (fig. 388). This arises from the lumbo-dorsal fascia, the crest of the ilium and the inguinal ligament and is inserted into the sheath of the rectus abdominis muscle and into the inferior margins of the ventral extremities of the three lower ribs. The aponeurosis, which helps to form the sheath of the rectus, divides in the upper abdominal region into two layers, one of which passes in front and the other of which passes behind the rectus to be inserted into the linea alba in the mid-ventral line. In the lower third of the ventral abdominal wall both layers pass in front of the rectus. The fibre-bundles which compose the internal oblique muscles do not all follow the usual course of the fibre-bundles of this layer. At the level of the iliac crest they pass nearly transversely across the body and below here they slant downward and forward. Just above the inguinal ligament and medial to its centre the internal oblique muscle is continuous with the thin **cremaster muscle** (fig. 389), which is prolonged over the spermatic cord and the tunica vaginalis of the testis and epididymis in the male and over the ligamentum teres in the female. The cremaster muscle is attached laterally to the inguinal ligament, medially to the outer layer of the sheath of the rectus near the insertion of the latter.

The **inner layer** of the thoraco-abdominal musculature is composed of fibre bundles which take a course transversely across the body. In the thoracic region it is represented by the **transversus thoracis** (fig. 386), a slightly developed muscle which arises from the costal cartilages of the third to sixth ribs and is inserted into the lower part of the sternum and into the xiphoid process. In the upper portion of the muscle the fibre-bundles extend obliquely downward and forward instead of transversely. In the abdomen this layer is represented by the **transversus abdominis** (fig. 390) which arises from the cartilages of the lower seven ribs, from the lumbo-dorsal fascia, the iliac crest and lateral part of the inguinal ligament and is inserted into the linea alba by means of an aponeurosis which lies behind the rectus in the upper two-thirds of the ventral wall of the abdomen and in front in the lower third. It is intimately fused with the aponeurosis of the internal oblique.

The main trunks of the anterior divisions of the last five or six thoracic nerves give rise to branches which supply the muscles both of the middle and inner layers of the lateral thoraco-abdominal musculature. In the abdominal region these trunks run in the main between the two layers. Some muscular branches are usually also supplied from the ilio-hypogastric and ilio-inguinal nerves. In the thoracic region the intercostal nerves run external to the subcostal muscles, through the substance of the costal part of the internal intercostal muscles, and internal to the parts of the internal intercostals which lie between the costal cartilages. Eisler includes the subcostal muscles and that part of the internal intercostals which lies internal to the nerve trunk, with the inner rather than with the middle layer of the thoracic musculature.

The **ventral part** of the muscular thoraco-abdominal wall is represented by a single muscle on each side, the rectus abdominis muscle, except just above the symphysis pubis where the rudimentary pyramidalis is usually found. The **rectus abdominis muscle** (fig. 388), is a band-like muscle which arises from the ventral surfaces of the fifth to the seventh costal cartilages and from the xiphoid process and is inserted into the superior ramus of the pubis. It is ensheathed by the aponeuroses of the lateral abdominal musculature described above. The component fibre-bundles run nearly parallel with the mid-sagittal line. Transverse inscriptions partially divide the muscles into segments. It is innervated by the last six or seven thoracic nerves. The **pyramidalis** (fig. 388) is a small muscle which arises from the superior pubic ramus and is inserted into the linea alba for about a third of the distance to the umbilicus.

The **lateral intertransverse muscles** of the lumbar region described on p. 417 probably belong to the ventro-lateral musculature of the trunk. The nerves supplying them come from the junction between the posterior and anterior divisions of the spinal nerves.

The **inguinal (Poupart's) ligament** and the **inguinal canal,** described in detail below, are of considerable practical interest because of the frequency of hernias in this region. In the quadrupeds the pressure of the weight of the abdominal viscera centres toward the umbilicus while in man it centres toward the ventral part of the line of attachment of the abdominal wall to the pelvis. The lower margin of the aponeurosis of the external oblique muscle is here strengthened to form the inguinal (Poupart's) ligament which extends from the anterior superior iliac spine to the pubic tubercle. Near the latter it is reflected (curves medialward) to the pubic crest forming the triangular **lacunar ligament** (Gimbernart's). The medial half of the inguinal ligament helps to bound a slit-like space, **inguinal canal** through which in the male the spermatic cord passes to the scrotum, and in the female, the round ligament passes to the labium majus. This canal begins on the inner side at the (internal) abdominal ring, which is situated above and medial to the centre of the inguinal ligament. The canal, which is about 4 cm. long, extends medialward and downward to the subcutaneous (external abdominal) ring, a slit-like opening in the aponeurosis of the external oblique just above the inguinal ligament. The canal is bounded ventrally by the aponeurosis of the external oblique and the cremaster muscle, below by the reflected portion of the inguinal ligament, dorsally by the transversalis fascia and above by the transversus, internal oblique, and cremaster muscles.

The **quadratus lumborum** (fig. 406), which extends from the twelfth rib to the ilium and ilio-lumbar ligament, is supplied by direct branches of the lumbar nerves in series with the nerves supplying the musculature of the abdominal wall. It will, therefore, be taken up with the intrinsic thoraco-abdominal muscles. It depresses the thorax and abducts and extends the spine. The psoas muscle, on on the other hand, which also lies at the back of the abdominal cavity, represents an extension of the intrinsic musculature of the limb to the spinal column (see p. 455).

The **diaphragm** (fig. 391), a dome-shaped muscle which is attached to the distal margin of the thorax and to the upper lumbar vertebræ, and separates the thoracic and abdominal cavities, arises in the embryo in the region of the neck, and maintains cervical relations through its innervation by the phrenic nerves, which spring one on each side usually from the third to fifth cervical nerves. It does not belong morphologically with the other muscles considered in this section, but is here included because of its physiological and anatomical relations and the convenience of treating it in connection with the intrinsic thoraco-abdominal muscles. A diaphragm completely separating the thoracic from the abdominal cavities is found only in the mammals. The central portion of the diaphragm is an aponeurosis or central tendon with a convex ventral and concave dorsal margin. Into this tendon is inserted the musculature which arises on each side from the xiphoid cartilage, the cartilages and tips of the last six or seven ribs and by means of three crura from the sides of the first four lumbar vertebræ.

In fishes and tailed amphibians the musculature of the body wall is composed of metamerically segmented musculature. In all higher vertebrates it is likewise at an early embryonic stage segmental, being composed of the ventro-lateral portions of the myotomes. The ventral ends of the myotomes give rise to a ventral longitudinal muscle which runs on each side of the body next the mid-line in front, and retains more or less of the primitive segmentation. The rectus abdominis and the infrahyoid muscles represent this system in man. Very frequently traces of the system may also be seen on the upper thoracic wall in the form of slender muscular and aponeurotic slips. The rectus muscle in man is usually developed from the last seven thoracic myotomes. The pyramidalis becomes split off from its lower end. The lateral part of the ventro-lateral portions of the thoracic myotomes usually gives rise to several strata of muscles which vary somewhat in different vertebrates, although quite similar among the mammals. In man the twelve thoracic and first two lumbar myotomes give rise to the lateral musculature of the thoraco-abdominal wall.

The quadratus lumborum represents the ventro-lateral portions of the lumbar myotomes with the exception of that portion of the first two which enter into the lateral abdominal musculature and of the fifth, which probably undergoes retrograde metamorphosis.

It will be noted that the abdominal wall is composed of musculature which has an origin chiefly from the thoracic myotomes. At an early stage of embryonic development both the thoracic and the abdominal viscera are covered by a non-muscular membrane. The myotomes extend into this from the thoracic region, and as the musculature is differentiated, it approaches the median line in front and extends distally to the pelvis. Owing to the rotation of the limbs the abdominal musculature is stretched ventrally over an area corresponding to the lumbar and sacral regions dorsally The last part of the thoraco-abdominal wall to be furnished with musculature is that about the umbilicus. Occasionally the process fails to be completed in this region.

Each spinal nerve supplies primarily the musculature derived from the myotome which lay caudal to it, and at first the musculature lies wholly superficial to the nerves. With subsequent differentiation the metamerism is somewhat obscured by anastomosis of nerves and fusion of myotomes; and a part of the internal oblique layer and all the transverse layer of the lateral musculature comes to lie on the inner side of the main nerve-trunks.

FASCIÆ

The fasciæ and the topographical relations of the thoraco-abdominal muscles may be followed in the sections shown in figs. 357, 384, and 407.

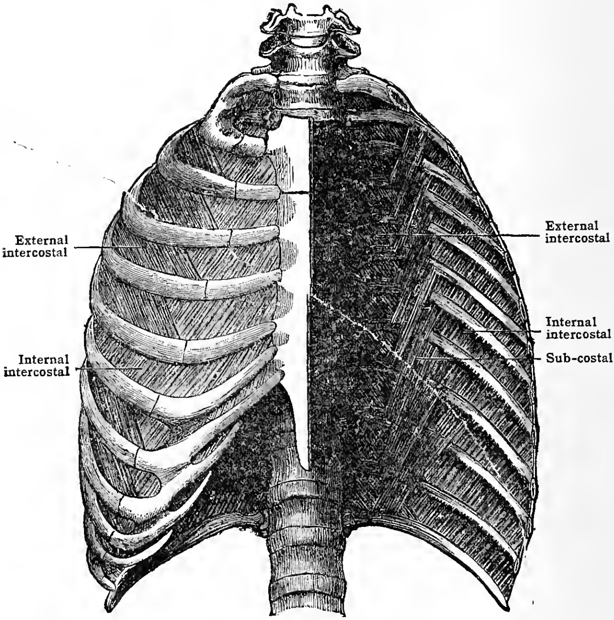
Tela subcutanea.—As mentioned above, most of the intrinsic thoracic musculature is covered by other muscles, while the superficial layer of the abdominal musculature is subcutaneous. A panniculus adiposus, **Camper's fascia,** in which much fat may be deposited is usually easily distinguishable, especially in the lower part of the ventral wall of the abdomen, from a membranous fascial sheet which is loosely attached to the underlying fascial envelopment of the muscles. To this membrane has been applied the term **Scarpa's fascia.** Near the groin it is separated from the panniculus adiposus by blood-vessels and lymphatic glands. It is closely bound to the linea alba between the two rectus muscles, to the fibrous structures in front of the pubic bone, to the fascia lata below the inguinal ligament, and to the crest of the ilium.

Over the scrotum of the male and vulva of the female both layers of the tela subcutanea are continued. In the male the fat of the more superficial layer disappears and the two layers blend with the fundiform (suspensory) ligament and fascia of the penis and the dartos and septum of the scrotum.

Muscle fasciæ and sheaths.—The posterior serrate muscles (fig. 380) are enveloped by two adherent layers of an aponeurotic sheet that extends as a single membrane between them and is attached lateralward to the ribs and medialward to the spines of the thoracic vertebræ. The membrane between the muscles may represent the rudiment of a primitive continuous muscle such as is found in some lower vertebrates. This membrane may usually be easily separated from the aponeurosis of the latissimus dorsi on its superficial surface and the lumbo-dorsal fascia beneath.

The intercostal muscles are covered by delicate, adherent membranes on each surface. The external intercostal muscles are continued as aponeurotic bands between the costal cartilages. These serve here as fasciæ for the internal intercostals.

Fig. 385.—The Intercostal Muscles.



The external oblique muscle is covered externally by a dense, adherent membrane and internally by a more delicate membrane except where the muscle is attached to the ribs or fused with the external intercostal muscles. Ventrally and distally these membranes are fused beyond the fleshy portion of the muscle to the broad aponeurosis that serves to ensheath the rectus muscle and cover the lower part of the abdominal wall (fig. 389). Dorsally the membranes are in part attached to the ribs and in part are fused to form a membrane which becomes adherent to the deep surface of the latissimus dorsi in the thoracic region and to the lumbo-dorsal fascia in the lumbar region.

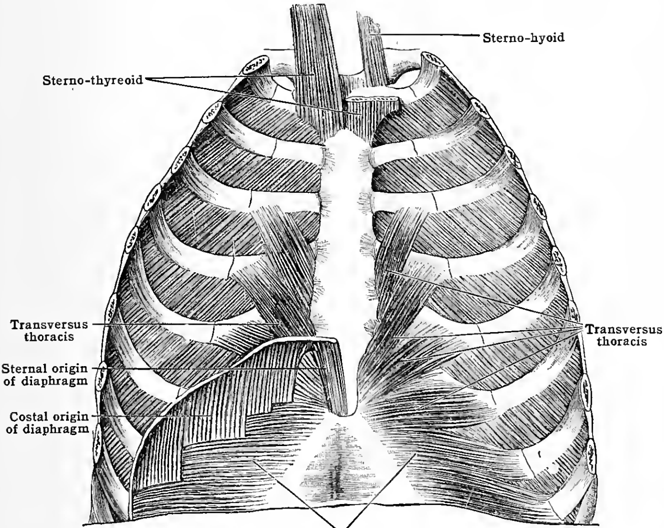
The internal oblique muscle and the transversus abdominis have similar membranous coverings which are fused to the aponeuroses of origin and insertion of these muscles. The membranes on the muscles are, however, much more delicate than that of the external oblique. More or less fusion between the two muscles with disappearance of the membranes covering the opposing surfaces takes place, especially in the lower part of the abdominal wall. The superficial muscle fasciæ of the external oblique and the fasciæ of the internal oblique are continued into the thin *cremasteric fascia* which covers the cremasteric muscle, spermatic cord and testis.

The diaphragm is covered on each surface by a more or less well-marked adherent membrane.

The transversalis fascia is a thin membrane which lies external to the peritoneum of the abdominal wall. It covers the peritoneal surface of the transversus muscle and its aponeurosis. Ventrally it is continued across the median line internal to the rectus abdominis. In the lumbar region the fascia divides at the lateral margin of the quadratus lumborum (fig. 384), one lamina of it passing dorsal to this muscle to be attached to the lumbo-dorsal fascia. The other lamina extends over the ventral surface of the quadratus and becomes fused with the psoas fascia. Proximally the transversalis fascia becomes fused with the fascial membrane adherent to the diaphragm. In the region of the iliac fossa the transversalis fascia is reflected from the transversus muscle to the ilio-psoas fascia, with which it usually becomes fused. Sometimes, however, it may be traced as a very delicate membrane over the iliac artery and vein. As these vessels pass below the inguinal ligament a process from the transversalis fascia is usually reflected into their sheath.

The **sheath of the rectus** (figs. 384, 407) is formed externally in the upper portion of its extent by the aponeurosis of the external oblique which fuses distal to the costal margin with the external layer of the aponeurosis of the internal oblique. In the lower portion of the abdomen this fusion takes place nearer the linea alba than in the upper portion. In the lower third of its extent the rectus is covered ventrally by the fused aponeuroses of the two oblique muscles conjoined with that of the transversus. Internally the rectus is covered in the upper two-thirds of the abdomen by the inner layer of the aponeurosis of the internal oblique conjoined with that of the transversus and by the transversalis fascia. In the lower third of the abdomen the aponeurosis of the internal oblique, together with that of the transversus, passes in front of the rectus, leaving the rectus in this portion of its abdominal surface covered merely by the transversalis fascia and the peritoneum. The line which marks the lower limit of the dorsal ensheathment of the rectus by the aponeurosis of the transversus muscle is called the **linea semicircularis,**

Fig. 386.—The Muscles attached to the Back of the Sternum.



or **fold of Douglas.** Between the transversalis fascia and the rectus just above the pubis there is a space filled with loose connective tissue or with fat.

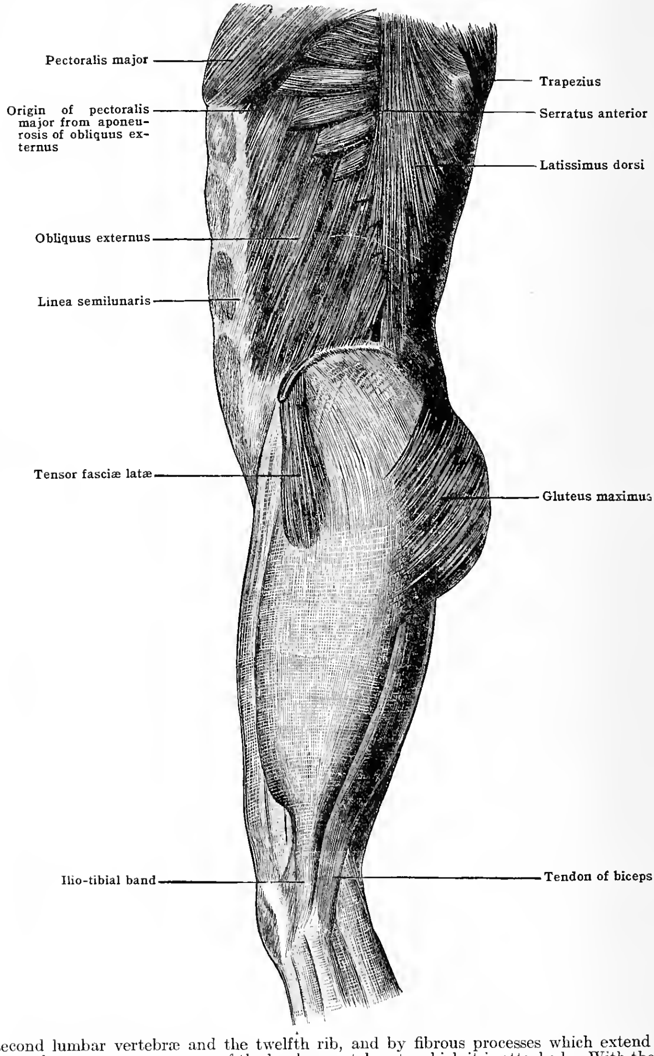
The pyramidalis lies beneath the ventral layer of the sheath of the rectus. From the latter it is sometimes separated by a distinct fascial layer.

Between the rectus muscles of each side the investing aponeuroses are firmly united into a dense tendinous band, the **linea alba** (fig. 389). This is broadest opposite the umbilicus. Above this it gradually grows narrower toward the xiphoid process to the ventral surface of which it is attached. From the tip of the xiphoid process it is often separated by a bursa. Toward the symphysis pubis it extends as a narrow line. Just above the symphysis it divides to be attached on each side to the tubercle (spine) of the pubis. Behind it broadens into the *adminiculum lineæ albæ* which is attached on each side to the pubis. The linea alba is composed mainly of the interlacing of the fibres which pass into it from the aponeurotic sheaths of the rectus abdominis. From it and Scarpa's fascia, a few centimetres above the symphysis, there arises a broad elastic band, the *fundiform ligament* (superficial suspensory ligament) of the penis, which sends a fasciculus on each side of the penis. Below the penis these fasciculi unite.* At the umbilicus there is a circular opening encircled by dense fibrous tissue and filled with a thick connective tissue, extending from the tela subcutanea to the subserosa.

* Alex. Hagenton has shown that the linea alba varies much in width. It is relatively wide in fat people and in fœtuses.

The *ventral layer* of the *lumbo-dorsal fascia* and its relations to the abdominal muscles also merit attention. This lies between the intrinsic dorsal musculature and the quadratus lumborum muscle and extends from the twelfth rib to the ilio-lumbar ligament. It is strengthened by the lumbo-costal ligament, which extends between the transverse processes of the first and

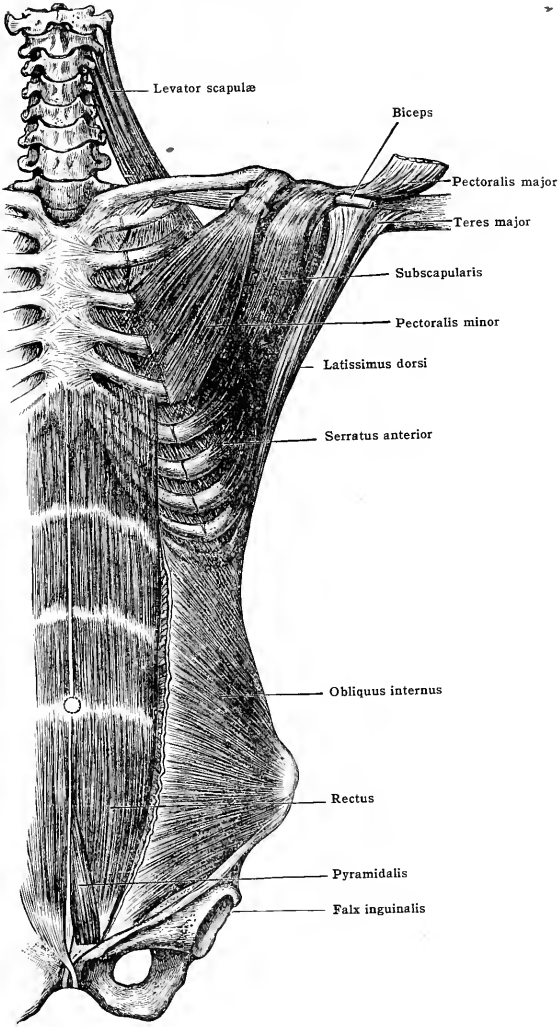
FIG. 387.—SUPERFICIAL MUSCULATURE OF ABDOMEN AND THIGH.



second lumbar vertebræ and the twelfth rib, and by fibrous processes which extend into it from the transverse processes of the lumbar vertebræ to which it is attached. With the lateral margin of this ventral layer the dorsal layer of the lumbo-dorsal fascia is fused. The dorsal aponeurosis of the transversus muscle is united to the lumbo-dorsal fascia at the line of junction of the ventral and dorsal layers. The internal oblique muscle, covered externally by a fascia continued dorsally from the external oblique, arises in part from the dorsal layer of the lumbo-dorsal fascia near the junction of the two layers.

The **inguinal ligament** (Poupart's ligament) (figs. 387, 389, 390) is a strong band which extends along the distal margin of the aponeurosis of the external oblique from the anterior superior iliac spine to the pubic tubercle. Internally the iliac fascia is fused to it. Distally the fascia lata of the thigh is attached to it. The deeper lateral abdominal muscles in part

Fig. 388.—The Pectoralis Minor, Obliquus Internus, Pyramidalis, and Rectus Abdominis.



arise from it. Medially near the attachment of the ligament to the pubic tubercle (spine) diverging fibres are given off which pass inward and upward to the pecten (crest) of the pubis and give rise to the triangular **lacunar ligament** (Gimbernat's ligament). This is fused with the fascia of the pectineus muscle and bounds the femoral ring. Above the inguinal ligament near its medial extremity lies the external opening of the inguinal canal, the **subcutaneous** (external)

inguinal ring [annulus inguinalis subcutaneus]. This opening is formed by the diverging of the lower medial fibres which compose the aponeuroiss of the external oblique muscle. The superior fibres form the upper boundary, *superior crus,* of the ring and pass to the front of the symphysis pubis. The inferior fibres form the inferior boundary, *inferior crus,* of the ring and pass to the pubic tubercle (spine). Between these two fibre bands *intercrural* (intercolumnar) *fibres* arch about the lateral boundary of the ring and serve to strengthen the anterior and inferior walls of the inguinal canal. Some of the fibres of the superior crus, intermingled with other fibres cross to the opposite side of the body and are inserted into the tubercle (spine) and crest of the pubis and into the superior crus of the opposite side. The structure thus formed is called the **reflected inguinal ligament** (Colles's ligament, or triangular fascia).

Inguinal canal [canalis inguinalis].—This term is applied to the slit in the lower margin of the abdominal wall through which, in the male, the spermatic cord passes, and in the female, the ligamentum teres. It is not a true canal. The inner end begins at the (internal) **abdominal ring** [annulus inguinalis abdominalis]. This is situated just above and slightly medial to the middle of the inguinal (Poupart's) ligament. Below the ligament in this region lies the femoral canal through which the femoral vessels pass into the thigh. The (internal) abdominal ring is covered by the peritoneum and the transversalis fascia. The latter here sends a shallow funnel-like extension outward to be attached to the spermatic cord. The base of this funnel-like depression toward the inguinal (Poupart's) ligament is formed by a thickened band of tissue, the *tractus ilio-pubicus*. Medially and laterally the bundles of fibrous tissue which constitute this tract spread out fan-like, medially over the sheath of the rectus and toward the pubis, laterally over the transversus muscle and toward the crest of the ilium. The transverse abdominal muscle arises from the inguinal ligament nearly as far as the lateral margin of the abdominal ring. The fibre-bundles of this portion of the muscle course ventralward above the base of the funnel mentioned above and are inserted by tendons forming a more or less complete aponeurosis, the "conjoined tendon" [falx inguinalis], common to it and the internal oblique into the ventral sheath of the rectus abdominis muscle, into the tubercle, crest and pecten of the pubis and sometimes into the pectineal fascia or the lacunar (Gimbernat's) ligament. Tendinous bands from the transversalis muscle curve downward medial to the (internal) abdominal ring and help to strengthen the transversalis fascia here. These bands constitute the *interfoveolar ligament* [ligamentum interfoveolare, Hesselbachi]. The fibrous bands constituting this ligament are attached to the lacunar ligament and the pectineal fascia.

From the internal ring the spermatic cord (or in the female the ligamentum teres) passes downward and forward in a space (inguinal canal) about 4 cm. long and then through the subcutaneous (external abdominal) ring which has been described in connection with the inguinal ligament. The ventral wall of the inguinal canal is composed of the aponeurosis of the external oblique, the intercrural fibres, and the cremaster muscle. Laterally it is also covered by the caudal portions of the internal oblique and transversus muscles. The caudal wall or floor of the space is formed chiefly by the lacunar (Gimbernat's) ligament and laterally also by the ilio-pubic tract. Cranialward the lateral part of the space is covered by the transversus and internal oblique muscles, the medial part by the cremaster muscle. The dorsal (internal) wall is formed mainly by the transversalis fascia. Medially the lacunar (Gimbernat's) ligament and the conjoined tendon (falx inguinalis), when this is well developed, help to form the dorsal wall. Lateral to these structures the dorsal wall is thinner but may be strengthened by a well developed ilio-pubic tract. Near the (internal) abdominal ring it is strengthened by the interfoveolar ligament, and sometimes by muscle slips (interfoveolar muscle).

Abdominal fossæ in the inguinal region.—The hernias so frequent in this region make a special study of the inner surface of the abdominal wall of considerable practical importance. Medial to the abdominal (internal) inguinal ring the inferior internal epigastric vessels give rise to a slight fold (*plica epigastrica*) which slants medialward and upward toward the rectus muscle. From the lateral margin of the tendon of insertion of the rectus muscle upward toward the umbilicus over the obliterated umbilical artery there extends a better marked fold, the *plica umbilicalis lateralis*. Lateral to the plica epigastrica lies the **fovea inguinalis lateralis,** with the internal inguinal ring. Between the plica epigastrica and the plica umbilicalis lateralis lies the **fovea inguinalis medialis.** In the latter region the fascia transversalis which here forms the inner wall of the inguinal canal is strengthened by two longitudinal fibrous bands belonging to the aponeurosis of the transversalis muscle and described above, the ligament interfoveolare at the medial side of the (internal) abdominal ring, and the falx inguinalis (conjoined tendon) lateral to the rectus muscle. These bands vary in width. When they are narrow the part of the internal wall of the inguinal canal covered merely by the thin transversalis fascia and the peritoneum is relatively large and, since this region lies behind the subcutaneous (external abdominal) ring, opportunity is offered for direct inguinal hernia.

MUSCLES

A. Ventral Division

The rectus abdominis (fig. 388).—*Origin*—Ventral surface of the fifth to seventh costal cartilages, the xiphoid process, and the costo-xiphoid ligament.

Insertion.—The upper border of the body of the pubis and the ventral surface of the symphysis.

Structure.—The muscle is long, flat, and somewhat triangular in form. Cranialward it is broad and thin; caudalward it becomes thicker as it converges toward the insertion. The fibre-bundles of the muscle have a longitudinal course. It is crossed by several incomplete, zigzag, transverse tendinous bands, **inscriptiones tendineæ,** better developed on the ventral than on the dorsal surface of the muscle and intimately united to the ventral sheath of the rectus. One of these, corresponding segmentally to the tenth rib, is usually situated opposite the umbilicus. Another, corresponding to the ninth rib, is situated midway between this and the lower margin of the thoracic wall, and one corresponding to the seventh rib is found at the level of the xiphoid process. Between this and the one corresponding to the ninth rib an additional inscription is frequently found. Below the umbilicus an inscription corresponding with the eleventh rib is often found (30 per cent.). In these inscriptions many of the fibre-bundles have their origin and insertion. The thoracic attachments take place by means of band-like fasciculi which extend upward from the highest inscription, the fibre-bundles of these fasciculi being inserted by short tendinous bands. The pubic attachment of the muscle takes place by a short, thick tendon, usually divisible into two portions, of which the broader, lateral portion is inserted into a rough area extending from the pubic tubercle (spine) to the symphysis, while the more slender medial portion is attached to the fasciæ in front of the symphysis pubis, where its fibres interdigitate with those of the opposite side. In addition to the attachments mentioned, some of the fibre-bundles are attached to the sheath of the rectus and many, after interdigitating, terminate in the intramuscular framework.

Nerve-supply.—The anterior branches of the six or seven lowermost intercostal nerves enter the deep surface of the muscle near its lateral edge. The cutaneous branches pass obliquely through its substance, while the muscular branches give rise to an intramuscular plexus. As a rule, the chief ventral branch of the tenth thoracic nerve enters the substance of the muscle slightly below the umbilical transverse inscription. The branches of the eleventh and twelfth nerves enter at a lower level. The main branch of the ninth nerve enters slightly below the preumbilical inscription; the eighth nerve, between this and the lower margin of the thorax. Either the sixth or seventh nerve may supply the fasciculi of origin. In addition to the main branches other smaller branches of the nerves of the abdominal wall are also usually distributed to the muscle. Each segment, either directly or through intramuscular plexuses, has a supply from more than one spinal nerve.

Action.—To depress the thorax and flex the spinal column. When the thorax is fixed the rectus serves to flex the pelvis upon the trunk.

Relations.—It lies between the transversalis fascia and the tela subcutanea and is ensheathed by the aponeuroses of the lateral abdominal muscles, as above described. The epigastric artery runs on its deep surface.

Variations.—The rectus muscle varies in the number of its tendinous inscriptions and in the extent of its thoracic attachment. It may extend farther than usual on the thorax. Frequently aponeurotic slips or slips of muscle on the upper part of the thorax indicate a more primitive condition in which the muscle extended to the neck. Absence of a part or the whole of the muscle has been noted. The muscles of the two sides may be separated by a considerable interval in the neighbourhood of the umbilicus. The muscle is relatively thicker in men than in women.

The pyramidalis (fig. 388).—*Origin.*—Upper border of the body of the pubis.

Structure and insertion.—The fibre-bundles extend toward and are inserted into the linea alba for about a third of the distance to the umbilicus, and give rise to a flat, triangular belly.

Nerve-supply.—Usually through a branch of the twelfth thoracic, which may extend into the muscle through the rectus abdominis. Not infrequently a special branch extends into the muscle from the ilio-hypogastric or ilio-inguinal or, rarely, from the genito-femoral.

Action.—To draw down the linea alba in the median line.

Relations.—It lies between two laminæ of the anterior layer of the sheath of the rectus.

Variations.—It is missing in about 16 per cent. of instances (Le Double). Dwight has found it absent in 81 out of 450 males and in 60 out of 223 females dissected at the Harvard Medical School. It may extend upward to the umbilicus or be but very slightly developed. It may be double. In many of the mammals it is missing. It is well developed in the marsupials and monotremes.

B. Lateral Division

1. *Serratus Group* (fig. 380)

The serratus posterior superior.—*Origin.*—By a broad, thin aponeurosis from the ligamentum nuchæ and the spines of the last one or two cervical and the first two or three thoracic vertebræ.

Structure and insertion.—The fibre-bundles take a nearly parallel course downward and lateralward and give rise to a flat belly which ends by four fasciculi on the upper margin of the second to the fifth ribs, lateral to the ilio-costalis.

Nerve-supply.—Through branches from the first four intercostal nerves. These nerves give rise to a plexus which passes across the deep surface of the muscle in the middle third between the tendons of origin and insertion.

Action.—To elevate the ribs to which the muscle is attached, and through them to enlarge the thorax.

Relations.—It lies upon the wall of the thorax and the intrinsic dorsal musculature and beneath the levator scapulæ, rhomboids, serratus anterior, and trapezius. Its fasciculi extend on the ribs to those of the serratus anterior (magnus).

The serratus posterior inferior.—*Origin.*—Through an aponeurosis, fused medially and inferiorly with the lumbo-dorsal fascia, from the last two or three thoracic and first two or three lumbar spines.

Structure and insertion.—From the aponeurosis arise four flat bands which are successively attached to the inferior margins of the last four ribs, lateral to the ilio-costalis.

Nerve-supply.—From the ninth to eleventh intercostal nerves arise branches which form a plexus that extends across the deep surface of the muscle in the middle third between the tendons of origin and insertion.

Action.—To depress and draw outward the four lower ribs and through them to enlarge the thorax. Together with the serratus posterior superior and the connecting aponeurotic fascia it aids in keeping the intrinsic dorsal muscles in place.

Relations.—It lies upon the intrinsic dorsal musculature, the lower dorsal part of the thorax, and the lumbo-dorsal fascia, and beneath the latissimus dorsi, the trapezius, and their aponeuroses.

Variations.—The fasciculi of both muscles vary in number and may be replaced by aponeurotic slips. Aberrant muscle fasciculi, **supracostales posteriores,** may be found in the fascia which connects the two muscles. In several of the lower mammals the two muscles are normally continuous.

2. *External Oblique Group*

The intercostales externi (fig. 385).—These muscles extend in the intercostal spaces from the tubercles of the ribs to the costal cartilagess. The intermediate muscles do not, however, often quite reach the cartilages. The first intercostal muscle may extend to the sternum. The others are continued through the intercostal region by thin aponeuroses, the **external intercostal ligaments,** the fibres of which have a direction corresponding to that of the muscle fibre-bundles. Dorsally the muscles are fused with the levatores, and ventrally the lower seven muscles are more or less fused with the corresponding fasciculi of the external oblique.

Origin.—From the lower margin of each rib external to the costal sulcus.

Structure and insertion.—The fibre-bundles take a parallel course obliquely forward and downward to the upper margin of the next rib. The proximal fibre-bundles are more oblique than the distal, and the muscles are best developed in the dorsal part of the intercostal spaces.

Nerve-supply.—By several branches from the corresponding intercostal nerves.

Action.—To elevate the ribs and enlarge the thorax.

Relations.—They are covered externally by the pectoral muscles, the serratus anterior, and serrati posteriores, the levatores costarum, the sacro-spinalis (erector spinæ), and the external oblique muscles. Internally they are separated by a slight amount of loose tissue from the internal intercostals, the membranes which continue these muscles medially, and from the subcostal muscles.

Variations.—When the twelfth rib is very small or is lacking, the eleventh intercostal muscle may be missing. When there is a supernumerary cervical or thirteenth thoracic rib, there may be an extra external intercostal muscle. Next to the first intercostal, the fourth most frequently reaches the sternum.

The levatores costarum (fig. 383).—These consist of a series of flat, triangular muscles, each of which *arises* from the tip and inferior margin of a transverse process and extends laterally with diverging fibre-bundles to be *inserted* into the dorsal surface of the rib below, from the tubercle to the angle. The first extends from the transverse process of the seventh cervical vertebra to the first rib. They increase successively in size from this to the last, which is attached to the twelfth rib. Those arising from the transverse processes of the eighth to the eleventh thoracic vertebræ send their more medial fibre-bundles across the rib below to join the lateral margin of the succeeding muscle (**levatores longi**). The levatores costarum are closely united to the external intercostals and are innervated by the intercostal nerves which pass forward in the corresponding intercostal spaces. The first muscle is innervated by the eighth cervical nerve.

Action.—To bend laterally and extend the spinal column.

Relations.—They are covered dorsally by the longissimus dorsi and the ilio-costalis.

Variations.—The first levator may be continued into the scalenus posterior. When greatly developed, the series of levators forms a serrate muscle.

The obliquus abdominis externus (fig. 387).—*Origin.*—By eight fleshy digitations from the external surface of the lower eight ribs immediately lateral to where they join the cartilages. The first five slips interdigitate with the serratus anterior (magnus), the last three with the latissimus dorsi.

Insertion.—(1) By a strong aponeurosis which extends over the rectus to the linea alba, where the more superficial fibres interdigitate across the median line, and to the inguinal (Poupart's) ligament; and (2) directly into the outer lip of the crest of the ilium. The aponeurosis over the rectus is usually partly fused with the aponeurosis of the internal oblique.

Structure.—The fibre-bundles which compose the flat fasciculi of origin diverge slightly as they pass forward and downward, and by fusion of their edges give rise to a flat sheet of muscle. The fasciculus taking origin from the fifth rib passes nearly directly ventrally, but the succeeding fasciculi incline somewhat downward, those from the seventh to the ninth ribs showing the greatest downward inclination. The lower margin of the fasciculus which arises from the seventh rib terminates opposite the umbilicus, that from the ninth rib extends toward the anterior superior spine of the ilium, and those from the last three ribs descend to the iliac crest. The first two fasciculi extend over the lateral margin of the rectus, the next two to its lateral edge. The fourth and fifth usually terminate along a line extending ventrally from the anterior superior iliac spine toward the rectus.

Nerve-supply.—The external oblique is supplied by rami from the lateral branches of the lower seven intercostal nerves and usually from the ilio-hypogastric as well. The rami of the first two or three nerves usually extend on the external surface of the muscle, while the others extend on the deep surface of the muscle as the cutaneous branches are passing through it toward the skin. The nerves of the external oblique take a more transverse direction than the fasciculi of the muscle. Thus the branch from the tenth intercostal nerve extends toward the umbilicus and that of the twelfth toward a point midway between the umbilicus and the symphysis pubis. The nerves have a segmental distribution corresponding with the primitive segmental condition of the muscle.

Action.—(1) To compress the abdomen; (2) to depress the thorax; (3) to flex the spinal column; and (4) to rotate the column toward the opposite side. With the thorax fixed it serves to flex and rotate the pelvis.

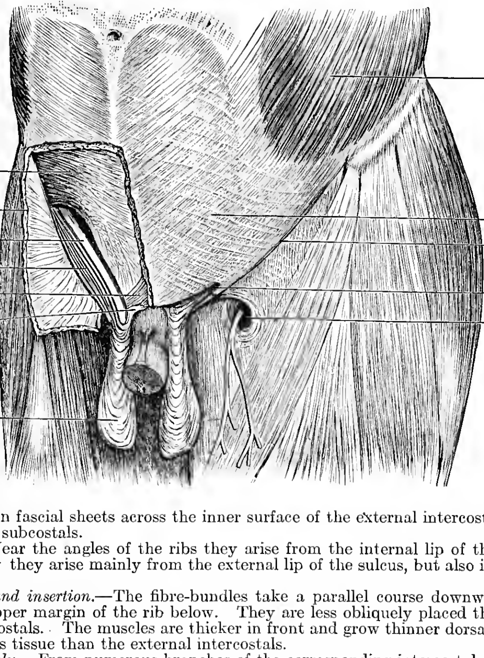
Relations.—It lies superficial to the lower ventro-lateral margin of the thorax and the internal oblique muscle. It is partly covered by the latissimus dorsi muscle behind. Otherwise it is subcutaneous.

Variations.—It may have a more or less extensive origin from the ribs. Broad fasciculi not infrequently are separated by loose tissue from the main belly of the muscle either on its deep or superficial surface. Occasionally tendinous inscriptions are found. These transverse inscriptions are constant in many of the smaller mammals. The **supracostalis anterior** is a rare fasciculus sometimes found on the upper portion of the thoracic wall. It is usually supplied by branches of the upper thoracic nerves and seems to be a continuation upward of the external oblique muscle. In some prosimians the external oblique extends normally to the first or second rib.

3. *Internal Oblique Group*

The intercostales interni (figs. 385, 386, 388).—These extend in the intercostal spaces from the angles of the ribs to the sternal ends of the spaces. The upper and lower muscles are usually continued dorsally slightly beyond the angles of the ribs, while the intermediate muscles frequently do not quite reach them. Dorso-medially the internal intercostals are continued in

FIG. 389.—STRUCTURES OF INGUINAL REGION.



the form of thin fascial sheets across the inner surface of the external intercostals and become fused with the subcostals.

Origin.—Near the angles of the ribs they arise from the internal lip of the costal sulcus. More ventrally they arise mainly from the external lip of the sulcus, but also in part from the internal lip.

Structure and insertion.—The fibre-bundles take a parallel course downward and dorsalward to the upper margin of the rib below. They are less obliquely placed than those of the external intercostals. The muscles are thicker in front and grow thinner dorsally. They contain less fibrous tissue than the external intercostals.

Nerve-supply.—From numerous branches of the corresponding intercostal nerves.

Action.—Investigators disagree as to the functions. It is probable that the portions of the muscles between the ribs serve to contract, those between the costal cartilages to expand, the thorax.

Relations.—Between the ribs they are covered by the external intercostal muscles and between the costal cartilages by the external intercostal ligaments. Between the internal and external muscles there is some loose areolar tissue. Proximally, for a short distance, the intercostal nerve in each interspace runs between the external and internal intercostal muscles, but more distally it runs first in the substance of and then on the internal surface of the internal intercostal. Eisler distinguishes that portion of the internal intercostal muscle which lies external to the nerve as the intercostalis intermedius, that which lies internal as the true internal intercostal. The terminal branches of the first six nerves, however, pass through the muscle on their way to the skin, while the last six pass beneath the inferior margin of the thorax. Internal to the internal intercostal muscles lie the transversus (triangularis sterni) and subcostal muscles, the diaphragm, and the pleural membranes. The more distal internal intercostal muscles are continuous with the internal oblique and the subcostal muscles.

Variations.—The tenth and eleventh internal intercostal muscles normally are but slightly developed and often may be wanting. The internal intercostals of the first three spaces may extend to the vertebræ.

The subcostales (fig. 385).—These muscles are due to an extension over two or more intercostal spaces of those fibre-bundles of the internal intercostal muscles which lie in the proximal part of the interspaces. They arise near the angles of the ribs, and are usually well developed only in the lower part of the thorax. The component fibre-bundles keep the general direction of the internal intercostals, but they converge toward the tendons of insertion, which are attached in each case to the second or third rib below, between the angle and the neck.

Nerve-supply.—The main nerve of supply for each muscle comes from the intercostal nerve running below the rib from which the muscle takes origin.

Action.—To depress the ribs and contract the thorax.

Relations.—They lie on the inner side of the internal and external intercostals and the ribs, and are covered by the pleural membranes.

Variations.—They vary much in development. Next to the lower fasciculi, the fasciculi in the cranial part of the thorax are those usually best developed.

The obliquus abdominis internus (fig. 388).—*Origin.*—From the lumbo-dorsal fascia the intermediate lip of the ventral two-thirds of the iliac crest, and the lateral half of the inguinal ligament.

Structure and insertion.—From the origin the fibre-bundles radiate forward in a flat sheet. The most dorsal extend to the lower three ribs, where they become continuous with the internal intercostals. The rest extend toward the lateral margin of the rectus, the upper ones toward the xiphoid process, the intermediate toward the umbilicus, the lower ones somewhat obliquely downward across the lower part of the abdomen. The fibre-bundles which extend toward the rectus terminate in an aponeurosis which in its upper two-thirds divides into two layers, one of which passes in front of and the other behind the rectus muscle to the linea alba. In the lower third the aponeurosis passes as a single membrane in front of the rectus. In the neighbourhood of the subcutaneous inguinal (external abdominal) ring the muscle is continued into the cremaster. Medial to the ring some fasciculi are attached to the tubercle of the pubis and to the symphysis.

Nerve-supply.—From branches of the last three intercostal and the ilio-hypogastric, ilio-inguinal and genito-femoral (?) nerves as these pass between this muscle and the transversus.

Action.—To depress the thorax, flex the vertebral column, and bend and rotate it toward the side on which the muscle is placed. When the thorax is fixed, the muscle serves to flex and rotate the pelvis.

Relations.—It lies between the external oblique and the transversus. The **trigonum lumbale** (triangle of Petit) is an area, variable in size, between the posterior margin of the external oblique, the lateral margin of the latissimus dorsi, and the crest of the ilium. In this area the internal oblique is subcutaneous.

Variations.—The attachments and the extent of development of the fleshy part of the muscle vary considerably. Occasionally tendinous inscriptions are found in the muscle which indicate a primitive segmental condition.

The cremaster (fig. 389).—The cremaster muscle is found well developed only in the male. It represents an extension of the lower border of the internal oblique muscle and possibly also of the transverse over the testis and spermatic cord.

Origin.—(1) Lateral, thick and fleshy, from about the middle of the upper border of the inguinal ligament, and (2) medial, thin and tendinous, from the sheath of the rectus muscle and the tubercle (spine) of the pubis.

Structure.—The lateral head is applied to the lateral side, the medial head to the medial side, of the spermatic cord. Both pass with this through the subcutaneous (external abdominal) ring of the inguinal canal and become spread in loops over the testis. Ensheathing the muscle and between the somewhat scattered fibre-bundles which compose it, there extends a thin, membranous layer of connective tissue, the **cremasteric** (Cowper's) fascia.

Nerve-supply.—The genital nerve (external spermatic), usually joined by a ramus from the inguinal nerve, gives rise to branches which spread over the muscle.

Action.—To lift the testis toward the subcutaneous inguinal (external abdominal) ring.

Relations.—It is covered by the aponeurosis of the external oblique, the cremasteric fascia, the dartos, and the skin. It covers the spermatic cord and the testis.

Variations.—In the female the muscle is represented by a few fasciculi on the round ligament. It may arise wholly from the transversalis fascia or be somewhat fused with the transversus muscle. The latter condition is especially frequent in muscular individuals.

4. *Transversus Group*

The transversus thoracis (triangularis sterni) (fig. 386).—*Origin.*—By aponeurotic bands from the dorsal surface of the lower half of the body of the sternum and the xiphoid process.

Structure and insertion.—The muscle is composed of several flat, thin fasciculi, partly fibrous, more or less isolated, which are inserted by aponeurotic bands into the dorsal surface of the cartilages of the second or third to the sixth ribs, and occasionally also into the tips of the bony portions of the ribs. The lower fasciculus is closely related to the cranial margin of the transversus abdominis.

Nerve-supply.—By rami from the ventral portions of the second to the sixth intercostal nerves. These nerves give rise to a longitudinal plexus across the deep surface of the muscle near the middle of the constituent fasciculi.

Action.—To depress the ribs in expiration.

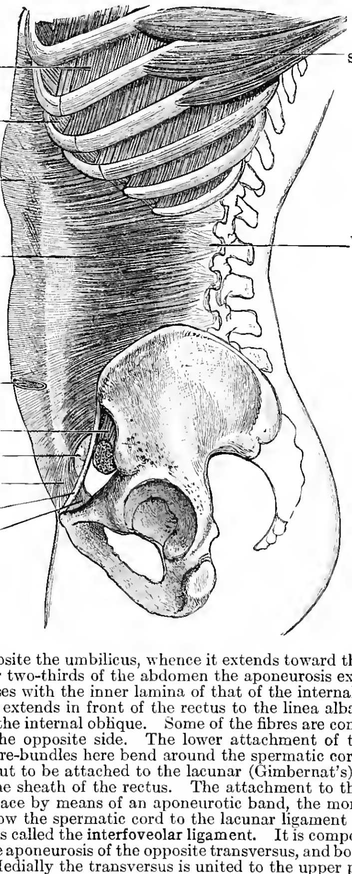
Relations.—The sternum, the costal cartilages, internal intercostal muscles, and the internal mammary vessels lie in front and the pleura and pericardium behind the muscle.

Variations.—It is an exceedingly variable muscle, both in the extent of its attachments and in the development of the individual fasciculi. The fasciculi vary in number from one to six. With this muscle Eisler would class the subcostal muscles and those portions of the internal intercostal muscles which lie internal to the intercostal nerves.

The transversus abdominis (figs. 386, 390).—*Origin.*—Directly from—(1) the inner side of the cartilages of the lower six ribs by dentations which interdigitate with the attachments of the diaphragm; (2) the internal lip of the iliac crest and lateral half of the inguinal ligament; and (3) through an aponeurosis from the lumbo-dorsal fascia.

Structure and insertion.—The fibre-bundles give rise to a broad, thin belly and take a nearly transverse course across the inner side of the abdominal wall. The most distal fibres, however, are inclined obliquely toward the pubis. The fleshy portion of the muscle terminates in a strong aponeurosis along a curved line, which extends above well under the rectus and emerges

FIG. 390.—TRANSVERSUS ABDOMINIS AND SHEATH OF RECTUS.



lateral to the rectus opposite the umbilicus, whence it extends toward the middle of the inguinal ligament. In the upper two-thirds of the abdomen the aponeurosis extends behind the rectus to the linea alba and fuses with the inner lamina of that of the internal oblique. In the lower third of the abdomen it extends in front of the rectus to the linea alba, and is here also fused with the aponeurosis of the internal oblique. Some of the fibres are continued into the aponeurosis of the muscle of the opposite side. The lower attachment of the muscle is somewhat more complex. The fibre-bundles here bend around the spermatic cord, on the medial side of which they are spread out to be attached to the lacunar (Gimbernat's) ligament and pectineal fascia, the pubis, and the sheath of the rectus. The attachment to the lacunar ligament and pectineal fascia takes place by means of an aponeurotic band, the more lateral fibres of which are dense and curve below the spermatic cord to the lacunar ligament and the pectineal fascia below this. This band is called the **interfoveolar ligament.** It is composed partly of bundles of fibres prolonged from the aponeurosis of the opposite transversus, and bounds the abdominal ring medially and below. Medially the transversus is united to the upper part of the os pubis, and to the sheath of the rectus by an aponeurotic band, the **falx inguinalis** (conjoined tendon). Between the interfoveolar ligament and the falx inguinalis the transversalis fascia forms the posterior wall of the inguinal canal. In this area a detached band of muscle-fibres is sometimes found. This is called the **musculus interfoveolaris.**

Nerve-supply.—The transversus is supplied with nerves by the last five or six thoracic and the ilio-hypogastric, inguinal and genito-femoral nerves as these course forward between this muscle and the internal oblique.

Action.—The chief function is to compress the abdominal viscera. Through the portions extending between the lower margins of the thorax on each side it serves to contract the thorax and so may aid in expiration.

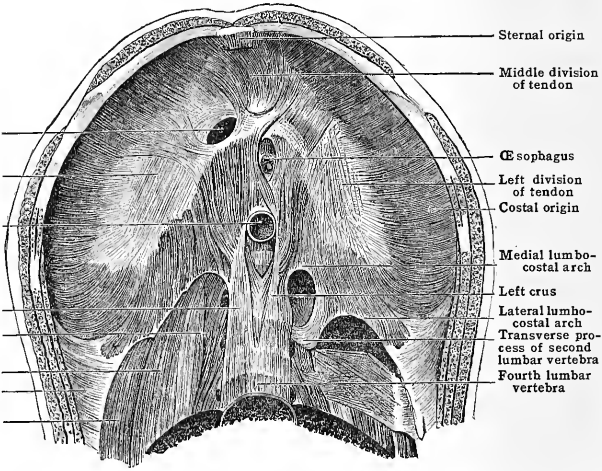
Relations.—It lies on the inner side of the lower ribs, the internal oblique and rectus muscles, and is covered on the deep surface by the transversalis fascia.

Variations.—It is very rarely absent. It shows considerable variation in the extent of its development. The **pubo-peritonealis** is a similar muscle which may pass from the pubic crest to the transversus near the umbilicus. The **pubo-transversalis** is a small muscle which may extend from the superior ramus of the pubis to the transversalis fascia near the abdominal inguinal ring. The **tensor laminæ posterioris vaginæ musculi recti abdominis,** essentially like the preceding, may extend from the inguinal ligament to the rectus sheath on the deep surface of the rectus muscle near the umbilicus. The **tensor laminæ posterioris vaginæ musculi recti et fasciæ transversalis abdominis** likewise extends from the transversalis fascia near the abdominal inguinal ring to the fold of Douglas.

C. Lumbar Muscle

The quadratus lumborum (fig. 406).—*Origin.*—From—(1) the internal lip of the iliac crest near the junction of the middle and dorsal thirds, and the iliolumbar ligament; (2) the transverse processes of the three or four lower lumbar vertebræ; and (3) the lumbo-dorsal fascia.

Fig. 391.—Diaphragm.



Structure and insertion.—From the origins there arises a complex quadrangular muscle belly from which spring the fasiculi of termination. These extend to—(1) the transverse processes of the upper three or four lumbar vertebræ; (2) to the fibre-bands which extend out laterally in the lumbar fascia from the transverse processes; and (3) to the medial part of the lower border of the twelfth rib.

Nerve-supply.—Through direct branches from the first three or four lumbar nerves.

Action.—It serves primarily to produce lateral flexion of the spinal column. When both muscles act together, they produce extension of the column. The muscle also serves to depress and fix the twelfth rib.

Relations.—It rests posteriorly on the lumbo-dorsal fascia and the transverse processes of the lumbar vertebræ. Its medial edge is partly covered by the psoas. In front of it also lie the kidney, the intestines, and the lumbar arteries and nerves. It is ensheathed by membranes continued over each surface from the transversalis fascia. Of these, the anterior is the better marked and is called the **lumbar fascia.**

Variations.—There is much individual variation in the internal structure of the muscle and in its attachments. Its insertion may extend to the eleventh rib.

The **psoas major** and **minor** belong essentially to the musculature of the lower limb and are there described (p. 455).

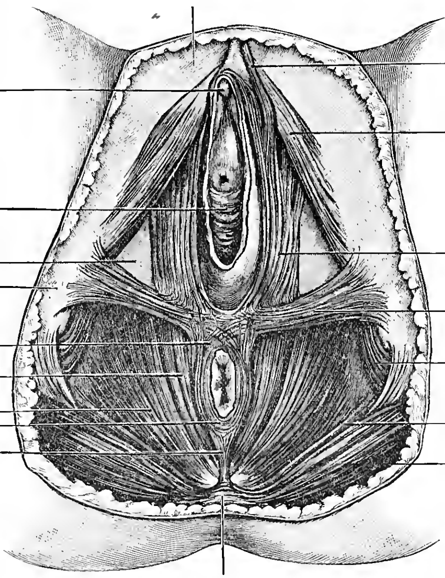
D. The Diaphragm

The diaphragm (figs. 386, 391).—This dome-shaped musculo-membranous sheet has, when seen from above, something of the outline of a kidney. It consists of a pair of muscles which arise one on each side from the thoracic wall and are inserted into a central tendon. Lateral to the tendon the diaphragm projects higher into the thoracic cavity than in the central area. On the right, in moderate expiration, it extends in adults to the height of the medial extremity of the fifth rib, and on the left to the fifth interspace.

Origin.—On each side from—(1) the lower border and back of the xiphoid process and the adjacent aponeurosis of the transversus abdominis or from the tendinous arch extending from the tip of the xiphoid process to the cartilages of the fifth and sixth ribs, (*sternal portion*); (2) the lower border and inner surfaces of the cartilages of the seventh and eighth ribs, the cartilages and osseous extremity of the ninth rib and the osseous extremities of the last three ribs (*costol portion);* and (3) from the lumbar vertebræ (*lumbar portion*). The lumbar portion is divided somewhat irregularly into three crura, between which pass blood-vessels and nerves.

The **lateral crus** arises from the lateral surface of the bodies of the first two lumbar vertebræ and from fibrous thickenings of the fascia over the psoas and quadratus lumborum muscles. Of these, one, the **medial lumbo-costal arch** (internal arcuate ligament), extends from the body of the second lumbar vertebra to the transverse process of the same vertebra; the other, the **lateral lumbo-costal arch** (external arcuate ligament), extends from the tip of the transverse

Fig. 392.—The Perineal Muscles in the Female.

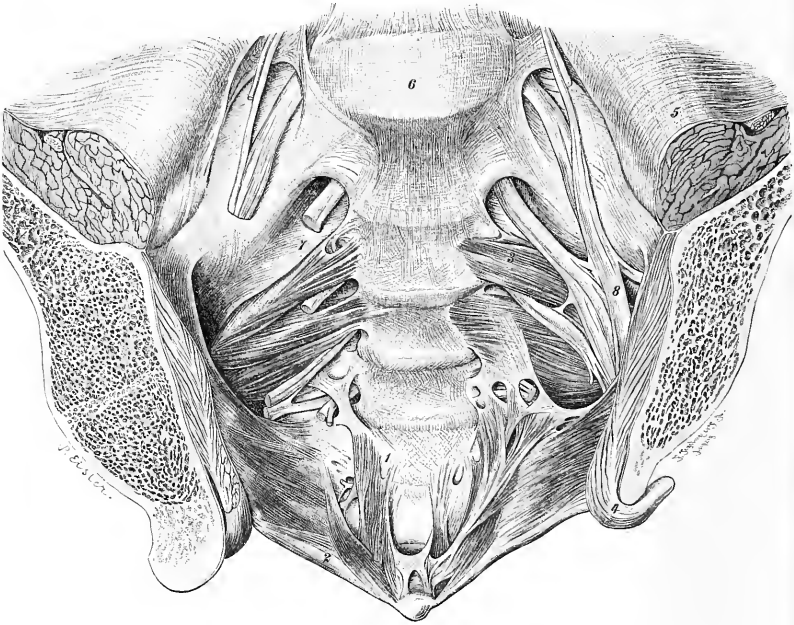


process of the second lumbar vertebra to the twelfth rib. The lateral crus is only inconstantly attached to this. The **intermediate crus** arises from the ventro-lateral surface of the body of the second lumbar vertebra from the sides of the bodies of the first two lumbar vertebræ and from the intervening discs. The **medial crus** arises from the front of the bodies of the third and the fourth lumbar vertebræ. On the left side it usually extends only to the third vertebra, and it does not always extend to the fourth on the right. The extremity and medial margin of this crus are tendinous, the lateral portion fleshy. On the second, third, and fourth, and the lower part of the first lumbar vertebræ the medial crus of each side is separated from its fellow by the **hiatus aorticus** (for the aorta and thoracic duct). Over the first lumbar vertebra they are fused by a process which extends from the right crus into the lower ventral surface of the left. Above here the right crus may be divided into two parts, one of which, fused with the left crus, passes on the left of the **hiatus œsophageus,** while the other passes on the right. Sometimes the hiatus œsophageus lies between the right and left crura. Frequently the left crus gives off a slip which passes to the ventral surface of the right below the hiatus.

The **costal portion** arises by a series of dentations which do not correspond perfectly in number with the ribs. Some costal cartilages have two dentations attached to them. It interdigitates with the transversus abdominis but in part arises from tendinous arches which bridge the origin of the transversus in the last three interspaces.

Structure and insertion.—The central tendon has somewhat the shape of a trifoliate leaf, the place of the stem being taken by the region occupied by the vertebral column, one leaflet lying on each side of this and one in front. The ventral part is usually placed somewhat to the left and is more or less completely fused with the left leaflet. Between the ventral and the right leaflets there is a large opening through which passes the inferior vena cava, the **foramen venæ cavæ**. The leaflets are fused in front and behind this.

Fig. 393.—Ventral Coccygeal Muscles (After Eisler.)—1. M. sacrococcygeus anterior. 2. M. coccygeus. 3. M. piriformis. 4. M. obturator internus. 5. Fascia iliaca, above the ilio-psoas. 6. Fibrocartilago intervertebralis lumbosacralis. 7. Ventral trunk of first sacral nerve. 8. Sacral plexus.



The fleshy portion of the muscle is composed of fibre-bundles which pass at first nearly vertically upward and then arch over to be attached to the margins of the central tendon. The sternal portion of the muscle is the shortest. It is often separated from the costal portion by a small space through which the superior epigastric vessels pass.

Nerve-supply.—From the phrenic nerves, one of which arises on each side from the third to the fifth cervical nerves. Each nerve penetrates the diaphragm lateral to the central tendon and breaks up into an extensive plexus on the inferior surface of the muscle. Some of the lower intercostal nerves also contribute to the sensory innervation of the margin of the muscle and possibly also slightly to the motor innervation. The sympathetic nerves furnish fibres for the blood-vessels.

Action.—To enlarge the thoracic cavity and thus cause inspiration. According to R. Fick, however, the diaphragm plays a less important part in inspiration than is usually assumed for it. The middle part of the central tendon is united to the pericardium and through this to the cervical fascia, and is, therefore, not very movable. In the contraction of the muscle it is the dorsal and lateral portions which in the main are flattened. The diaphragm aids in defecation, parturition and vomiting, by the pressure it exerts on the abdominal viscera. It also acts as a constrictor of the œsophagus.

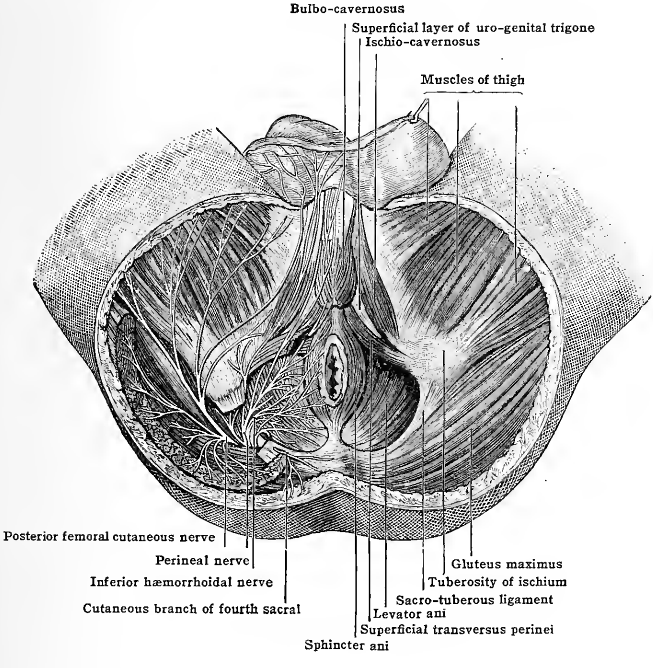
Relations.—Above lie the heart and the lungs; below lie the liver, stomach, duodenum, pancreas, spleen, kidneys, and suprarenal bodies.

Variations.—The sternal portion of the muscle is frequently absent. Infrequently the diaphragm is incompletely developed dorsally on the left side. This condition is rarer on the right side. The extent of the various insertions of the diaphragm shows considerable individual differences. The vertebral portion of the muscle may be slightly fused with the psoas or with the quadratus lumborum. Some fusion of the ventral portion of the muscle with the transversus thoracis has also been seen. Small fasciculi may pass to neighbouring structures: the œsophagus, stomach, liver, mesentery, etc. Muscle fasciculi are frequently found in the central tendon.

V. MUSCULATURE OF THE PELVIC OUTLET

In order to understand the musculature of the pelvic outlet it is necessary first to consider briefly the structure of the pelvis. It is bounded laterally and in front by the ilium below the terminal (ilio-pectineal) line, the ischium and the pubis, and by the obturator membrane and the sacro-spinous (small sciatic), sacro-tuberous (great sciatic) and the interpubic ligaments. The pubis, ischium and the obturator membrane are covered by the obturator internus muscle (figs. 392, 401) which here takes its origin and which converges toward and passes through the lesser sciatic notch on its way to its insertion on the great trochanter of the femur. The piriformis muscle (figs. 393, 396), which arises from the sides of the pelvic surface of

FIG. 394.—THE MALE PERINEUM. (Modified from Hirschfeld and Leveillé.)



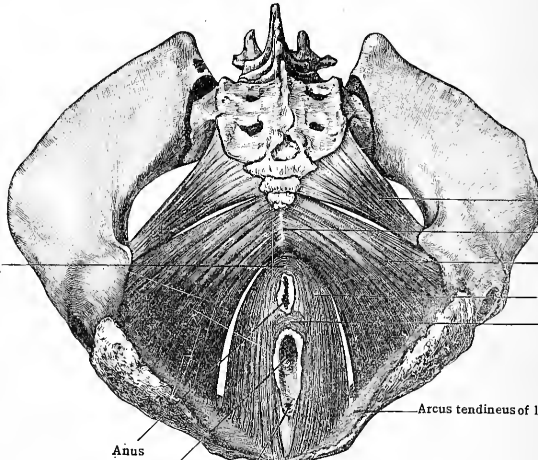
the sacrum, from the posterior border of the great sciatic notch and the neighbouring part of the sacro-tuberous (great sciatic) ligament nearly fills up the great sciatic notch on its way to its insertion on the great trochanter. The walls of the pelvis are thus padded by muscles which belong to the limb. The muscles are covered by fascia best developed over the obturator internus muscle as the *obturator fascia*. The gluteus maximus muscle (figs. 392, 394, 400, 401), which arises from the back of the ilium, the sacrum, and the coccyx, and is inserted into the femur and the fascia of the thigh overlaps to some extent the sacro-tuberous ligament, and in the standing position the tuberosity of the ischium so that its lower margin forms an accessory boundary to the pelvic outlet.

The outlet of the pelvis thus bounded by bone, ligaments and by muscles belonging to the lower extremity presents two triangles (figs. 392, 394), an anterior or urogenital triangle, with the base between the two ischial tuberosities and the apex below the symphysis pubis, and a posterior or rectal with the base between the ischial tuberosities and the apex at the coccyx which projects into it here. The outlet is closed by a special musculature divisible into three groups of muscles and fascia; those of the pelvic diaphragm and anus, those of the urogenital diaphragm, and those of the external genitalia.

The *pelvic diaphragm* [diaphragma pelvis] extends from the upper part of the pelvic surface of the pubis and ischium to the rectum which passes through it to be surrounded by the external sphincter. The urogenital trigone or *urogenital diaphragm* [diaphragma urogenitale] lies between the ischio-pubic rami superficial to the pelvic diaphragm and surrounds the membranous urethra and in the female also the vagina. The *external genital* muscles lie superficial to the trigone.

The muscles of the **pelvic diaphragm** are two in number on each side, the coccygeus, and the levator ani (figs. 395, 396, 397). The **coccygeus** arises from the

Fig. 395.—The Pelvic Diaphragm in the Female, from below and behind.

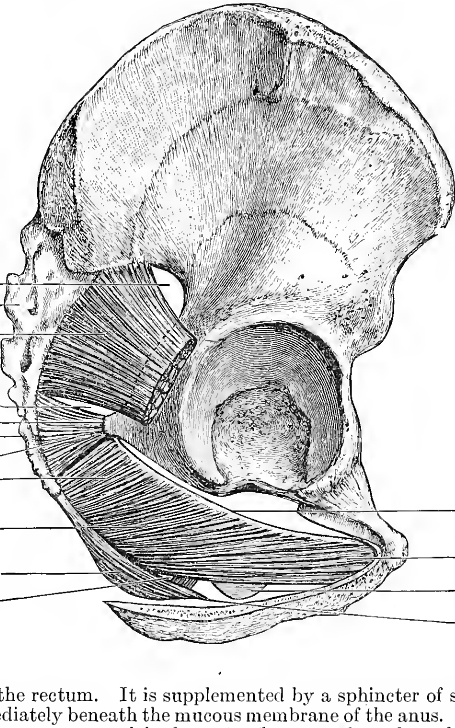


ischial spine and is inserted into the lateral margin of the lower sacral and the upper coccygeal vertebræ. It is closely applied to the pelvic surface of the sacrospinous (small sciatic) ligament. In so far as it is active it flexes and abducts the coccyx.

The **levator ani** arises (figs. 395, 396, 397) from the inner side of the pubis, along a line extending laterally from the inferior margin of the symphysis to the obturator canal, and from the obturator fascia along a line, the *arcus tendineus*, extending from the pubis to the spine of the ischium. The levator ani is inserted into the median raphe back of the anus, the ano-coccygeal raphe, into the tip and sides of the coccyx and into an aponeurosis, which is attached to the anterior sacrococcygeal ligament. It is divisible into three portions, a *pubo-coccygeal*, an *iliococcygeal*, and a *pubo-rectal*. The levator ani muscles of the two sides are separated by a slit which extends from the rectum to the symphysis pubis and in which in the male lie the lower part of the prostate, and the membranous urethra (fig. 396), and in the female the vagina and urethra (fig. 395). Back of the rectum some of the fibre-bundles from the muscles of the two sides interdigitate, while others terminate in the ano-coccygeal raphe. A few fibre-bundles also interdigitate across the median line, in front of the rectum (pubo-coccygeal, fig. 395) and some are inserted into the walls of the rectum. The levator ani and coccygeal muscles of the two sides form a funnel-shaped muscular support for the pelvic viscera (fig. 399). When the abdomino-thoracic diaphragm contracts, as during inspiration, the pressure on the viscera is transmitted to the pelvic diaphragm which resists the pressure and elevates the viscera when the abdomino-thoracic diaphragm relaxes. The levator ani muscle also constricts the rectum and pulls it forward and in the female constricts the vagina from side to side.

As it passes through the pelvic diaphragm, the rectum for about two and a half centimetres is surrounded by a special **external sphincter** muscle (figs. 393, 394, 397), divisible into three concentric layers as described below. This muscle, especially differentiated from the primitive sphincter of the cloaca,

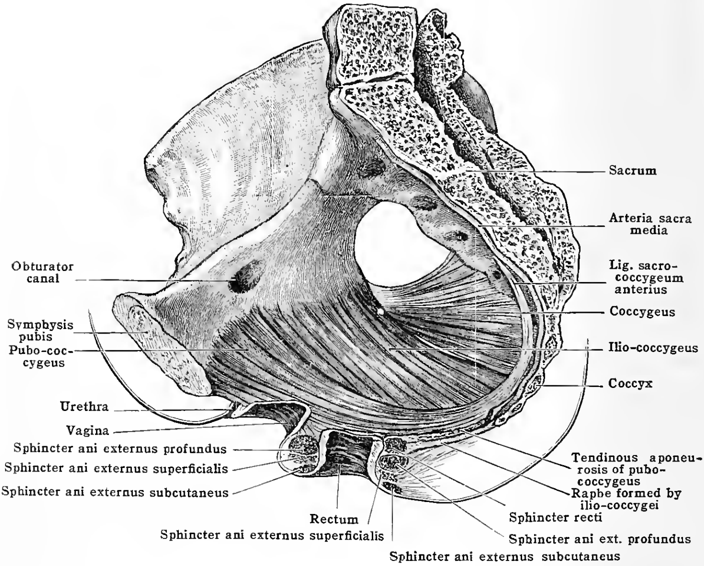
FIG. 396.—LATERAL VIEW OF MUSCLES OF THE FLOOR OF THE PELVIS. (A portion of the ischial and pubic bones sawn away.)



serves to close the rectum. It is supplemented by a sphincter of smooth muscle which lies immediately beneath the mucous membrane of the anus. It is attached behind to the coccygeus, and in front to the central tendon of the perineum described below.

The lateral origin of the levator ani, as above described and as shown in figs. 396 and 399, is considerably above the osseous and muscular margin of the pelvic outlet. The muscles of each side converge toward the post-anal region so that a space is left between the lateral wall of the pelvis, and the levator ani and external sphincter (fig. 399). This space, the **ischio-rectal fossa,** is filled with fat (fig. 400, 401, 402). It is deepened laterally by the lower margin of the gluteus maximus muscle (fig. 400). In the fascial canal (Alcock's canal) in the lateral wall of the fossa run the internal pudic vessels and nerves (fig. 401). Above the pelvic diaphragm in the median part of the pelvic cavity are found the bladder, the ampulla of the rectum, and the prostate gland (in the male) or the vagina and uterus (in the female). Laterally on each side there is a subperitoneal space, filled with connective tissue and containing blood-vessels and nerves (fig. 402). Fasciæ invest each surface of the pelvic diaphragm (*diaphragmatic fascia*) and extend about the viscera (*endopelvic fascia*).

FIG. 397.—SAGITTAL SECTION OF THE PELVIS TO SHOW THE PELVIC DIAPHRAGM AND EXTERNAL SPHINCTER ANI.

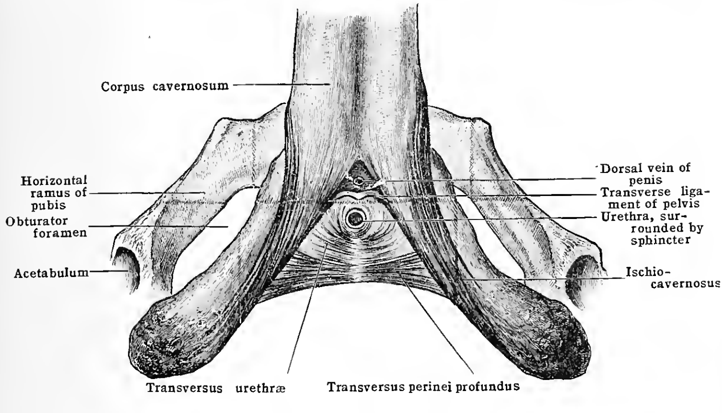


The muscular apparatus of the anterior or urogenital triangle of the pelvic outlet is much more complicated than that of the posterior or rectal triangle just described. We have seen that between the levator ani muscles of each side in front of the rectum there is a slit which extends to the symphysis pubis and that through it, the lower part of the prostate and the urethra extend in the male, the urethra and the vagina in the female. Between the ischio-pubic rami there is stretched a triangular muscular and fibrous membrane, which likewise surrounds these urogenital ducts and which serves to strengthen the pelvic wall in this region. This structure is known as the **urogenital trigone** (figs. 398, 400, 403). The musculature within it, called by Holl the accessory or urogenital diaphragm, includes two muscles (fig. 398), the sphincter urogenitalis (urethræ) and the deep transverse perineal muscle. The *sphincter* embraces the urethra and associated structures. The component fibre-bundles arise chiefly from the fibrous tissue in the angle beneath the symphysis pubis, but partly also from the descending pubic rami. They pass analward and medialward on each side of the urethra and then partly interdigitate across the median line, partly terminate in a median raphe. Some fibre-bundles embrace in the male the lower part of the prostate and Cowper's gland. In the female the fibre-bundles of the sphincter partly terminate in the wall of the vagina. Some of them are continued downward on each side of the vagina and interdigitate with fibre-bundles from the deep transverse perineal muscle. The *deep transverse perineal* muscle (fig. 398) arises on each side from the ischio-pubic ramus. It constitutes a flat band of muscle, the fibre-bundles of which in part interdigitate across the median line, and in part are inserted into a median raphe.

The musculature of the urogenital diaphragm is enclosed between two well marked **fascial layers** (fig. 400, 403), the deep (superior) and superficial (inferior) layers of the urogenital trigone (triangular ligament). The anterior margins of the two fascial layers are fused to form the transverse ligament of the pelvis which extends between the inferior pubic rami, beneath the dorsal nerves and veins of the penis (clitoris). At the anal margin of the musculature these two layers are also fused with one another. The deep layer of the urogenital trigone forms the floor of the anterior recess of the ischio-rectal fossa (fig. 400).

Superficial to the urogenital trigone lie the external genitalia (figs. 392, 394). Voluntary muscle is here found in connection with the crura of the penis (clitoris) and the bulb of the penis (vestibule). Although the musculature in the two sexes is fundamentally similar, nevertheless, owing to the differences in the structure of the genitalia in the two sexes, it is convenient to take up first the external genital musculature in the male and then that in the female.

Fig. 398.—Muscles between the Two Layers of the Urogenital Trigone (Male.)



In the male the crus penis, the posterior part of the corpus cavernosum, is relatively large. It lies in the groove between the ischio-pubic ramus and the urogenital trigone (fig. 398), to the former of which it is firmly united. It is enwrapped on its free medial surface by the **ischio-cavernosus** muscle (erector penis) (figs. 398, 402). The fibre-bundles of this muscle arise from the ischial tuberosity and from the ischio-pubic ramus on each side of the attachment of the crus. It is inserted into the medial and ventral surfaces of the crus near the attachment of the suspensory ligament. Some of the fibre-bundles may frequently be traced to the dorsal surface of the root of the penis (levator penis muscle).

The corpus spongiosum [corpus cavernosum urethræ] terminates posteriorly in the bulb which lies on the urogenital trigone between the two crura (figs. 394, 402). It is united to the superficial layer of the trigone (fig. 402). It is enveloped by the **bulbo-cavernosus** muscle, composed of right and left halves united by a median raphe on the superficial surface of the bulb (fig. 394). Each half consists of several superimposed layers of fibre-bundles described below. The component fibre-bundles arise from the superficial layer of the urogenital trigone, from fibrous tissue on the dorsum of the bulb in the angle between the two crura, from the lateral surface of the corpus cavernosum penis in front of the ischio-cavernosus and from the dorsal surface of the penis. It is inserted into a tendinous structure situated in front of the anus, the central tendon of the perineum, and into the median raphe on the free surface of the bulb. By its contraction the bulbo-cavernosus forces semen or urine from the bulbous part of the urethra.

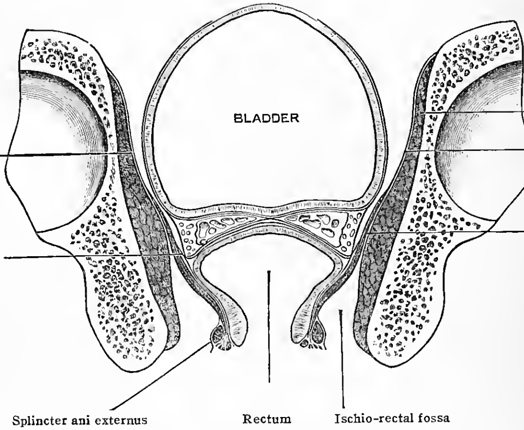
The **superficial transverse muscle** of the perineum (figs. 392, 394) arises on each side from the ascending ramus of the ischium and is inserted into the central tendon of the perineum. It is frequently weakly developed. It acts with the deep transverse perineal muscle in fixing the perineum and thus offering support for the action of other muscles.

In the **female** (fig. 392) the *ischio-cavernosus* does not differ markedly from that in the male although usually it is smaller. The superficial transverse muscles are, on the other hand, usually relatively better developed. The central tendon of the perineum is likewise usually better developed in women and is more elastic, a characteristic of value in childbirth.

The chief difference in the musculature in the two sexes is found in the *bulbo-cavernosus* (fig. 392). This, in the female, arises from the back of the clitoris, the corpus cavernosum and the trigone. It covers the outer side of the bulb of the vestibule and the gland of Bartholin. It is inserted into the central tendon of the perineum. The chief function of the pair of muscles is to constrict the vagina.

The external genital muscles are covered by a deep layer of the tela subcutanea,

FIG. 399.—DIAGRAM TO SHOW THE FASCIÆ OF THE PELVIS IN SECTION. (After Holl.)



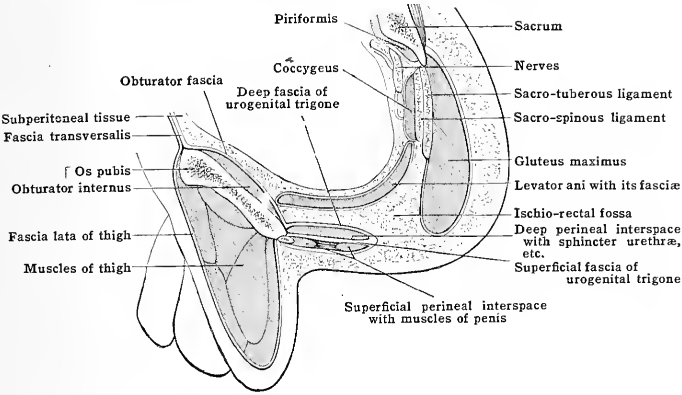
Colles' fascia, which is firmly fused with the two layers of the urogenital trigone at the anal margin of the latter.

MORPHOLOGICAL REMARKS

While the shoulder-girdle and the muscles which extend from this and from the trunk to the upper extremity are superficially placed with respect to the trunk, and do not interrupt the trunk musculature the reverse is true of the hip-girdle and the musculature of the lower extremity. The hip-girdle is firmly united to the spinal column at the sacrum. The muscles which arise from the trunk and are attached to the lower limbs are few in number compared with those of the upper extremity and, unlike the latter, are deeply placed. Thus the psoas major muscle (fig. 406) arises on each side of the lumbar region of the spinal column at the back of the abdominal cavity and is inserted into the femur and the piriformis (fig. 406) arises from the front of the sacrum at the back of the pelvic cavity and is inserted into the great trochanter of the femur. The skeleton and musculature of the lower extremity, furthermore, markedly interfere with the continuity of the trunk musculature which in the lower vertebrates and in the human embryo may be followed continuously to the caudal end. The interruption is much less marked behind than in front. The intrinsic dorsal spinal musculature extends well down over the back of the sacrum, but on the back of the lower end of the sacrum and on the back of the coccyx there is found merely the inconstant sacro-coccygeus posterior. Of the ventro-lateral musculature the musculature of the abdominal wall, as is indicated by its innervation, is derived from the lower thoracic and the first one or two lumbar myotomes; the quadratus lumborum, at the back of the abdominal cavity (fig. 406), from the first three or four lumbar myotomes. Beyond here there is an interruption until we come to the musculature of the pelvic outlet which, in part, may be looked upon as modified trunk musculature belonging to the last three sacral myotomes. The intervening region is "cut out" for the reception of the base of the lower extremity.

It is of interest to note that more and more of the ventro-lateral wall of the trunk is "cut out" as the mid-ventral line is approached. Thus while the quadratus lumborum behind represents spinal segments as far caudal as the third or fourth lumbar, the rectus abdominis in front represents segments merely as far caudal as the twelfth thoracic. Similarly while the

Fig. 400.—Sagittal Section through the Urogenital Trigone and Ischio-rectal Fossa to the Left of the Middle Line. (Diagrammatic.)



coccygeus at the back part of the pelvic outlet represents the third and fourth sacral segments, the levator ani at the front represents chiefly the fourth.

The musculature which in the tailed mammals is used to move the tail as well as to wall off the pelvic cavity and close rectal and urogenital openings, in man is modified wholly for the latter functions. It constitutes the pelvic diaphragm.

The musculature of the urogenital diaphragm of the external genitalia and anus in man is differentiated from the primitive sphincter of the cloaca.

FASCIÆ

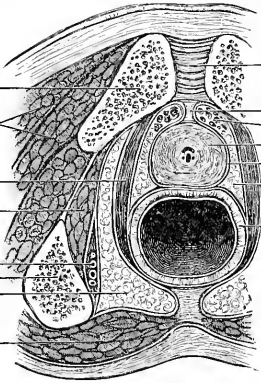
The **tela subcutanea** in the male perineal region contains many bundles of smooth muscle fibres continuous with and similar to the dartos of the scrotum (corrugator cutis ani). At the sides where it passes over the lower margin of the gluteus maximus it contains a large amount of fat, but in the dorsal region over the coccyx and sacrum, as in the mid-perineal region, the fat is limited in amount. In the labia majora of the female perineum there is much fat in the tela subcutanea.

The **ischio-rectal fossa** (figs. 401, 402) is bounded laterally by the obturator internus muscle and fascia, the tuberosity of the ischium and the ischio-pubic ramus, medially by the levator ani and coccygeus muscles and fasciæ, ventrally by the dorsal aspect of the urogenital trigone and dorsally by the gluteus maximus muscle. An *anterior recess* extends forward well toward the body of the pubis between the levator ani, the ischio-pubic ramus and the urogenital trigone. A *posterior recess* may likewise be traced backward covered by the lower edge of the gluteus maximus (figs. 400, 401). The fossa is filled with loose fatty tissue continuous with that of the tela subcutanea. Through it pass the hæmorrhoidal, and long and short perineal branches of the pudic artery and nerve. The main trunks of these vessels and nerves lie in a special fascial compartment (Alcock's canal) in the lateral wall (fig. 401).

The external genital organs are covered by a special deep layer of the tela subcutanea, the **superficial perineal (Colles') fascia** (fig. 402). This is attached on each side to the lower margin of the ischio-pubic ramus and to the ischial tuberosity. At the posterior margin of the superficial transverse perineal muscle it fuses with the two fascial layers of the trigone. It is adherent to the central tendon of the perineum and to the raphe of the bulb. Anteriorly it is continuous with the deep layer of the tela subcutanea covering the scrotum, the penis, and the lower part of the abdominal wall. In rupture of the urethra urine is prevented, by the attachments of the tela, from getting further back than the posterior edge of the trigone, but anteriorly it may extend to the surface of the abdomen. Here it may extend upward for a considerable distance, but it is kept from the thighs by the attachment of the deep layer of the tela subcutanea (Scarpa's fascia) to the inguinal ligament. Beneath the superficial perineal fascia are found the crura of the penis and their muscles, the bulb of the corpus spongiosum and its muscles, the superficial transverse perinei muscles, and the perineal vessels and nerves (fig. 402).

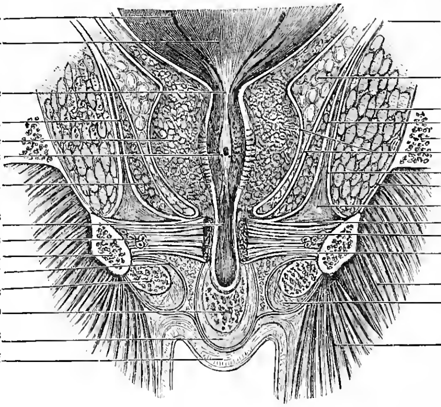
Muscle fasciæ.—The muscles of the urogenital diaphragm, the urogenital (urethral) sphincter and the transversus perinei profundus, are contained between two fascia layers which constitute the **superficial** (inferior) and **deep** (superior) **layers of the urogenital trigone** (the superficial or inferior and the deep or superior layers of the triangular ligament).

Fig. 401.—Section showing the Ischio-rectal Fossa in its Relations to the Pelvic Viscera.



The *superficial* (*inferior*) *layer* (figs. 392, 394, 400, 402, 403) which lies between the external genitalia and the urogenital diaphragm, is composed of strong bands of fibrous tissue which extend transversely across the subpubic arch and are attached to a ridge on the ischio-pubic rami. It is separated from the arcuate (subpubic) ligament by a mass of fibrous tissue through which the dorsal veins and nerves of the penis (clitoris) run, and in which there is a venous plexus.

Fig. 402.—Vertical Frontal Section of the Pelvis, showing Fasciæ. (Modified from Braune.)



Beneath this tissue a fibrous band, the *transverse ligament* of the pubis, extends between the descending pubic rami. This represents a region of fusion of the deep and superficial layers of the fascia of the trigone. Posterior to the deep transverse muscle the two layers are likewise fused. The superficial layer is better developed in the front than in the back part of the space. It is pierced by the urethra (about 3 cm. below the symphysis) by the ducts of the bulbo-urethral

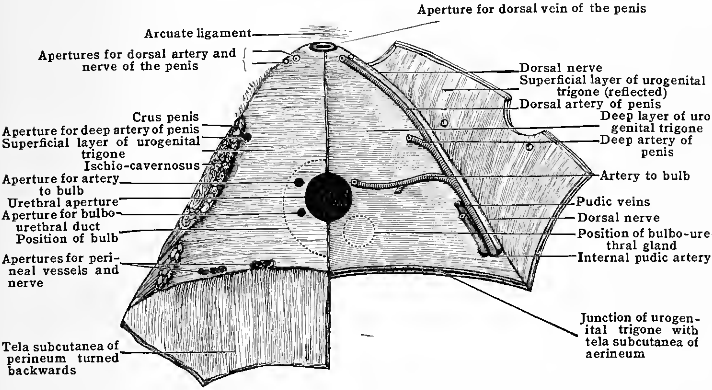
(Cowper's) glands, the arteries of the bulb, and the dorsal nerves and arteries of the penis. In the female it is pierced by the vagina as well as by the structures mentioned above.

Beneath the superficial layer of the fascia of the trigone, in addition to the muscles of the urogenital diaphragm, there are found the membranous urethra, the bulbo-urethral glands (Cowper's), the internal pudic arteries and the pudic nerves (in part).

The *deep (superior) layer of the urogenital trigone* (figs. 400, 402, 403) lies between the muscles of the urogenital diaphragm and the ischio-rectal fossa and levator ani. It may be looked upon as a continuation of the obturator fascia across the pubic arch. Posterior to the deep transverse perineal muscle it fuses with the superficial layer of the fascia of the urogenital trigone. In this region in the male it fuses with a fascial membrane, the *prostatico-perineal* fascia, which extends upward between the rectum and prostate, and is attached to the posterior wall of the latter. In the female it is fused with the fibrous tissue which lies between the vagina and the rectum.

The **muscle fasciæ of the pelvis** (figs. 399, 400, 401, 402, 407, B) have been described in various ways by different authors. They may be subdivided into parietal and diaphragmatic.

FIG. 403.—DIAGRAM OF THE SUPERFICIAL AND DEEP LAYERS OF THE UROGENITAL TRIGONE.



The **parietal fasciæ** (fig. 399) cover the muscles which extend from the interior of the pelvis to the thigh (the obturator internus and piriformis muscles). Above, the fascia on each side is attached to the linea terminalis and is continuous with the fascia transversalis and the iliac fascia. It is attached to the margins of the greater and lesser sciatic notches and to the ischio-pubic ramus and the body of the pubis. Between the ischio-pubic rami it is stretched across the subpubic arch and forms the superior or deep layer of the urogenital trigone described above. The portion of parietal pelvic fascia over the obturator internus muscle is called the obturator fascia.

The **diaphragmatic pelvic fasciæ** cover both surfaces of the pelvic diaphragm and are reflected upon the viscera. The fasciæ covering the two surfaces of the levator ani are attached to the parietal (obturator) fascia along the line of origin of the muscle.

The line of attachment of the levator ani divides the obturator fascia into two parts (fig. 399), a pelvic part above the line of attachment, covered by peritoneum, and an ischio-rectal part below the line of attachment. The latter bounds the lateral wall of the ischio-rectal fossa. The former part is much the thicker. It consists morphologically of two fused membranes, the obturator fascia proper and the aponeurosis of the ilio-coccygeal portion of the levator ani, which although usually fused with the obturator fascia, may frequently be traced to the terminal (ilio-pectineal) line from which in tailed mammals this portion of the levator takes origin. The two layers of fascia also become continuous at the medial margin of the muscle where this faces the urogenital passage (fig. 399). Posteriorly, the inner layer fuses with the tendinous insertion of the pubo-coccygeus portion of the muscle and the fasciæ of the muscles of each side are continuous. It also fuses with a fascia covering the coccygeus muscle.

The thin perineal layer of the levator fascia behind the rectum fuses with that of the opposite side and is attached to the coccyx and the ano-coccygeal raphe. About the anus it helps to form a covering for the external sphincter. Ventrally it is attached to the ischio-pubic rami. It forms the medial wall of the ischio-rectal fossa.

Endo-pelvic fascia (figs. 401, 402).—The peritoneum is reflected from the pelvic wall onto the viscera much higher up than the level at which the viscera are attached to the pelvic diaphragm. Between the pelvic fascia covering the deep surface of the pelvic diaphragm (levator ani and coccygeus muscles) and the peritoneum there is thus left a space, subperitoneal space (fig. 467 B). In the median plane in this region in the male are found the bladder, prostate, seminal vesicles, the ureter and ductus deferens in their course near the bladder, and the ampulla of the rectum. In the female we find here the bladder, the vagina, the uterus, and the ampulla of the rectum. Between these medially placed viscera and the lateral wall of the pelvis there is an irregularly shaped space, *cavum pelvis subperitoneale*, bounded above by peritoneum, below by the fascia covering the pelvic diaphragm and filled with connective tissue of varying density. The tissue in this space in the female is continuous with that between the two peritoneal surfaces of the broad ligament. Between the viscera in the subperitoneal region and about their walls the connective tissue is more or less definitely condensed into membranes which constitute the endopelvic fascia, variously described by different authors. The fascia covering the pelvic diaphragm, especially that on the deep surface, is fused to the endopelvic fascia where the viscera pass through the pelvic diaphragm. In the connective tissue of the subperitoneal space are found the hypogastric artery and vein and their chief branches, and various visceral nerves. The subperitoneal space above the pelvic diaphragm is to be compared with the subcutaneous space below the pelvic diaphragm known as the ischio-rectal fossa and described above.

MUSCLES

A. Muscles of the Pelvic Diaphragm, Coccyx, and Anus

The coccygeus (figs. 393, 395, 397, 400).—*Origin.*—From the ischial spine and the neighbouring margin of the great sciatic notch. *Structure and insertion.*—The fibre-bundles diverge to be inserted partly directly, partly by means of an aponeurosis, into the lateral margin of the fourth and fifth sacral vertebræ and of the coccyx. Usually the muscle is composed in considerable part of tendinous connective tissue, especially on the dorsal side of the cranial portion, and the ventral side of the caudal portion.

Nerve-supply.—From the pudendal plexus several small nerves enter the cranial margin and pelvic surface of the muscle. They arise usually from the third and fourth sacral nerves.

Action.—Insofar as the muscle is active it flexes and abducts the coccyx.

Relations.—Ventrally the muscle bounds the pelvic cavity, from which it is separated by the pelvic fascia, beneath which runs the nerve to the levator ani muscle. The dorsal surface is partly covered by the sacro-spinous (lesser sciatic) ligament and helps to bound the ischio-rectal fossa (posterior recess).

Variations.—The muscle varies greatly in the extent of its fleshy development. It may be doubled. It may be partially fused with the levator ani. Occasionally it is absent.

The sacro-coccygeus anterior (fig. 393).—This inconstant muscle, when well developed, arises from the sides of the fourth and fifth sacral and from the front of the first coccygeal vertebra and from the sacro-spinous ligament. The short fibre-bundles which compose it make up a somewhat irregular belly which is inserted into the anterior sacro-coccygeal ligament and into the second to fourth coccygeal vertebræ dorsal to the insertion of the levator ani. The innervation is from the fourth and fifth sacral nerves.

The sacrococcygeus posterior is an inconstant muscle consisting of a few muscle bundles which extend from the dorsal surface of the lower sacral vertebræ or from the posterior iliac spine to the dorsal surface of the coccyx. It lies beneath the superficial layer of the sacro-tuberous (great sciatic) ligament.

The levator ani (figs. 392, 394, 395, 396, 399, 401) is divisible into three portions, the ilio-coccygeus, the pubo-coccygeus and the pubo-rectalis.

The *ilio-coccygeus* (fig. 397) *arises* from the ischial portion of the arcus tendineus (white line). This extends from the ischial spine and posterior part of the arcuate line to the superior ramus of the pubis near the obturator canal, curving downward for a variable distance below the obturator canal. The constituent fibre-bundles form a muscular sheet which is inserted into the side of the coccyx and into the median raphe (ano-coccygeal) which extends from the tip of the coccyx to the rectum. Many fibre-bundles cross the median line.

The *pubo-coccygeus* (figs. 395, 397) *arises* from the inner surface of the os pubis, along a line extending from the lower margin of the symphysis pubis to the obturator canal, and from the arcus tendineus as far backward as the origin of the ilio-coccygeus. The fibre-bundles form a sheet of muscle which passes backward, downward, and medialward past the urogenital organs and the rectum on each side and is *inserted* by means of an aponeurosis into the anterior sacro-coccygeal ligament. Back of the rectum some of the fibre-bundles of the muscle sheets of each side interdigitate across the median line. Some of the more superficial fibres are inserted into the deep part of the ano-coccygeal raphe. Some of the fibre-bundles which arise nearest the symphysis are inserted on each side into the rectum. The pubo-coccygeus lies to some extent on the pelvic surface of the insertion of the ilio-coccygeus.

The *pubo-rectalis* (fig. 395) *arises* (a) from the body and descending ramus of the pubis beneath the origin of the *pubo-coccygeus*, (b) from the neighbouring part of the obturator fascia and (c) from the fascia covering the pelvic surface of the urogenital trigone. The fibre-bundles form a thick band on each side of the rectum behind which those of each side are inserted into the ano-coccygeal raphe. Many fibre-bundles may be traced into the muscle of the opposite side. Some of the more superficial fibre-bundles are reflected medialward in front of rectum and may be followed into the superficial transverse perineal muscle, others may be followed into the sphincter ani externus, or even to the skin.

Nerve-supply.—By a special nerve which arises usually from the fourth sacral, runs across the pelvic surface of the muscle and gives a special branch to each portion.

Action.—To flex the coccyx, raise the anus and constrict the rectum. It resists the downward pressure which the thoraco-abdominal diaphragm exerts on the viscera during inspiration.

Relations.—Between the right and left muscles in front lie the urethra and the lower part of the prostate in the male, the urethra and vagina in the female. In the triangle between the ischio-pubic rami of each side lies the urogenital diaphragm separated from the pubo-rectal part of the muscle by the deep layer of the trigone from which some of the fibres of the latter arise. Back of the urogenital diaphragm the muscle helps to bound the ischio-rectal fossa.

Variations.—The muscle shows great individual variation in structure which causes it to be variously described by different authors.

The **sphincter ani externus** (figs. 392, 394, 396, 397, 399) is made up of bundles of muscle fibres which surround the anus for nearly two centimetres. It is elliptical in form. Behind the anus the fibre-bundles of each side in part interdigitate, forming a ring. They are attached to the skin, and in part are attached through a tendon, the *ligamentum ano-coccygeum,* to the back of the coccyx. In front of the anus the fibre-bundles also in part interdigitate with one another, in part are inserted into the skin and in part interdigitate with the fibre-bundles of the transverse perineal and bulbo-cavernosus muscles. At the point where these muscles meet, about two and a half centimetres in front of the anus, there may be a visible mass of fibrous tissue, the *central tendon of the perineum,* but this is not always distinct. It is usually better developed in the female than in the male perineum. The external sphincter is divisible into three portions, a subcutaneus, a superficial and a deep (fig. 397). The three parts are connected by fibre-bundles, and are not always distinct. The *subcutaneous division* is small and immediately encircles the anal orifice. The *superficial division* lies external to the subcutaneous ring and descends further toward the rectum. It is shown in figs. 392, 394. It is the only part attached to the coccyx. In front it is attached to the central tendon of the perineum, but some fibres are continued into the bulbo-cavernosus. The *deep portion* forms a heavy ring above the rectum beneath the superficial part. It is distinctly, though not completely, separated from the pubo-rectal portion of the levator ani by fascial tissue containing the inferior hæmorrhoidal vessels. Some of the fibre-bundles of the deep portion may be traced in front of the anus across the mid-line to the ascending ramus of the opposite side and form part of the superficial transverse perineal muscle.

Nerve-supply.—From the inferior hæmorrhoidal branches of the pudendal (internal pudic) and frequently also by a perineal branch from the fourth sacral.

Action.—To keep the anus closed.

Relations.—Externally it is surrounded by the fat of the ischio-rectal fossa, internally near the skin it surrounds the sphincter ani internus, composed of smooth muscle, deeper it lies next the mucous membrane, for a distance of two centimetres from the skin.

Variations.—The muscle shows considerable individual variation in structure.

The *recto-coccygeus* or muscle of Treitz, is a triangular bundle of smooth muscle fibres. The origin of the muscle is from the second and third coccygeal vertebræ. It is inserted by its apex into the posterior wall of the rectum and the perirectal fascia. It retracts and elevates the rectum.

B. Muscles of the Urogenital Diaphragm

The urogenital diaphragm is composed of two closely united muscles, the deep transverse perineal muscle and the urogenital sphincter.

The **transversus perinei profundus** (fig. 398) is a flat muscle which *arises* from the inner side of the inferior ischial ramus and is *inserted* into the median raphe. Many of the fibre-bundles interdigitate with those of the opposite side and some may be followed into the external sphincter of the anus and into the urogenital spincter and other perineal muscles.

Nerve-supply.—By the perineal branch of the pudendal (internal pudic).

Action.—The pair of muscles draw back and fix the central tendon of the perineum and thus give firm support for the action of the urogenital sphincter.

Relations.—The inferior surface is separated (often incompletely) by the inferior layer of the urogenital trigone from the superficial transverse perineal muscle. The superior surface is covered by the deep layer of the urogenital trigone, into which the superficial layer is reflected about the anal margin of the muscle.

Variations.—The muscle is variable in structure and may be absent. (It is more frequently absent in the female than in the male.)

The **sphincter urogenitalis** differs in the male and female owing to the passage of the vagina through the perineum in the latter. In each sex it is convenient to consider the muscle as divided into two parts, a peri-urethral and an infra-urethral (vaginal).

In the male (fig. 398) the peri-urethral part, the *m. sphincter urethræ membranaceæ* is composed of fibre-bundles which are circularly placed about the membraneous urethra. The more external fibre-bundles are attached to the crura of the penis near their junction, to the transverse ligament of the pubis and to the fasciæ of the trigone. Some of them partially ensheath the lower part of the prostate, and others envelop the bulbo-urethral (Cowper's) glands. Some of the fibre-bundles take a longitudinal course along the urethra. Bundles of smooth muscle fibres are intermingled with the striated, and the fibrous framework of the musculature is marked by the large amount of elastic tissue which it contains. The infra-urethral part, the *m. transversus urethræ,* is closely associated with the urethral part. The fibre-bundles arise on each side from the inferior ramus of the pubis. They pass for the greater part beneath the urethra and interdigitate with that of the opposite side or are inserted into a median raphe. A few fibre-bundles may pass above instead of below the urethra. The transverse urethral muscle, first described by Guthrie (On the anatomy and diseases of the neck of the bladder, London, 1834) is inconstant. Its existence as a normal constituent of the male perineal musculature has been disputed by Delbet (Poirier and Charpy) and others.

In the *female* the peri-urethral part, *sphincter urethræ,* differs in no essential respects from the corresponding muscle in the male. Some of the fibre-bundles form a true sphincter about the urethra. The *infra-urethral* part, on the other hand, seems to vary greatly in different individuals so that the descriptions given by different authors are somewhat contradictory. It is better developed in women who have not borne children than in those who have. It may be looked upon as composed of two portions, a *m. transversus vaginæ* and an *m. constrictor vaginæ.*

The *transversus vaginæ* arises from the ischio-pubic rami and is inserted into the lateral wall of the vagina. Some of the fibre-bundles pass above and some below the vagina. This muscle corresponds with the transversus urethræ of the male but is, apparently, seldom fully developed. The *m. constrictor vaginæ*, on the other hand, seems to be more constant. It is composed of fibre-bundles which embrace the lateral wall of the vagina and are inserted above into the peri-urethral framework, below into the raphe between the two deep transverse perineal muscles. Some of the fibre-bundles are attached to the vaginal wall. Some interdigitate with the sphincter urethræ, others with the deep transverse perineal muscle and with the transversus vaginæ.

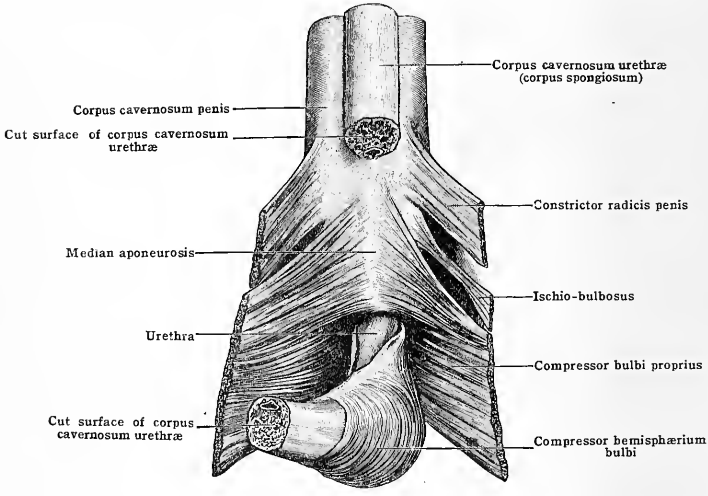
Nerve-supply.—By a branch from the perineal nerve.

Action.—To compress or close the urethra and in the male to compress the prostate and Cowper's glands, in the female to compress the vagina and Bartholin's glands.

Relations.—On the pelvic side it is separated from the levator ani by the deep layer of the urogenital trigone, and on the perineal side it is separated from the superficial muscles by the superficial layer of the trigone. Toward the anus it is closely associated with the deep transverse perineal muscle. Venous plexuses are well developed near the sphincter urethræ in both sexes, but especially in the female.

Fig. 404.—Bulbo-cavernosus in the Male.

The two halves have been reflected from the median raphé, and the bulb turned downward after division of the corpus spongiosum. (The ischio-bulbosus is not present on the right side.)



Variations.—It has already been pointed out that there is considerable variation in the muscles composing urogenital sphincter. Occasionally a rudimentary *ischio-pubicus* is found arising from the ischio-pubic ramus and terminating in a tendon which unites with that of the opposite side beneath the dorsal vein of the penis (clitoris). The tendon may be present as the transverse ligament of the pelvis when the muscle itself is absent. It represents the compressor of the dorsal vein found in lower mammals.

C. External Genital Muscles

The **bulbo-cavernosus** (figs. 394, 404) in the male ensheaths the bulb. The fibre-bundles *arise* from the dense tissue covering the corpus cavernosum at the root of the penis and from the subpubic connective tissue dorsal to the bulbar part of the urethra and are *inserted* into its median raphe on the ventral side of the bulb and into the central tendon of the perineum. Several parts may be more or less clearly distinguished.

1. *The constrictor radicis penis arises* usually from the lateral surface of the corpus cavernosum penis at the base of the penis, but may arise from the under surface or from the dorsal surface, or even from the suspensory ligament of the penis. The fibre-bundles pass obliquely backward and medialward and are *inserted* into the median raphe on the perineal surface of the bulb.

2. The *compressor bulbi proprius arises* (1) from a strong fibrous aponeurosis situated between the corpus spongiosum and the united crura of the penis and firmly adherent to the former, and (2) from the superficial layer of the trigone. The fibre-bundles ensheath the bulb and are *inserted* into the posterior part of the median raphe and into the central tendon of the

perineum. To a greater or less extent, depending on the development of the two muscles, the compressor covers the more posterior part of the constrictor.

3. The *compressor hemisphærium bulbi arises* from a tendon common to the muscles of the two sides on the dorsum of the bulbous part of the urethra near the membranous part. The fibre-bundles embrace the hemisphere of the bulb and are inserted into the median raphe. This muscle is covered by the preceding. It not only compresses the bulb, but also is a sphincter of the urethra.

4. The *ischio-bulbosus* is placed by Holl in this group. It *arises* from the pelvic surface of the tuberosity and of the inferior ramus of the ischium and when well developed is inserted into the median raphe, superficial to the compressor bulbi proprius or the constrictor radicis proprius. Frequently, however, it does not extend over the bulb but is *inserted* into the inferior surface of the corpus cavernosum. It is more frequently absent than present. (See fig. 404.)

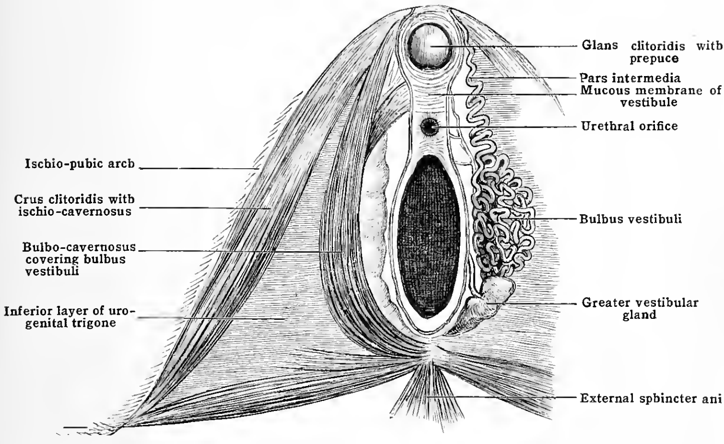
Nerve-supply.—The perineal division of the pudic nerve sends several branches to the bulbo-cavernosus.

Action.—It compresses the bulb and at the same time the bulbous portion of the urethra. The turgescence of the penis is thus increased and urine or semen is expelled from this portion of the urethra.

Relations.—It lies beneath the skin and subcutaneous tissue.

Variations.—The muscle is variable in structure as is indicated by the different descriptions given by different authors. The *compressor venæ dorsalis* described by Houston is composed of

FIG. 405.—DIAGRAMMATIC REPRESENTATION OF THE PERINEAL STRUCTURES IN THE FEMALE.



a few fasciculi which arise from the sheath of the corpus spongiosum, and from the median raphe and are united to those of the opposite side by a tendon which passes over the dorsal vein.

The *bulbo-cavernosus* (*sphincter vaginæ*) (fig. 392, 405) in the female arises (1) from fibrous tissue dorsal to the clitoris, (2) from the tunica fibrosa of the corpus cavernosum and from the superficial layer of the urogenital trigone in the angle between the crura of the clitoris. The fibre-bundles form a band of tissue about two centimetres wide at the side of the vagina and are inserted into the posterior part of the superficial (inferior) layer of the trigonum and into the central tendon of the perineum where some of the fibre-bundles interdigitate with those of other muscles attached here. The fibre-bundles arising from the back of the clitoris correspond with those of the constrictor radicis penis in the male. The other fibre-bundles correspond with those of the compressor bulbi proprius in the male.

Nerve-supply.—From the perineal division of the pudic.

Action.—To compress the vagina.

Relations.—It covers the bulb of the vestibule and the great vestibular gland (Bartholin's). It is covered by skin and superficial fascia.

The ischio-cavernosus (figs. 398, 405) (erector penis or clitoridis) *arises* from the pelvic surface of the tuberosity and inferior ramus of the ischium, back and on each side of the attachment of the crus. The fibre-bundles form a thin sheet which is spread over the crus into the medial and inferior surfaces of which it is *inserted* near the symphysis pubis. It is better developed in the male than in the female.

Nerve-supply.—By branches of the perineal nerve.

Action.—By constricting the crus to maintain turgescence of the penis or clitoris.

Relations.—Superficially it is covered by skin and subcutaneous tissue. Laterally it lies next the ischio-pubic ramus. Medially it bounds a space lying between the crus and the bulb and filled with fat.

Variations.—The muscle in the male is much larger than in the female. Some of the more anterior fibre-bundles may extend to the dorsal surface of the penis (clitoris) and form a *pubo-cavernosus* or levator penis muscle.

The **transversus perinei superficialis** (figs. 392, 394, 405) arises from the inferior ischial ramus. The fibre-bundles extend in front of the rectum superficial to the deep transverse muscle and are inserted into the central tendon of the perineum. Some cross to the opposite side. Some of the fibre-bundles are continuous with those of the external sphincter or of the pubo-rectalis of the opposite side.

Action.—It acts with the deep transverse muscle in fixing the central part of the perineum.

Nerve-supply.—By a branch from the perineal division of the pudic.

Variations.—It is frequently absent or poorly developed.

VI. THE MUSCULATURE OF THE LOWER LIMB

The lower limbs are used chiefly for the support and propulsion of the body. Variety of movement is subordinated to strength and precision. In contrast with the upper limbs, which perform a vast variety of complex movements under conscious control, the lower limbs are called upon to perform chiefly the relatively simple movements which are used in walking or running, without our paying much attention to them.

The contrast between the two extremities is best marked in the girdles, the relations of which to the trunk have already been described, p. 444. The shoulder girdle is constantly called upon for movements in various directions which increase the freedom of action of the whole extremity. The sterno-clavicular and acromio-clavicular joints are movable so that the scapula can be carried in various directions over the thorax. The bones of the hip-girdle on each side, on the other hand, are ossified into a single hip-bone (os innominatum). The two hip-bones are almost immovably united to one another in front by the symphysis pubis and behind each is united to the sacrum by a joint which, although a diarthrosis, likewise permits but slight movement. The sacrum in turn is composed of vertebræ firmly ossified together. The pelvis, composed of the two hip-bones and the sacrum forms a strong support for the trunk. Such movements as it makes are due chiefly to the lumbo-sacral joint and to a less extent to the joints between the lumbar vertebræ. These joints permit the pelvis, in a limited manner, to be flexed and extended, abducted, adducted, and rotated. Flexion is produced by the rectus and the oblique muscles of the abdomen (fig. 387) and by the psoas muscles (fig. 406), extension is produced by the quadratus lumborum (fig. 406) and the sacrospinalis (fig. 381). Rotation and abduction are produced when these muscles act on one side only. The weight of the body in the sitting posture is transmitted through the sacrum and hip-bones to the ischial tuberosities. In this position the pelvis is flexed. The weight of the body in the standing position is transmitted to the femora through the acetabulum on each side. In this position the pelvis is extended. In walking the pelvis is rotated forward toward the limb that is being advanced.

The hip-joint is a true ball-and-socket joint, but freedom of movement is greatly limited by the powerful musculature which surrounds it, as well as by the ligaments. Movements here, however, are freer than at the shoulder-joint, if the shoulder girdle be left out of consideration. At the hip-joint the most frequent and most free movements are those of flexion and extension, the main movements in walking or running; but abduction, adduction, circumduction, and rotation are of the greatest importance in balancing the body.

At the knee-joint the main movements are also those of flexion and extension and the musculature is so arranged that the chief flexors of the knee which lie at the back of the thigh are extensors of the hip (fig. 408) while the extensor musculature of the knee which lies at the front of the thigh flexes the hip (fig. 411). Flexion of the hip, however, through the action of gravity on the foot passively brings about flexion at the knee, while flexion of the knee likewise passively brings about flexion of the hip, since the flexed knee tends to swing forward. These passive movements, due to gravity, are of importance in walking. The gastrocnemius (fig. 413), the most powerful extensor of the ankle-joint, is also a powerful flexor of the knee-joint. At the knee-joint, in addition to flexion and extension, some rotation is possible, best marked when the knee is flexed. This rotation is of value in walking over rough ground in that it helps to accommodate the foot to the ground. It is also of value in sitting on a flat surface. While there is thus some rotation at the knee-joint not found at the elbow-joint, the free movement of the radius about the ulna which accompanies pronation and supination in the forearm, is unrepresented in the leg where the fibula is firmly united to the tibia at each end.

The joint between the bones of the leg and the tarsus permits merely of flexion and extension in contrast to the wrist-joint which also permits of adduction and abduction. Flexion and extension are also more limited at the ankle than at the wrist. On the other hand, the movements of inversion and eversion which take place in the intertarsal joints are not needed in the wrist because of the pronation and supination of the forearm. Inversion and eversion of the foot are of value in walking on rough ground.

The movements of the toes resemble those of the fingers except that they are, in most individuals, far more restricted. The greatest restriction is seen at the joint between the metatarsal of the big toe and the tarsus, as compared with that between the metatarsal of the thumb and the carpus.

The musculature of the inferior extremity, like that of the superior, can be divided according to its development and innervation into two great subdivisions which correspond with the musculature on the dorsal and ventral sides of the (shark's fin. The dorsal musculature is supplied by nerve branches which arise from the back of the lumbo-dorsal plexus (femoral, gluteal, and peroneal nerves), the ventral musculature by branches which arise from the front of the plexus obturator and tibial nerves). Owing, however, to the rotation which the limb makes during embryonic development, the musculature which primitively lies on the dorsal side of the limb-bud comes to lie on the front and lateral side of the extremity and the musculature of the ventral side of the limb-bud comes to lie on the back and medial side of the extremity or in the sole of the foot. The side of the limb which primitively was toward the head becomes the medial side of the limb, and that which faced caudalward comes to lie laterally. While this makes the primitive relations of the musculature of the limb at first somewhat confusing, it is possible to approximate these primitive conditions by abducting the limb and rotating it so that the sole of the foot faces forward. An understanding of the innervation of the limb is thus greatly facilitated.

In the region of the hip the musculature of the **dorsal division** is that which arises from the spinal column and ilium and is inserted into the upper part of the femur and into the fascia of the thigh. It includes the chief flexor of the thigh, the *ilio-psoas* (fig. 406), and the most powerful extensor, the *gluteus maximus* (fig. 413), as well as several important rotators and abductors, *gluteus medius* and *minimus, piriformis* and *tensor fasciæ latæ* (fig. 408). The ilio-psoas is innervated by nerves from the back of the lumbar, the other muscles by nerves from the back of the sacral plexus. The musculature of the *ventral division* arises from the pubis and ischium, is inserted into the femur near the great trochanter and serves to adduct the thigh and rotate it lateralward, *obturator internus, gemelli, quadratus femoris* (fig. 408) and *obturator externus* (fig. 406). The obturator externus is innervated by the obturator nerve from the front of the lumbar plexus, the other muscles by special branches from the front of the sacral plexus.

In the thigh there are three well-marked groups of muscles, an anterior or extensor group (fig. 411), a medial or adductor group (fig. 411), and a posterior or flexor group (fig. 408). The anterior group belongs to the primitive dorsal division, the other two groups to the ventral division.

The muscles of the **anterior group** (fig. 411) the *sartorius* and *quadriceps* arise from the ilium and the shaft of the femur and are inserted into the tibia. The quadriceps flexes the thigh and extends the leg. The sartorius flexes both the thigh and the leg and rotates the former lateralward, the latter medialward. They are innervated by the femoral nerve. The muscles of the **medial group** (fig. 411), *gracilis, pectineus, adductor brevis, longus,* and *magnus,* arise from the pubis and the inferior ramus of the ischium and are inserted into the shaft of the femur. They adduct and flex the thigh. They are innervated by the obturator nerve. The adductor magnus gets part of its nerve-supply from the sciatic. The pectineus usually gets all or most of its supply from the femoral. The reasons for including it in this group are given below. The **posterior group** (fig. 408) consists of the *semitendinosus* and *semimembranosus,* which arise from the ischial tuberosity, and of the *biceps,* one head of which also arises from the ischial tuberosity while the other arises from the shaft of the femur. The semimembranosus and semitendinosus are inserted into the tibia, the biceps into the fibula. They are innervated by branches of the sciatic. They extend the thigh and flex the knee. The semitendinosus rotates the leg medialward, the biceps lateralward.

In the leg there are also three groups of muscles, an anterior, a lateral and a posterior. The two former belong to the dorsal division and are innervated by the peroneal nerve. The last belongs to the ventral division and is innervated by the tibial nerve. The muscles of the **anterior group** (fig. 415), the *tibialis anterior, extensor digitorum longus, peroneus tertius* and *extensor hallucis longus,* arise from the tibia and fibula and are inserted into first and fifth metatarsals and into the two distal rows of phalanges. They flex the ankle and extend the toes. The extensor digitorum longus and peroneus tertius evert the foot. The muscles of the **lateral group** (fig. 415), the *peroneus longus* and *brevis,* arise from the fibula. send tendons behind the lateral malleolus and are inserted respectively into the first and the fifth metatarsals. They extend and evert the foot. The **posterior group** (figs. 413, 416) may be separated into two subdivisions, a superficial and a deep. The *superficial subdivision* (fig. 413) consists of the *gastrocnemius,* which arises from the two epicondyles of the femur, and the *soleus* which arises from the tibia and fibula. These powerful extensors of the ankle are inserted by means of the tendon of Achilles into the calcaneus. The gastrocnemius is a flexor of the knee as well as an extensor of the ankle. A rudimentary muscle, the *plantaris,* arises near the lateral head of the gastrocnemius and is inserted into the fibrous tissue of the heel.

The deep group (fig. 416) consists of one muscle, the *popliteus,* a medial rotator and flexor of the leg, which arises from the lateral condyle of the femur and is inserted into the tibia; and of three muscles, the *flexor digitorum longus, flexor hallucis longus* and *tibialis posterior,* which arise from the tibia and fibula, send tendons behind the medial malleolus and are inserted into the plantar surface of the tarsus and into the terminal phalanges of the toes. They invert the foot and flex the toes.

In the foot one muscle on the dorsum represents the primitive dorsal division, the *extensor digitorum brevis* (fig. 418), supplied by a branch from the peroneal nerve. On the other hand the primitive ventral division is well represented in the sole of the foot, not only by the muscles associated with the long flexor tendons, quadratus plantæ, lumbricales (fig. 420), but also by the short flexor of the toes (fig. 419), by the special musculature of the big and little toes (fig. 421) and by the interosseous muscles (fig. 422). The *flexor digitorum brevis* (fig. 419), the most superficial of these muscles, arises from the calcaneus and is inserted into the second row of phalanges of the four more lateral toes. The *quadratus plantæ* arises from the calcaneus and is inserted into the tendon of the long extensor of the toes. It makes the action of the tendon on the digits more direct. The four *lumbrical muscles* run from this tendon to the medial sides of the four lateral toes. They flex the digits. Of the intrinsic muscles of the great toe (figs. 419, 421), the *abductor* arises from the calcaneus; the *flexor brevis* from the cuneiform bones; and the *adductor,* by one head from the long plantar ligament, by the other from the capsules of the metatarso-phalangeal joints. All are inserted into the base of the first phalanx. Of the *muscles of the little toe* (figs. 419–421), the *abductor* arises from the calcaneus, the *flexor* and *opponens* from the cuboid. The two former are attached to the base of the first phalanx, the last to the fifth metatarsal. The *interosseous muscles* which arise between the metatarsals are so arranged that the three plantar abduct and the four dorsal adduct the four lateral toes to and from an axis passing through the second toe. The muscles of the sole of the foot which send tendons to the sides of the bases of the first row of phalanges help to flex the digits on the metatarsals and to extend the toes at the first row of interphalangeal joints. These are much less effective extensors of the phalanges than are the corresponding muscles of the hand and, unlike the latter, seem, in most individuals, to exert but little extensor action on the third row of phalanges. The muscles of the sole of the foot are supplied by the lateral and medial plantar branches of the tibial nerve.

The muscle fasciæ of the inferior extremity are well developed. The *fascia lata,* which encloses the musculature of the back of the hip and the musculature of the thigh, is especially strong on the lateral side where it includes the longitudinal bundles of fibres which compose the ilio-tibial band. From the fascia lata strong intermuscular septa extend on each side of the quadriceps group of muscles to the femur. Medially beneath the sartorius muscle (fig. 410), septa help to bound Hunter's canal in which lies the femoral artery on its way to the popliteal space behind the knee. In the leg there is likewise a strong cylindrical fascial sheath which encloses the musculature and sends septa on each side of the peroneal group to the fibula. A transverse septum also separates the deep from the superficial muscles of the calf. The fascia of the leg is especially well developed near the ankle where it helps to hold in place the tendons which pass from the muscles of the leg into the foot. Muscle fasciæ are well developed both on the dorsum and in the sole of the foot.

A. MUSCULATURE OF THE HIP

1. Ilio-Femoral Musculature

The iliac blade divides these muscles into an **anterior group** (ilio-psoas), supplied by nerves from the lumbar plexus, and a **posterior group** (the gluteal muscles, piriformis, and tensor fasciæ latæ, supplied by nerves from the sacral plexus.

In most of the limbed vertebrates these two groups of muscles are represented, but they present marked specific variations in the different forms. Primitively, the iliacus group lies on the proximal portion of the lateral surface of the ilium.

(a) Anterior Group
(Figs. 406, 411)

The fan-shaped **iliacus** muscle arises from the iliac fossa. The fusiform **psoas major** muscle arises from the sides of the last thoracic and of the lumbar vertebræ and extends along the medial margin of the iliacus muscle. The two muscles are inserted by a common tendon into the lesser trochanter of the femur. Together they constitute the **ilio-psoas** muscle. The small, flat, fusiform **psoas minor** lies on the medial surface of the psoas major and extends from the twelfth thoracic vertebra to the ilio-pectineal eminence. The ilio-psoas flexes the thigh at the hip and the pelvis on the trunk. The psoas minor aids in flexing the pelvis.

The ilio-psoas muscle arises in the human embryo from a blastema which at first surrounds the femoral nerve and later extends proximally over the ilium (iliacus) and toward the lumbar vertebræ (psoas). The iliacus is phylogenetically the more primitive. In the shoulder it is probably represented by the infraspinatus. The psoas minor is much better developed in many of the lower mammals than in man.

FASCIÆ

The **fasciæ** and the relations of these muscles are shown in figs. 384 and 407.

The iliac and psoas muscles are covered by a dense fascia which is but slightly adherent to the underlying muscles. It is best developed in the pelvic region, where it extends from the iliac crest and ilio-lumbar ligament to the iliac portion of the linea arcuata and is called the **iliac fascia**. Superiorly it is continued over the psoas muscle as the **psoas fascia** and is attached medially to the sacrum and the lumbar region of the spinal column. Laterally it unites with the lumbar fascia and superiorly it is strengthened to form the medial lumbo-costal arch (fig. 391). Infiriorly the **ilio-pectineal fascia** extends over the ilio-psoas muscle to its femoral insertion. It is firmly united on each side of the muscle to the capsule of the hip-joint and to the femur. As it passes beneath the inguinal ligament it is united to this by tendinous processes. Beyond the ligament it is less dense than in the pelvic region.

MUSCLES

The psoas major (figs. 406, 411).—*Origin.*—(1) By a series of thick fasciculi from the intervertebral discs between the twelfth thoracic and the fifth lumbar vertebra, from the adjacent parts of the bodies of these vertebræ and from tendinous arches which bridge over the middle of the sides of the first four lumbar vertebræ; and (2) by a series of more slender fasciculi from the lower borders and ventral surfaces of the transverse processes of the lumbar vertebræ.

Structure and insertion.—From these origins parallel fibre-bundles descend nearly vertically and give rise to a fusiform muscle which lies at the side of the vertebral bodies and extends along the border of the true pelvis toward its insertion. A tendon arises deep in the muscle near the last lumbar vertebra, and becomes free on its dorso-lateral surface slightly above the inguinal (Poupart's) ligament. On the medial side the attachment of fibre-bundles continues to the insertion of the muscle into the small trochanter. The iliacus muscle is attached to the lateral side of the tendon from near the ilio-pectineal eminence downward.

Nerve-supply.—Delicate branches pass into the psoas muscle from the trunks which unite to form the femoral (anterior crural) nerve, i. e., from the fourth, third, second, and often the first lumbar nerves.

The iliacus (figs. 406, 411).—*Origin.*—(1) From the iliac crest, the ilio-lumbar ligament, and the greater part of the iliac fossa, the anterior sacro-iliac ligaments, and often from the sacrum, and (2) from the ventral border of the ilium between the two anterior spines.

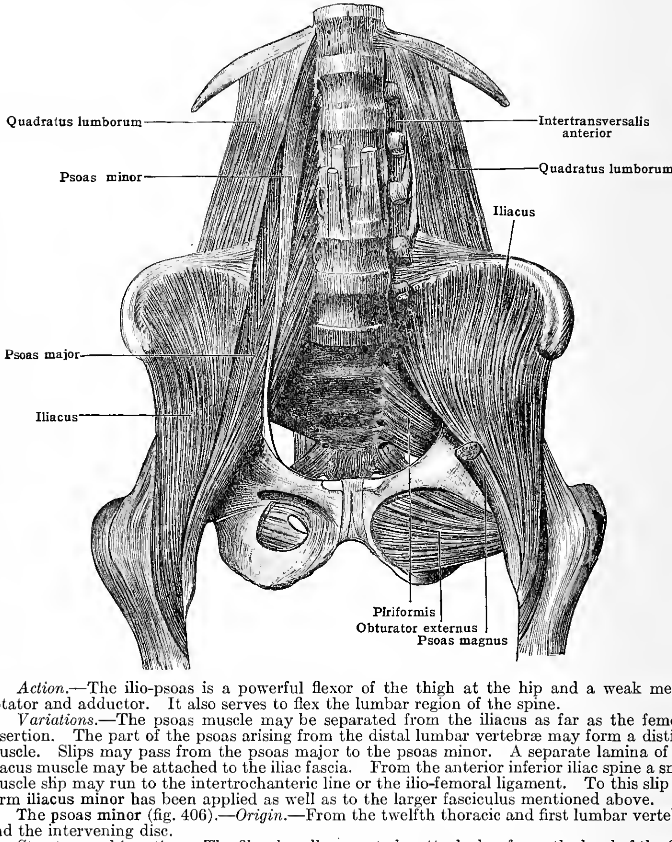
Structure and insertion.—From these areas of origin the fibre-bundles pass to be inserted—(1) in a penniform manner on the lateral surface of the tendon which emerges from the psoas above the inguinal (Poupart's) ligament, and (2) directly on the femur immediately distal to the small trochanter. The lateral portion of the muscle arise from the ventral border of the ilium and is adherent to the direct tendon of the rectus femoris and the capsule of the hip-joint. It is sometimes more or less isolated (*m. iliacus minor, ilio-capsulo-trochantericus,* etc.).

Nerve-supply.—Nerve branches, often united in a plexiform manner, arise from the femoral (anterior crural) nerve and pass across the surface of the iliacus muscle about midway between the crest of the ilium and the combined ilio-psoas tendon. Special nerve branches are usually likewise distributed from the main trunk of the femoral nerve to the fleshy portion of the muscle which extends over the acetabulum and the head of the femur.

Relations.—The psoas major lies lateral to the lumbar vertebræ and in front of the quadratus lumborum and intertransverse muscles. The psoas minor passes downward across its ventral surface. Both psoas muscles are crossed by the crura of the diaphragm. The kidney with its adipose capsule lies lateral to them opposite the first two lumbar vertebræ. For the rest, their fascia is covered ventro-laterally by retro-intestinal and retro-peritoneal tissue in which the vena cava inferior runs in front of them on the right side, the inferior mesenteric vein in front of them on the left side, and the ureter, the spermatic or ovarian, and the renal and colic vessels on each side. The external iliac artery lies medial to the psoas major in the pelvis, and beyond the inguinal (Poupart's) ligament the femoral artery lies ventral to it. The lumbar plexus arises between its origins from the vertebral bodies and discs and those from the transverse processes. The nerves springing from the lumbar plexus take courses subject to much individual variation through the muscle on the way to their destinations. Fasciculi of the muscle may thus be separated by the femoral (anterior crural) nerve or other branches of the lumbar plexus.

The iliacus muscle in the region of the pelvis is covered by retro-peritoneal fat. The psoas muscle crosses its medial margin and from between the two muscles the femoral nerve usually emerges to pass into the thigh above the iliacus. Beyond the inguinal ligament the iliacus lies in front of the capsule of the hip-joint and the straight tendon of the rectus femoris, and is crossed by the sartorius.

Fig. 406.—Psoas, Iliacus, and Quadratus Lumborum.



Action.—The ilio-psoas is a powerful flexor of the thigh at the hip and a weak medial rotator and adductor. It also serves to flex the lumbar region of the spine.

Variations.—The psoas muscle may be separated from the iliacus as far as the femoral insertion. The part of the psoas arising from the distal lumbar vertebræ may form a distinct muscle. Slips may pass from the psoas major to the psoas minor. A separate lamina of the iliacus muscle may be attached to the iliac fascia. From the anterior inferior iliac spine a small muscle slip may run to the intertrochanteric line or the ilio-femoral ligament. To this slip the term **iliacus minor** has been applied as well as to the larger fasciculus mentioned above.

The psoas minor (fig. 406).—*Origin.*—From the twelfth thoracic and first lumbar vertebræ and the intervening disc.

Structure and insertion.—The fibre-bundles pass to be attached as far as the level of the fifth lumbar vertebra to a flat tendon which appears about the mid-lumbar region and is inserted into the ilio-pectineal eminence. It is intimately united to the iliac fascia.

Nerve-supply.—The branch to the psoas minor arises usually from the first and second lumbar nerves, often in company with the genito-femoral (genito-crural).

Action.—To flex the pelvis.

Relations.—It is closely applied to the ventral surface of the psoas major.

Variations.—The muscle is inconstant in development and is frequently absent. Gruber has found it absent on both sides in 183 out of 450 bodies, on one side in 69.

Bursæ

B. iliopectinea.—A large bursa between the ilio-psoas muscle, the ilio-pectineal eminence, and the capsule of the hip-joint. **B. iliaca subtendinea.**—A small bursa between the tendon of insertion of the ilio-psoas and the lesser trochanter.

(*b*) Posterior Group

(Figs. 387, 407, 408, 413)

The muscles of this group arise from the ilium and sacrum, cover the dorso-lateral surface of the hip, and are inserted into the great trochanter and shaft of the femur and into the ilio-tibial band. They lie in three planes. In the **first layer** (fig. 387) are the flat, quadrilateral **tensor fasciæ latæ,** which arises from the front of the crest of the ilium and is inserted into the ilio-tibial band, and the thick, rhomboid **gluteus maximus,** which arises from the dorsal portion of the iliac ala, the lumbo-dorsal fascia, the sacrum and coccyx, and the sacro-tuberous (great sacro-sciatic) ligament, and is inserted in part into the ilio-tibial band and in part into the back of the upper part of the shaft of the femur. The **ilio-tibial** band is a flat tendon which descends, closely fused with the fascia lata, to the lateral side of the upper extremity of the tibia. In the **second layer** (fig. 408) are the flat, thick, triangular **gluteus medius** and the 'pear-shaped' **piriformis** The former arises from the upper and back part of the outer surface of the ala of the ilium, the latter from the ventral surface of the sacrum and the posterior border of the great sciatic notch. Both are inserted into the top of the great trochanter. The **third layer** (fig. 409) is composed of the triangular **gluteus minimus,** which arises from the inferior ventral portion of the outer surface of the ala of the ilium, and is inserted into the front of the great trochanter of the femur.

The muscles of this group extend, flex, abduct, and rotate the thigh at the hip. The gluteus maximus and medius are in part extensors, the gluteus minimus and the tensor fasciæ latæ are flexors of the hip-joint. All the muscles serve to abduct, the gluteus maximus acting thus when the hip is flexed. When the thigh is extended the lower part of the gluteus maximus is an adductor. The gluteus maximus and posterior part of the gluteus medius and the piriformis act as lateral, the anterior part of the gluteus medius, the gluteus minimus, and the tensor fasciæ latæ as medial, rotators. The gluteus maximus and the tensor fasciæ latæ through the ilio-tibial band keep the extended knee-joint firm. The gluteus maximus is supplied by the inferior gluteal nerve, the piriformis by special nerves, and the other muscles of the group by the superior gluteal nerve. All these nerves arise from the upper part of the back of the sacral plexus.

The gluteus medius, gluteus minimus, and piriformis form a group of muscles which in the embryo have a common origin and are more or less fused in the adult. The gluteus maximus arises in two distinct, though associated, portions, and the tensor fasciæ latæ as another distinct portion. The two muscles, however, are probably to be considered as parts of a primitive caudo-pelvo-tibial musculature, while the gluteus medius group is represented in the lower forms by an ilio-femoral musculature. The former group is often closely associated with the extensor muscles of the thigh in the lower forms (frog), and in some of the lower mammals extends its insertion to the plantar fascia (ornithorhynchus). In the arm this group is perhaps represented by the deltoid, the latissimus dorsi, and the teres major, while the gluteus medius group is represented by the subscapularis.

FASCIÆ

The **tela subcutanea** of the gluteal region is very thick, contains much fat, and is often divisible into two layers, of which the deeper is closely adherent to the fascia lata and through this to the gluteus maximus. Over the great trochanter a subcutaneous bursa is usually found (**bursa trochanterica subcutanea**).

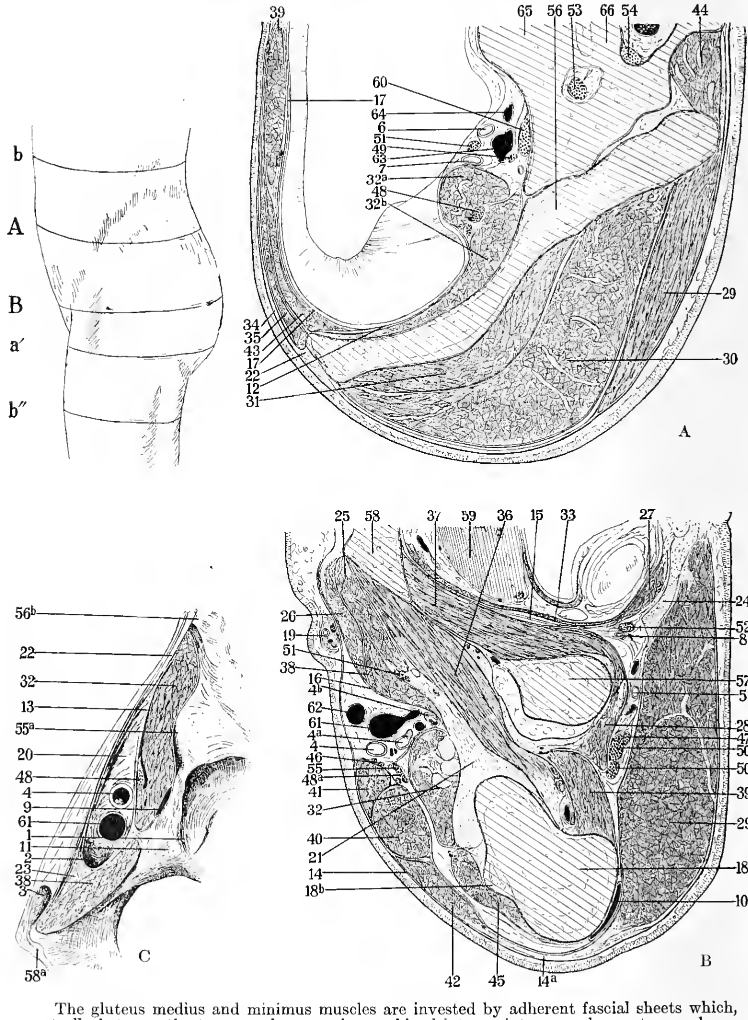
Muscle fascia.—The muscles of the hip and thigh are enclosed in a dense fascia, the fascia lata (figs. 387, 407). This arises from the tuber ischii, the sacro-tuberous (great sacro-sciatic) ligament, the back of the sacrum and the coccyx, the crest of the ilium, the inguinal (Poupart's) ligament, and the pubic and ischial rami, and extends to the tibia and the fascia covering the muscles of the leg. It is composed mainly of bundles of fibres running transversely to the long axis of the limb. In the region of the gluteal groove it is strengthened by a transverse fibrous band which arises from the tuberosity of the ischium and arches upward over the lower border of the gluteus maximus muscle.

In the region of the hip the fascia lata invests both surfaces of the tensor fasciæ latæ and the gluteus maximus, and is closely bound to these muscles through intramuscular septa. Between these two muscles the fascia covers the fascia of the gluteus medius, to which it is adherent near the iliac crest, but from which it is separated by loose tissue more distally. Anteriorly the fascia is fused with the ilio-pectineal fascia and the inguinal (Poupart's) ligament.

More distally the tendons of the tensor fasciæ latæ and of the superficial portion of the gluteus maximus become incorporated with the deep surface of the fascia lata and give rise to the **ilio-tibial band** [tractus iliotibialis].

Fig. 407, A and B.—Transverse Sections through the Left Side of the Pelvis in the Regions Indicated in the Diagram.

C. Section through the muscles of the left inguinal region parallel to the inguinal (Poupart's) ligament (after Spalteholz). *b* in the diagram indicates Section *B*, fig. 384, p. 421; *a′* and *b′* indicate sections *A* and *B*, fig. 410, p. 465. (For legends, see p. 459.)



The gluteus medius and minimus muscles are invested by adherent fascial sheets which, ventrally between the two muscles, may be combined into an intermuscular septum or be so slightly developed that the muscles are fused. The fascial sheet covering the gluteus medius toward the iliac crest is fused with the deep surface of the fascia lata. This fusion results in the formation of septa between the gluteus medius and the gluteus maximus and tensor fasciæ latæ.

The piriformis in the pelvic cavity is covered on the anterior surface by a special slightly developed fascia. This fascia also covers the pelvic surface of the sacral plexus. Outside the pelvis the piriformis is covered by an adherent membrane which usually is separated by loose tissue from the surrounding structures.

MUSCLES

I. First Layer

The tensor fasciæ latæ (figs. 387, 411).—*Origin.*—(1) By a tendinous band from the external lip of the iliac crest, and the upper part of the notch between the anterior superior and anterior inferior spines of the ilium, and (2) from the septum between it and the gluteus medius.

Structure and insertion.—The nearly parallel fibre-bundles pass distally and laterally and are united to tendon fasciculi which become incorporated with the ilio-tibial band (tractus iliotibialis) about one-third of the way down the thigh.

Nerve-supply.—The superior gluteal nerve sends a branch through the ventral margin of the gluteus minimus to terminate in the middle third of the deep surface of the tensor fasciæ latæ near its dorsal border.

Action.—To rotate medially, flex, and abduct the thigh, and to make tense the fascia lata.

Relations.—It lies over the gluteus medius, the proximal part of the rectus femoris, and the vastus lateralis.

Variations.—It may be divided into two parts, one rising from the anterior superior spine, the other from the iliac crest. Accessory slips may arise from the inguinal ligament, the crest of the ilium, or the fascia over the lower part of the abdominal wall. Union of the muscle with the gluteus maximus has been observed, thus making a muscle much resembling the deltoid of the shoulder. By some the fascia lata between the tensor and the gluteus maximus is considered an atrophied part of a deltoid of the hip.

The gluteus maximus (figs. 387, 413).—*Origin.*—(1) From the dorsal fifth of the outer lip of the iliac crest, the outer surface of the ilium dorsal to the posterior gluteal line, the lumbodorsal fascia between the posterior superior spine of the ilium, and the side of the sacrum, and (2) from the lateral portions of the fourth and fifth sacral and the coccygeal vertebræ and from the back of the sacro-tuberous (great sacro-sciatic) ligament.

Insertion.—Into (1) the ilio-tibial band; (2) the gluteal tuberosity of the femur and the adjacent part of the tendinous origin of the vastus lateralis (fig. 407).

Structure.—The large fibre-bundles of which the muscle is composed take a somewhat parallel course from origin to insertion. From the areas of origin and the enveloping fascia fibrous bands extend into the muscle. The belly is divisible into two portions, a superficial and a deep. The division may be much more clearly recognised in the embryo than in the adult. The superficial portion is the larger, and includes all of that part of the muscle which springs from the ilium and the more superficial portion of that arising from the sacrum and the upper part of the coccyx. The deep portion includes that part of the muscle attached to the side of the sacrum and the coccyx, and to the sacro-tuberous ligament. The superficial portion and some of the fibre-bundles of the deep portion terminate in the ilio-tibial band along a line extending from the great trochanter to the end of the upper third of the femur. The deep portion is inserted chiefly by a flat tendon into the gluteal tuberosity, and also directly into the adjacent portion of the origin of the vastus lateralis.

Nerve-supply.—Two branches (inferior gluteal) arising from the sacral plexus either separately or united, are usually given to the muscle. One of these curves anteriorly across the deep surface of the proximal superficial portion of the muscle in the middle third between the tendons

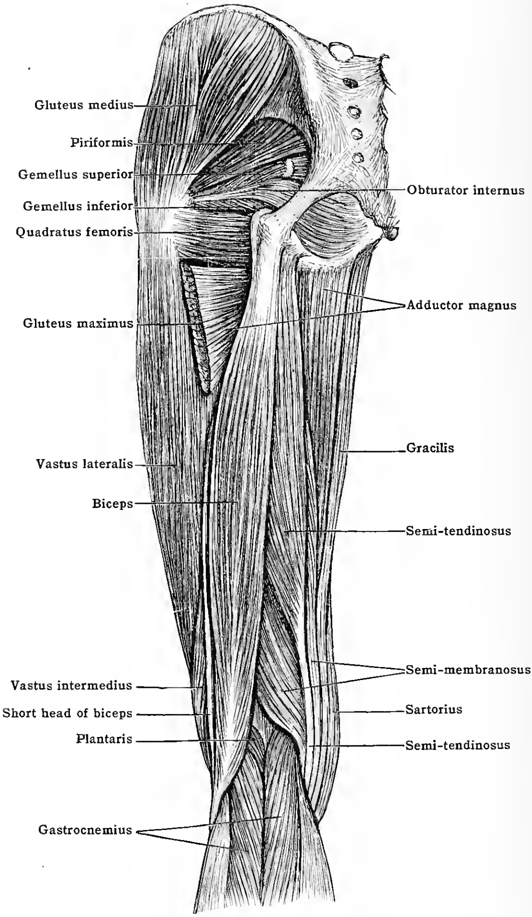
of origin and insertion, the other descends to enter the middle third of the distal deep portion of the muscle.

Action.—It is the most powerful extensor of the thigh. It also serves slightly to rotate the limb lateralward and to make tense the fascia lata, and through the ilio-tibial band to keep the extended knee-joint steady. When the thigh is extended the major part of the muscle is an adductor but the upper part is a weak abductor. The whole muscle is an abductor when the thigh is flexed. It is brought powerfully into play in climbing and in walking up hill.

Fig. 408.—The Lateral Rotators and the Hamstring Muscles.



Relations.—It is covered by the fatty superficial tissue of the buttock. It extends over the posterior portion of the ilium, the lateral surface of the sacrum and coccyx, the sacro-tuberous ligament, and the great trochanter. It covers the tuber of the ischium in the standing but not in the sitting position. Immediately beneath the muscle lie portions of the gluteus medius, piriformis, obturator internus, gemelli, quadratus femoris, obturator externus, and hamstring muscles, and of the gluteal vessels and nerves and the sciatic nerve.

Variations.—Few anomalies are recorded. The deep distal portion of the muscle may be more isolated than normal in the adult. A special coccygeo-femoral muscle may run from the coccyx to the linea aspera, or from the sacro-tuberous ligament to the fascia of the leg. A special fasciculus, the ischio-femoralis, may arise from the tuberosity of the ischium and become inserted into the lower border of the muscle near the great trochanter. The sacral, ischial, or coccygeal origin may be lacking, or the origin of the muscle may be from the sacrum only.

II. Second Layer

The muscles of this layer are the gluteus medius and the piriformis.

The gluteus medius (fig. 408).—*Origin*.—From (1) the ventral three-fourths of the iliac crest, and the outer surface of the ilium between the anterior and posterior gluteal lines and (2) the investing fascia.

Structure and insertion.—The fibre-bundles converge upon both surfaces of a broad tendon nearly to its insertion on an oblong impression on the postero-superior angle and the external surface of the great trochanter. The more posterior fibre-bundles of the superficial stratum of the ventral portion of the muscle cross obliquely those of the deeper dorsal portion near the tendon of insertion. From the tendon an aponeurotic extension is usually continued into the tendon of the vastus lateralis.

Nerve-supply.—From the superior gluteal nerve a branch passes to the dorsal portion of the muscle and one or more twigs of the branch to the tensor fasciæ latæ enter the ventral portion of the muscle. The branches enter the middle third of the muscle between its tendons of origin and insertion. The nerve-fibres arise usually from the fourth and fifth lumbar and first sacral nerves. The branch to the dorsal portion of the muscle has a lower spinal origin than those to the ventral portion.

Action.—To abduct the thigh. The anterior portion of the muscle is a flexor and a medial rotator, the posterior a lateral rotator and an extensor. When the muscle acts as a whole, it is a medial rotator.

Relations.—Upon the muscle lie the tensor fasciæ latæ and gluteus maximus muscles and the fascia lata; beneath it lie the gluteus minimus muscle, the superior gluteal nerve and vessels, and the great trochanter.

Variations.—It may be divided into two distinct portions, or it may be fused with the piriformis or the gluteus minimus or both. A special fasciculus may extend to the superior portion of the great trochanter.

The piriformis (fig. 408).—*Origin*.—From (1) the lateral part of the ventral surface of the second, third, and fourth sacral vertebræ; (2) the posterior border of the great sciatic notch; and (3) the deep surface of the sacro-tuberous (great sacro-sciatic) ligament near the sacrum.

Structure and insertion.—The fibre-bundles converge upon a tendon which is inserted upon the anterior and inner portion of the upper border of the great trochanter. The insertion of fibre-bundles continues nearly to the great trochanter. An accessory slip of insertion may pass to the gluteus minimus.

Nerve-supply.—From a nerve which arises either directly from the first or second sacral nerve or from a loop between them. The nerve enters the deep surface of the muscle in its middle third. There may be two or more nerves.

Action.—It is an extensor, abductor, and lateral rotator of the thigh. It causes medial rotation when the hip is flexed.

Relations.—Its ventral surface faces the sacral plexus, the rectum, and the hip-joint. It is covered dorsally by the gluteus maximus. It lies between the gluteus medius and the superior gemellus. Between the piriformis and the superior gemellus the sciatic nerve usually passes into the thigh. The superior gluteal nerve and vessels pass dorsally above its superior margin; the inferior nerve and vessels beneath its inferior margin.

Variations.—It is rarely absent. The origin may extend to the first sacral or to the fifth sacral vertebra and the coccyx. It may be fused with the gluteus medius or minimus or more rarely with the superior gemellus. Its tendon of insertion may be fused with that of the gluteus medius or the obturator internus. In about 20 per cent. of bodies it is divided partly or completely into two portions, between which the sciatic nerve or its peroneal (external popliteal) division usually passes. Rarely the tibial instead of the peroneal portion may pass between the two fasciculi, or the muscle may be divided into three or more fasciculi, between which the branches of the sciatic nerve pass.

III. Third Layer

The gluteus minimus (fig. 409).—*Origin*.—From the outer surface of the ilium between the anterior and inferior gluteal lines; (2) from the septum between it and the gluteus medius near the anterior superior iliac spine; and (3) from the capsule of the hip-joint.

Structure and insertion.—The fibre-bundles converge upon a tendon which appears on the middle of the ventral border and gradually spreads over the lateral surface. The muscle is thickest in front, where it is usually bound by an intermuscular septum to the gluteus medius. The tendon is inserted into the ventral surface of the great trochanter of the femur.

Nerve-supply.—From twigs of the branch of the superior gluteal nerve which goes to the tensor fasciæ latæ. These twigs enter the middle third of the muscle as the tensor branch passes across it.

Action.—To abduct the thigh and rotate it medialward. The anterior part of the muscle is a flexor, the posterior an extensor.

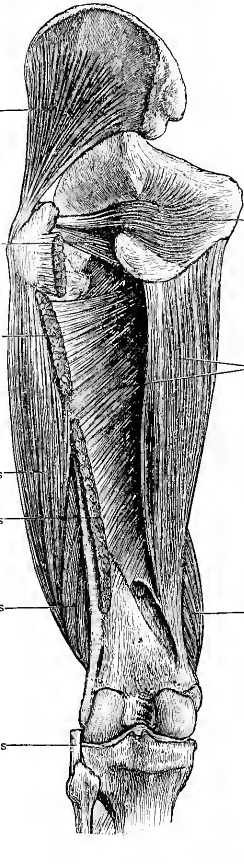
Relations.—It is covered by the gluteus medius and piriformis muscles. Beneath it lie the inferior part of the iliac ala, the hip-joint (to the capsular ligament of which it is bound), and the direct tendon of the rectus femoris muscle.

Variations.—It may be fused with the gluteus medius or the piriformis. It may send a slip to the fascia lata or the vastus lateralis. It may be divided into two distinct divisions, an anterior and a posterior. Very frequently from the anterior margin of the muscle a special fasciculus is more or less isolated (the **scansorius**, invertor femoris, small anterior gluteal, etc.). The **accessorius of the gluteus minimus** is a small muscle fasciculus which may lie under cover of the gluteus minimus and extend to be inserted into the capsule of the hip-joint.

Bursæ

B. ischiadica m. glutei maximi.—A small inconstant bursa between the tuber ischii and the gluteus maximus muscle. **B. trochanterica m. glutei maximi.**—A large bursa constantly

Fig. 409—The Deep Muscles of the Back of the Thigh.



present between the fascial tendon of the gluteus maximus and the posterior lateral surface of the great trochanter and the origin of the vastus lateralis muscle. **B. gluteofemorales.**—Two or three small bursæ on each side of the tendon of attachment of the gluteus maximus to the femur. **B. trochanterica m. glutei medii anterior.**—A small bursa constantly present between the tendon of the gluteus medius muscle and the lateral surface of the great trochanter. **B. trochanterica m. glutei medii posterior.**—A small bursa frequently present between the tendons of the piriformis and the gluteus medius. **B. trochanterica m. glutei minimi.**—A fairly large bursa generally present between the margin of the great trochanter and the tendon of this muscle. **B. m. piriformis.**—A small bursa frequently present between the tendons of the piriformis and superior gemellus muscles and the femur.

2. Ischio-pubo-femoral Musculature of the Hip

The muscles belonging to this group (the obturator internus, the two gemelli, the quadratus femoris and the obturator externus, extend from the pubis and ischium across the back of the hip-joint to the great trochanter and the neighbouring part of the shaft of the femur. They are powerful lateral rotators of the thigh. The **obturator internus** (fig. 409), a large, flat, triangular muscle, arises from the pelvic surface of the innominate bone and from the obturator membrane. At the lesser sciatic notch its tendon is joined by the two **gemelli** (fig. 408), one of which arises on each side from the bony projections which make the notch, and the combined tendon is inserted into the trochanteric (digital) fossa. The **quadratus femoris** (fig. 408) passes from the tuber of the ischium to the femur behind and below the great trochanter. These muscles are supplied by special nerves which arise from the front of the sacral plexus and enter the deep surfaces of the muscles. A fifth muscle, attached to the greater trochanter and associated with this group, the **obturator externus,** is differentiated near the adductor muscles of the thigh and is supplied by a branch from the obturator nerve. It arises from the outer surface of the bones bounding the ventral two-thirds of the obturator foramen and is inserted by a tendon into the trochauteric (digital) fossa.

These muscles seem to have no certain representatives in the arm, where the shoulder-joint is entirely ensheathed by the dorsal musculature. It is possible that the pectoral group has a corresponding embryonic origin. The group is represented, with marked variations, in the lower extremities of amphibia and all higher vertebrates.

FASCIÆ

Within the pelvis the obturator internus lies on the obturator membrane. It is covered by the **obturator fascia**, which is attached to the body of the pubis, to the iliac portion of the arcuate line, to the ventral margin of the great sciatic notch, to the ischial spine, to the sacro-tuberous (great sacro-sciatic) ligament, and with the falciform process of that ligament, to the ischial and pubic rami. Near the upper part of the obturator foramen the fascia instead of being attached to bone is reflected over the muscle and attached to the obturator membrane. It here helps to bound the canal for the obturator vessels and nerve. The upper part of the fascia lies beneath the pelvic peritoneum and the levator ani. The lower part forms the outer boundary of the ischio-rectal fossa. The fascia is continued as a thin, adherent membrane over the obturator internus and the gemellus muscles to their attachment. The quadratus femoris is invested by a thin adherent fascial sheet.

MUSCLES

The obturator internus (fig. 409).—*Origin.*—From (1) the pelvic surface of the pubic rami near the obturator foramen; (2) the pelvic surface of the ischium between the foramen and the great sciatic notch; (3) the deep surface of the obturator internus fascia; (4) the fibrous arch which bounds the canal for the obturator vessels and nerve; and (5) the pelvic surface of the obturator membrane except in the lower part.

Structure and insertion.—From this extensive area of origin the fibre-bundles converge toward the lesser sciatic notch and become applied to the broad tendon of insertion. At the notch the muscle curves laterally and extends outward and upward to its insertion into the fore part of the trochanteric fossa of the femur. The tendon is formed of five or six bands which begin high in the muscle and converge into a common tendon situated on the deep surface of the muscle as the latter curves about the ischium. The tendon bands at first throw the tendon into folds which run in ridges in the fibro-cartilage which lines the notch. The attachment of fibre-bundles continues upon the dorsal surface of the tendon to half way between the lesser sciatic notch and the great trochanter.

Nerve-supply.—A special nerve to the obturator internus arises from the front of the sacral plexus, usually from the lumbo-sacral cord and the first and second sacral nerves. This nerve passes lateral to the sacro-spinous (lesser sciatic) ligament, then re-enters the pelvis through the lesser sciatic notch and sends out branches of distribution on the pelvic surface of the obturator internus.

Action.—This muscle with its two companions, the gemelli, is a powerful lateral rotator of the thigh. It is also an extensor and abductor when the thigh is bent at a right angle.

Relations.—The chief pelvic relations have been described in connection with the obturator fascia which completely covers the medial surface of the muscle. The muscle passes out between the two sacro-ischial (sacro-sciatic) ligaments. Outside the pelvis the gemellus muscles run on each side of the tendon, which is here closely applied to the capsule of the joint. Dorsal to it lie the gluteus maximus, the sacro-tuberous (great sacro-sciatic) ligament, the inferior gluteal (sciatic) vessels, and the sciatic and posterior cutaneous nerves. The nerve of the quadratus femoris runs beneath the obturator internus and gemellus muscles.

Variations.—It varies in the extent of its insertions. It may be divided into two parts, a pubic and an ischial. Fasciculi may be sent to the postero-inferior part of the ilio-pectineal eminence, the tendon of the psoas minor, the tuber ischii, the sacro-tuberous (great sacro-sciatic) ligament, the ischial spine, etc.

The gemellus superior (fig. 408).—*Origin.*—From the outer surface of the ischial spine and the neighbouring edge of the lesser sciatic notch.

Structure and insertion.—The fibre-bundles encircle the upper border and ventral aspect of the tendon of the obturator internus. They are inserted into the upper border of this tendon, and sometimes also into the trochanteric fossa.

Nerve-supply.—From a small nerve which arises either directly from the plexus or as a branch of the nerve to the obturator internus or of that to the quadratus femoris. This nerve usually enters the deep surface of the muscle near the junction of its ischial and middle thirds.

Action.—It is essentially a part of the obturator internus.

Relations.—It lies between the piriformis and the tendon of the obturator internus. Proximally it adjoins its fellow beneath this tendon; distally, the two gemelli enclose the tendon in a musculo-tendinous sheath.

Variations.—It may be wanting or may have a more extensive origin than usual. It may be joined to the piriformis or to the gluteus minimus or be joined more closely than usual to the obturator tendon.

The gemellus inferior.—*Origin.*—From the upper part of the inner border of the tuberosity of the ischium, the sacro-tuberous (great sacro-sciatic) ligament and from the neighbouring edge of the lesser sciatic notch.

Structure and insertion.—The fibre-bundles converge upon the inferior border of the tendon of the obturator internus, and are inserted by tendon-fibres into this or into the great trochanter below the obturator internus tendon.

Nerve-supply.—From a branch of the nerve to the quadratus femoris. This branch enters the deep surface of the muscle near the junction of the ischial with the middle third.

Action.—It is essentially a part of the obturator internus.

Relations.—It lies between the quadratus femoris and the tendon of the obturator internus.

Variations.—It is rarely absent. It may be joined to the quadratus femoris. It is frequently closely bound up with the obturator internus. It may be doubled.

The quadratus femoris (fig. 408).—*Origin.*—From the upper part of the outer border of the tuber of the ischium.

Structure and insertion.—The fibre-bundles take a nearly parallel course and are inserted into the vertical ridge which terminates above on the inferior dorsal angle of the great trochanter.

Nerve-supply.—From a nerve which arises usually from the lumbo-sacral cord and the first sacral nerve and passes under the gemelli and the tendon of the obturator internus. The nerve enters the deep surface of the muscle near the junction of the ischial and middle thirds.

Action.—It is a powerful lateral rotator and a weak adductor of the thigh.

Relations.—It is covered by the gluteus maximus. Between this muscle and the quadratus femoris runs the sciatic nerve. The obturator externus muscle lies in front. The inferior gemellus extends along its superior border. The adductor minimus adjoins it distally.

Variations.—It is absent in from 1 to 2 per cent. of instances. (Schwalbe and Pfitzner.) It may be double near its femoral insertion. It may be fused with the inferior gemellus or the adductor magnus. It may send a fasciculus to the semimembranosus.

The **obturator externus** (figs. 407, 409).—*Origin.*—From the lateral surface of the pubic and ischial rami, where they bound the obturator foramen, and from the surface of the obturator membrane.

Structure and insertion.—Often the muscle is distally divided into three fasciculi, a superior from the superior pubic ramus, a middle from the inferior pubic ramus and the obturator membrane, and an inferior from the ischium. The fibre-bundles converge upon a tendon which is at first deeply buried, then appears on the lateral surface of the muscle and is continued as a rounded tendon over the capsule of the joint to its insertion into the dorsal part of the trochanteric fossa.

Nerve-supply.—The obturator nerve gives rise, usually in the obturator canal, to a branch which bifurcates to enter the superior border and ventral surface of the muscle in its middle third.

Action.—It is a powerful lateral rotator of the thigh and is also a weak adductor.

Relations.—It is covered by the pectineus, the ilio-psoas, and the adductor magnus muscles in front, and by the quadratus femoris behind near its insertion. It covers over the obturator membrane. The obturator nerve passes either above the muscle or through its upper portion.

Variations.—The reported variations are few. It may be joined by a slip from the adductor brevis.

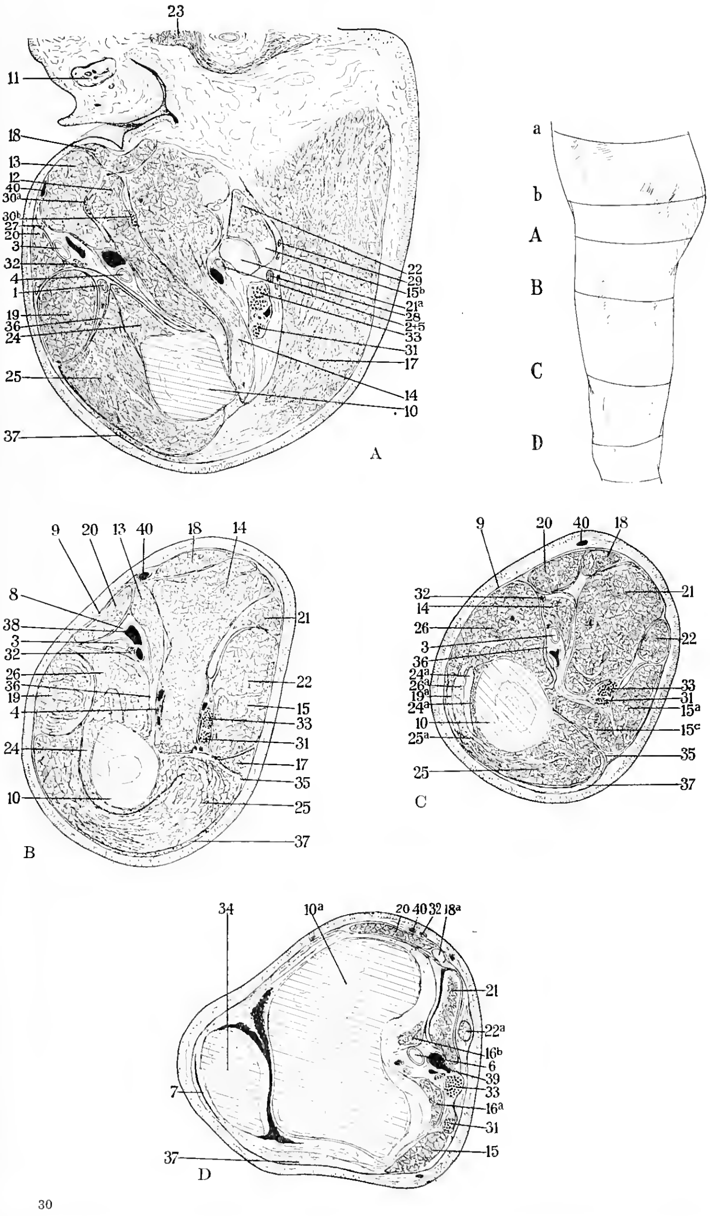
Bursæ

B. m. obturatoris interni.—A fairly large bursa constantly present between the tendon of the obturator internus muscle and the lesser sciatic notch. It may extend on each side beneath the gemellus muscles. **B. m. quadrati femoris.**—A small bursa frequently found between this muscle and the small trochanter. **B. m. obturatoris externi.**—A bursa is sometimundes of between the tendon of this muscle and the capsule of the joint.

B. MUSCLES OF THE THIGH

In the thigh three groups of muscles may be recognised, an anterior or extensor (figs. 411, 412), a medial or adductor (figs. 409, 411, 412), and a posterior, flexor or hamstring group (figs. 408, 413).

Fig. 410, A–D.—Transverse Sections through the Left Thigh in the Regions indicated in the Diagram.



In the proximal part of the thigh the anterior group of muscles is separated from the medial group by the ilio-psoas muscle (fig. 411) and by the femoral blood-vessels and nerve, and from the posterior group by the gluteus maximus (fig. 413). More distally it is separated from the medial group by the medial intermuscular septum and from the posterior by the lateral intermuscular septum (see p. 468). The medial and posterior groups are closely associated. The adductor magnus belongs ontogenetically to both.

The three groups of muscles, with numerous modifications, are represented in the thighs of amphibia and all higher vertebrates. In the human arm they are likewise represented, the adductor group in a much reduced form by the coraco-brachialis. The quadriceps is represented by the triceps in the arm, the long head of the triceps corresponding with the rectus femoris. The hamstring muscles are represented by the biceps and the brachialis.

FASCIÆ

The **fasciæ** and the relations of the musculature of the thigh may be followed in the cross-sections figs. 407, 410, 414.

The **tela subcutanea** of the thigh varies considerably in thickness in different regions, but is well developed throughout and contains a considerable amount of fat. Over the front of the thigh, especially in the upper medial region, one or more deeper membranous layers may usually be separated from the superficial adipose layer. Between the former and the latter are situated the inguinal lymphatic nodes and the saphenous vein. The deepest layer near the inguinal (Poupart's) ligament is fused with the fascia lata (see below). Medially it is attached to the pubic arch. Thus fluids beneath the tela subcutanea of the abdomen and perineum do not readily pass into the region of the thigh.

Over the lower half of the patella a subcutaneous bursa (**b. præpatellaris subcutanea**) is found. Another is usually found over the upper end of the patellar ligament (**b. infrapatellaris subcutanea**).

The muscles of the thigh are enclosed in a dense fascial sheet, the **fascia lata** (figs. 387, 410). The gluteal portion of this and the ilio-tibial band have already been described (p. 457). The ventral portion of the fascia, composed chiefly of transverse fibres, is a dense, fibrous membrane. Above it is attached to the inguinal ligament from the anterior superior spine to the pubic tubercle. Below it extends over the knee, where it is united to the capsule of the joint and is strengthened by expansions from the vastus lateralis and medialis. Between the front of the patella and the fascia is a bursa (**b. præpatellaris subfascialis**). Above the knee the fascia is strengthened by an *arciform process* which extends obliquely distally across the fascia from the ilio-tibial band to the capsule of the knee. This gives rise to a fold in the skin when the leg is extended and the muscles are not tense. Over the medial and posterior regions of the thigh the fascia is less dense. It extends from the body and inferior ramus of the pubis, the inferior ramus and tuber of the ischium, and the sacro-tuberous ligament into the fascia of the back of the leg. Above the popliteal space it is strengthened by a transverse band of fibres. Near the knee the tendons of the quadriceps, sartorius, gracilis, and semitendinosus become bound to the fascia by membranous laminæ.

The relations of the fascia lata to the inguinal ligament and the iliac fascia are somewhat complex. The fascia of the ilio-psoas muscle extends over the muscle to its femoral insertion. Above the inguinal ligament this fascia is called the **fascia iliaca**; below the ligament, the **fascia ilio-pectinea**. This fascia is firmly united to the lateral extremity of the inguinal ligament. The pectineus muscle is likewise invested with a fascial membrane which extends over the muscle from the pubis to the femur and is fused laterally with that of the ilio-psoas. This combined fascia is firmly bound between the two muscles to the ilio-pectineal eminence. The ilio-pectineal fascia divides the space beneath the inguinal ligament into a lateral **lacuna musculorum,** which contains the ilio-psoas muscle and the femoral (anterior crural) nerve, and a medial **lacuna vasorum,** which contains the femoral artery and vein. Medial to the vein is the **femoral ring,** bounded medially by the **lacunar (Gimbernat's) ligament.** This is closed off from the abdominal cavity by a septum derived from the transversalis fascia, the **femoral septum,** but offers passage for lymph-vessels.

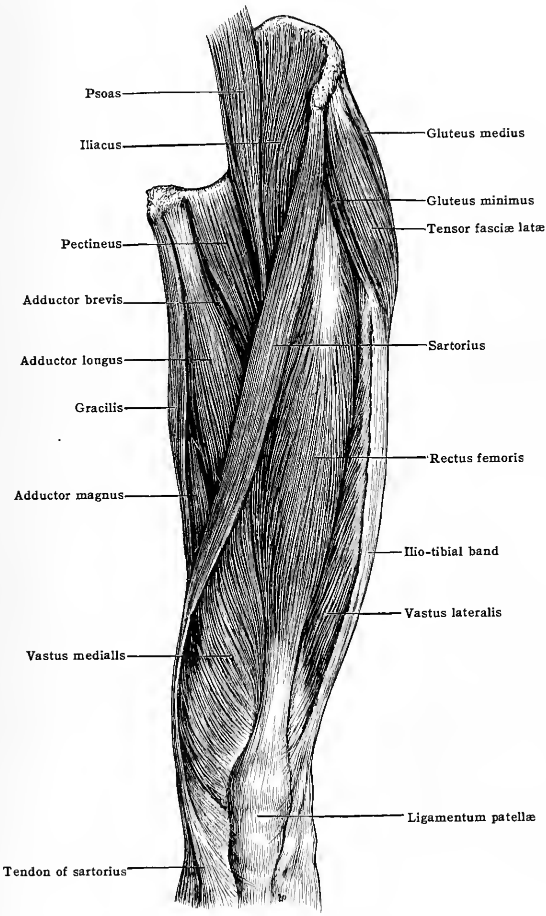
N. cutaneous femoris posterior (small sciatic). 29. N. gluteus inferior. 30. N. obturatorius—a, superficial branch; b, deep branch. 31. N. peroneus communis (external popliteal). 32. N. saphenus (great saphenous). 33. N. tibialis (internal popliteal). 34. Patella. 35. Septum intermusculare laterale. 36. Septum intermusculare mediale. 37. Tractus iliotibialis (ilio-tibial band). 38. Vena femoralis. 39. Vena poplitea. 40. V. saphena magna (great saphenous vein).

Beyond the inguinal ligament the fasciæ of the ilio-psoas and pectineal muscles line a triangular space, the **ilio-pectineal fossa,*** through which run the femoral vessels (fig. 407). The sartorius muscle partly overlies the distal lateral margin of this fossa. The fascia lata is here reflected from the surface of the sartorius to the ilio-psoas fascia, and becomes fused with it. From the medial margin of the sartorius a process of the fascia is continued over the lateral and upper part of the fossa, and is attached to the inguinal and lacunar (Gimbernat's) liga-

Fig. 411.—Muscles of the Front of the Thigh.



ments (fig. 389). Over the lower extremity of the fossa a process is continued medially into the pectineal fascia. On the medial margin of the fossa the fascia lata is continued directly into the pectineal fascia. The lateral concave margin of the fascia overlying the fossa is called the **falciform margin**; the upper extremity of this, the **superior cornu**; the distal extremity, the **inferior cornu.** The oval space bounded by the margo falciformis is called the fossa ovalis (saphenous opening). This is covered by the **fascia cribrosa,** which some consider a deep layer

* This lies within *Scarpa's triangle* [trigonum femorale], a space bounded by the inguinal (Poupart's) ligament and the sartorius and long adductor muscles.

of the tela subcutanea and others a portion of the fascia lata. This fascia cribrosa contains many openings for the passage of blood-vessels and lymphatics. The space which lies medial to the femoral vessels between the femoral ring and the fossa ovalis is called the **femoral canal** (crural canal).

From the fascia intermuscular septa descend in between the underlying muscles. Of these, the medial and lateral intermuscular septa are the best marked (fig. 410).

The **lateral intermuscular septum** separates the extensor muscles from the hamstring group. It extends from the tendon of the gluteus maximus to the lateral epicondyle. It is composed chiefly of longitudinal fibres and is thickest distally. The vastus lateralis is united to its ventro-lateral surface; the short head of the biceps, to its dorso-medial surface.

It will be noted that this septum serves to divide primarily ventral from primarily dorsal musculature, with the exception of the short head of the biceps, which, though primarily dorsal, occupies a position, perhaps secondarily acquired, with the primarily ventral muscles.

The **medial intermuscular septum** serves to divide the anterior extensor from the medial adductor musculature. It is perhaps simplest in the region immediately distal to the ilio-pectineal fossa (fig. 410 B). Here a well-marked septum may be seen extending to the femur between the sartorius and quadriceps on the one side, and the adductor longus and brevis on the other. The septum here, next the muscles, has on each side a membranous lamina. Between the two laminæ there is a looser tissue in which run blood-vessels and nerves. A fibrous membrane extends between the rectus and sartorius to the septum.

More distally the sartorius comes to overlie the septum (fig. 410 C). The sheath of the sartorius on the lateral margin becomes fused with the fascia of the vastus medialis, and on the medial margin to a membrane that covers the ventral surfaces of the adductor longus and magnus. Beneath the sartorius and between the adductor longus and the vastus medialis is a triangular space bounded by the sheaths of these muscles, and filled with a loose areolar tissue in which run the chief blood-vessels of the thigh. This space, first described by John Hunter, is known as **Hunter's canal,** or the **adductor canal.** Still more distally the vessels with their surrounding fibrous tissue pass through the hiatus tendineus, between the long tendon of the adductor magnus and the femur, to the back of the thigh. The septum here passes behind the posterior surface of the vastus medialis to the femur.

MUSCLES

1. The Anterior Group

(Figs. 411, 412)

This group, which forms a semi-conical mass pointed upward, is composed of the quadriceps femoris and the sartorius muscles, innervated by the femoral nerve.

The **sartorius** is a long, ribbon-like muscle which arises from the anterior superior spine of the ilium and extends along the medial margin of the quadriceps, passing obliquely across the upper part of the thigh, and then descending to the dorse-medial side of the knee, whence its tendon curves forward to be inserted into the ventro-medial surface of the superior extremity of the tibia.

The **quadriceps femoris** is composed of four muscles differentiated from a common embryonic origin. Of these, the **rectus femoris,** which arises from the ventro-lateral margin of the ilium by two tendons, is the most superficial and the most completely differentiated. The **vastus lateralis,** which arises from the superior extremity of the ventral surface of the shaft of the femur and from the lateral lip of the linea aspera; the **vastus medialis,** which arises from the medial lip of the linea aspera and from the intertrochanteric line; and the **vastus intermedius** (crureus), which arises between these two and beneath the rectus from the surface of the femur, are less distinctly differentiated from one another. The vastus intermedius and vastus lateralis are partly fused at the insertion, the intermedius and medialis at their origins. From the four muscles arises a tendon which is inserted into the tuberosity of the tibia. In this tendon, which is closely applied to the capsule of the knee-joint, lies a sesamoid bone, the patella.

The sartorius and the rectus flex the thigh; the quadriceps extends the leg; the sartorius flexes the leg and rotates the thigh lateralward and the leg medialward.

In the embryo the sartorius has an origin distinct from that of the quadriceps. In the anthropoid apes it is much more developed than in man.

In addition to supplying the muscles of this group, the femoral nerve also gives branches to the iliacus muscle (p. 455) and the pectineus muscle (p. 472).

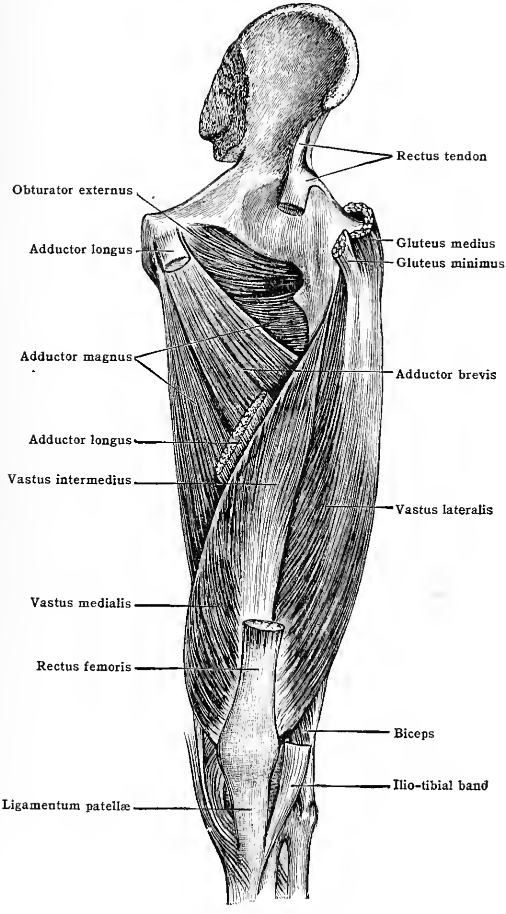
The sartorius (fig. 411).—*Origin.*—From the anterior superior spine of the ilium and the area immediately below this.

Insertion.—Into the medial surface of the tibia near the tuberosity and into the neighbouring fascia of the leg.

Structure.—The muscle arises by short tendinous strands. The fibre-bundles take a nearly parallel course. The component muscle-fibres are said to be the longest in the body. Near the medial epicondyle of the femur the tendon of insertion makes its appearance on the deep aspect of the muscle. On the superficial surface of the tendon the muscle-fibres are inserted as far as the distal margin of the knee-joint. From there the tendon turns forward to its insertion.

Nerve-supply.—Usually two branches enter the deep surface of the proximal third of the sartorius. One or both of them may be bound up with an anterior cutaneous nerve passing

Fig. 412.—The Deep Muscles of the Front of the Thigh.



through the muscle. The first of the branches is distributed chiefly to the lateral and proximal, the second to the medial and distal, portions of the muscle. Within the muscle is a complex plexus.

Action.—(1) To flex the thigh at the hip, abduct and rotate it lateralward; (2) to flex the leg and rotate it slightly medialward; (3) to make tense the medial part of the fascia lata.

Relations.—The sartorius lies in a fascial canal bounded by the fascia lata and by intermuscular septa which descend from this. It crosses the rectus femoris, ilio-psoas, the adductor longus and magnus, and the vastus medialis muscles, the femoral vessels and nerve, and the knee-joint. At its insertion its tendon covers the gracilis and semitendinosus.

Variations.—It may arise from the inguinal ligament or be inserted into the fascia lata, the medial epicondyle, or the capsule of the knee-joint. It may be longitudinally divided into two parts. The tendon of the secondary slip is in such instances usually attached to the capsule of the knee-joint, but sometimes is attached to the fascia over the vastus medialis or to the anterior wall of the adductor canal. More frequently the muscle is partly divided proximally or distally. The secondary tendon of origin may arise from the anterior inferior spine, the ilio-pectineal eminence, etc. The muscle is very rarely absent. It may be crossed by a tendinous inscription, or more rarely it is rendered digastric by an intervening tendon.

The quadriceps femoris (figs. 411, 412).—This, as pointed out above, is composed of the rectus femoris and the vastus lateralis, intermedius, and medialis.

The rectus femoris (fig. 411).—*Origin.*—By two tendons. The anterior 'straight' tendon is attached to the anterior inferior spine of the ilium; the posterior 'reflected' tendon to the postero-superior surface of the rim of the acetabulum. The two tendons unite so as to form a small arch above the capsule of the joint.

Structure and insertion.—From this arch an aponeurotic expansion descends upon the front of the muscle nearly to the middle of the thigh. This expansion is broad above, becomes narrower as it descends, and is continued a short distance as a narrow intramuscular tendon after it disappears from the surface. The tendon of insertion begins on the back of the muscle above the middle of the thigh, expands into a broad aponeurosis, and finally becomes a strong band which is inserted into the proximal border of the patella. The fibre-bundles pass in a bipenniform manner from the back and sides of the tendon of origin to the front and sides of the tendon of insertion.

Nerve-supply.—As a rule, two branches enter the muscle. One of these enters the deep surface of the muscle in its upper fourth, and is distributed mainly to the proximal part of the lateral half. The other enters the medial margin of the muscle near the junction of the proximal and middle thirds, and is distributed chiefly to the medial half and distal portion of the muscle.

The vastus lateralis (vastus externus) (fig. 412).—*Origin.*—From—(1) the shaft of the femur along the antero-inferior margin of the great trochanter and in front of the gluteal tuberosity; and (2) the lateral intermuscular septum along the upper half of the linea aspera.

Insertion.—By a flat tendon into—(1) the proximo-lateral border of the patella; and (2) the front of the lateral condyle of the tibia and the fascia of the leg.

Structure.—The fibre-bundles arise partly from the bone, partly from an aponeurosis which covers the proximal two-thirds of the muscle, and from the lateral intermuscular septum. They take a parallel course distally in a ventro-medial direction, and are inserted into an aponeurosis which lies on the deep surface of the muscle and receives fibres until within a few centimetres of the patella. Ventrally this aponeurosis fuses with the rectus tendon, laterally with that of the vastus medialis, and dorsally it receives some of the fibre-bundles of the vastus intermedius. Commonly the muscle is distinctly divisible for the greater part of its course into two sheets, a superficial and a deep. The deep sheet is often subdivided into two laminæ.

Nerve-supply.—Usually there are three nerves, one of which, accompanied by blood-vessels, runs on the inner surface of the superficial sheet midway between the tendons of origin and insertion, the second between the two laminæ of the deep layer, and the third passes through the innermost lamina to be distributed in part to the vastus intermedius (crureus) muscle.

The vastus medialis (vastus internus) (fig. 412).—*Origin.*—From the whole extent of the medial lip of the linea aspera and from the distal half of the intertrochanteric line. The origin takes place by means of an aponeurosis which is adherent to the tendons of insertion of the adductor muscles.

Structure and insertion.—The fibre-bundles arise from the deep surface of this aponeurosis and are inserted on the medial surface and margin of a tendon which begins on the deep surface of the muscle about its middle near the lateral margin. On the distal lateral border of the muscle it is inserted into the medial half of the proximal margin of the patella and into the medial condyle of the tibia and the fascia of the leg. For some distance near the knee the lateral margin of the tendon is united to those of the vastus intermedius (crureus), lateralis (externus) and the rectus.

Nerve-supply.—The nerve to this muscle descends on its medial surface, often bound up with the saphenous nerve for a part of its course. It gives off successive branches and finally sinks into the muscle substance. These branches enter about midway between the origin and insertion of the fibre-bundles of the muscle.

The vastus intermedius (crureus) (figs. 409, 412).—*Origin.*—From (1) the distal half of the lateral margin of the linea aspera and its lateral bifurcation; (2) the antero-lateral surface of the shaft of the femur. Between the origin of the vastus intermedius (crureus) and that of the vastus medialis the shaft of the femur is free from muscle attachment.

Structure and insertion.—On the ventral surface of the muscle lies an aponeurosis which extends from its proximal fourth to the proximal margin of the patella. The fibre-bundles of the muscle are inserted into the deep surface of this and into the deep surface of the aponeurosis of insertion of the vastus lateralis. The proximal fibre-bundles descend vertically, the medial and lateral, especially the latter, obliquely to their insertion. Medially the tendon is more or less fused with that of the vastus medialis, and laterally with that of the vastus lateralis. The muscle is composed of muscle lamellæ superimposed concentrically about the shaft of the femur. The deepest, most distal of these is called the articularis genu (subcrureus). The fibre-bundles of this layer are inserted into the capsule of the joint or into the superior margin of the patella.

Nerve-supply.—Several branches are usually distributed to this muscle. To the lateral region a branch from the nerve to the vastus lateralis is usually given; to the middle of the muscle another branch descends from the femoral (anterior crural) nerve; to the medial portion there extend several twigs from the nerve to the vastus medialis.

Tendon of the quadriceps.—The quadriceps tendon may be more or less distinctly divided into layers, of which the superficial layer belongs to the rectus, the deep to the vastus intermedius, and the intermediate to the vastus lateralis and medialis. Some of the more superficial fibres of the tendons of the two vasti, however, cross in front of the rectus tendon. The combined tendon of the quadriceps is in part attached to the superior and lateral margins of the patella, and in part extends over the patella into the patellar ligament. A part of the tendon fibres of the vastus lateralis and medialis run on each side of the patella to the ventral surface of the condyles of the tibia. These form the **retinacula patellæ mediale and laterale.** The medial is the broader and better developed. With the retinacula are included bundles of fibres which run from the epicondyles to the patella and into which some muscle fibre-bundles are inserted. From the apex of the patella to the tuberosity of the tibia the quadriceps tendon is continued as the **patellar ligament** (fig. 415).

Nerve-supply.—The relations of the branches of distribution to the various parts of the muscle have been pointed out above in connection with each head. The general relations of these branches of the femoral nerve are as follows:—From the femoral nerve near the proximal end of the vastus medialis the branches for the vastus lateralis, vastus intermedius (crureus), and rectus pass distally and laterally between the rectus and vastus intermedius (crureus) to be distributed to the muscles named, while the chief nerve for the vastus medialis descends on the medial side of this muscle in company with the saphenous nerve. The branches to the vastus lateralis and intermedius are commonly bound up in a single nerve-trunk for some distance. The branches to the rectus are usually bound up with this trunk for a shorter distance. The nerve to the vastus medialis may be united to this trunk for a slight distance, but more frequently it is more or less bound up with the saphenous nerve.

Action.—The quadriceps is the extensor of the leg. The rectus femoris also flexes the thigh at the hip and is a weak abductor of the thigh. The articularis genu makes tense the capsule of the knee-joint.

Relations.—The quadriceps is covered ventrally immediately by the fascia lata. The sartorius runs along its medial margin; the tensor fasciæ latæ lies over the proximal quarter of its lateral surface. Dorsal to the vastus lateralis lie the gluteus maximus and biceps; dorsomedial to the vastus medialis, the three adductor muscles and the semimembranosus. Next the vastus medialis lies the adductor canal with the femoral vessels and the saphenous nerve.

Variations.—The variations of this muscle, aside from a greater or less fusion of its parts, are not marked. The attachment of the rectus femoris to the anterior inferior spine, which takes place in the embryo later than its insertion above the acetabulum, may be wanting. On the other hand, this tendon may extend to the anterior superior spine. Occasionally the deep reflected tendon may be wanting. The **rectus accessorius** is a fasciculus rarely found, which arises by a tendon from the rim of the acetabulum and is inserted into the ventral edge of the vastus lateralis. It is innervated by a twig from the branch to the rectus.

Bursæ

B. m. recti femoris (superior).—A small bursa between the deep tendon of the rectus femoris and the edge of the acetabulum. Rare. **B. m. recti femoris (inferior).**—Between the tendon of the rectus and the combined tendon of the vastus lateralis and medialis. Occasional. **B. præpatellaris subtendinea.**—A bursa between the tendon of the quadriceps and the periosteum of the patella. Of the three præpatellar bursæ—the subcutaneous, subfascial, and subtendinous—as a rule only one occurs. When two or three exist, they usually communicate freely with one another. **B. suprapatellaris.**—A bursa between the anterior surface of the lower end of the femur and the tendon of the quadriceps. It usually communicates with the joint cavity. **B. infrapatellaris profunda.**—A bursa between the patellar ligament and the tibia. It seldom communicates with the joint cavity. **B. m. sartorii propria.**—A bursa, fairly large, between the tendon of the sartorius and the tendons of the semitendinosus and gracilis muscles. This usually communicates with the bursa anserina (see p. 474).

2. The Medial (Adductor) Group

(Figs. 409, 411, 412)

To this group of muscles belong the gracilis, the pectineus, the adductors brevis, longus, and magnus, and the obturator externus. The most superficial of the group is the **gracilis** (figs. 408, 411). This ribbon-shaped muscle arises from the inferior pubic and ischial rami, extends along the medial side of the thigh, and gives rise to a tendon which curves forward from behind the medial condyle of the femur to be inserted under the tendon of the sartorius into the medial side of the upper extremity of the tibia. The quadrilateral **pectineus** arises from the body and superior ramus of the pubis; the triangular **adductor longus** from the superior ramus medial to this (fig. 411). The pectineus is inserted into the pectineal line of the femur; the adductor longus into the middle third of the linea aspera. The triangular **adductor brevis** (fig. 412) arises from the inferior pubic ramus below the adductor longus. It is inserted into the pectineal line and the upper third of the linea aspera. The large, triangular **adductor magnus** (figs. 409, 412) arises from the inferior ramus and the tuber of the ischium and is inserted behind the short and long adductors into the whole length of the linea aspera, and by a special tendon into the adductor tubercle of the femur. The deepest muscle of the group, the **obturator externus,** which arises from the outer surface of the bones bounding the ventral two-thirds of the obturator foramen, and is inserted by a tendon into the trochanteric (digital) fossa, has been described in connection with the ischio-pubo-femoral muscles of the hip.

All the muscles of this group adduct the thigh. The gracilis, obturator externus, adductor brevis and the lower part of the adductor magnus (when the thigh is extended) rotate it lateralward. The pectineus, adductor longus, and the adductor magnus rotate it medialward. Those attached to the pubis flex the thigh. The gracilis flexes the leg and rotates it medialward. The inferior part of the adductor magnus extends the thigh.

The muscles of this group are supplied by the obturator nerve, except the pectineus, which usually gets its whole supply from the femoral (anterior crural) nerve, and the adductor magnus, which gets a part of its supply from the sciatic nerve.

In embryonic development the pectineus arises in close conjunction with the obturator group, and in the adult it may get the whole or a part of its nerve-supply from the obturator nerve or from the accessory obturator nerve. In the lower mammals the nerve-supply may come from the femoral (anterior crural) or the obturator nerve or from both. It is not certain whether the innervation from the femoral nerve indicates that the muscle belongs phylogenetically, if not ontogenetically, with the primitive dorsal musculature of the limb. By some it is considered to be derived in part from the primitive dorsal, in part from the primitive ventral, musculature. The adductor magnus arises in the embryo as two distinct portions, one connected with the flexor group of muscles, the other with the adductor group. These two portions later become fused. Primitively the sciatic portion of the adductor magnus and the semimembranosus constitute a single medial flexor muscle.

The gracilis (figs. 408, 411).—*Origin.*—By a flat tendon from the medial margin of the inferior ramus of the pubis and the pubic extremity of the inferior ramus of the ischium.

Structure and insertion.—The nearly parallel fibre-bundles which arise between two laminæ of the tendon form a thin band of muscle which is narrower and thicker distally than proximally. They are inserted on a tendon which begins as an aponeurosis on the posterior border and medial surface of the muscle in the distal third of the thigh, becomes free as a rounded cord a little proximal to the medial condyle of the femur, runs behind the condyle, and then turns forward to be inserted by an expanded process into the tibia below the medial condyle.

Nerve-supply.—The nerve enters the deep surface of the muscle near the junction of the superior and middle thirds.

Action.—To adduct, flex and (slightly) rotate the thigh lateralward, and flex the leg. With the knee flexed, it acts as a medial rotator of the leg.

Relations.—It occupies a position beneath the fascia lata and superficial to the adductor brevis, longus, and magnus muscles. Distally the sartorius lies in front, the semimembranosus behind. Its tendon crosses the tibial collateral ligament of the knee-joint and the tendons of the semitendinosus and the semimembranosus, and is overlapped by that of the sartorius.

Variations.—The pubic origin of the muscle may be much reduced or may be double. Its tendon of insertion may give rise to an accessory fasciculus which extends distally in the leg. In some of the apes the tendon descends normally much farther down the leg than in man.

The pectineus (fig. 411.)—*Origin.*—(1) From the pecten (crest) of the os pubis, the bone in front of this, and the pectineal fascia near this origin; and (2) from the anterior margin of the obturator sulcus and from the pubo-capsular ligament. Laterally the two areas of origin are usually separated by most of the superior surface of the body of the pubis. Medially they come together.

Structure and insertion.—From each area of origin a separate lamina arises. The fibre-bundles of each layer take a nearly parallel course and terminate between two tendinous lamellæ which fuse to be inserted into the upper half of the pectineal line behind the small trochanter. The fibre-bundles of the superficial layer cross those of the deep slightly obliquely. The muscle faces ventrally at its origin, laterally at its insertion.

Nerve-supply.—From a branch of the femoral (anterior crural) nerve, which passes behind the femoral artery and vein and through the pectineal fascia to enter the ventral surface of the muscle. It may also be supplied by the accessory obturator nerve, when present, or by a branch from the obturator. When both the femoral (anterior crural) and obturator nerves supply this muscle, the femoral supplies the superficial, the obturator, the deep lamina (Paterson).

Action.—To flex and adduct the thigh (as in crossing the legs).

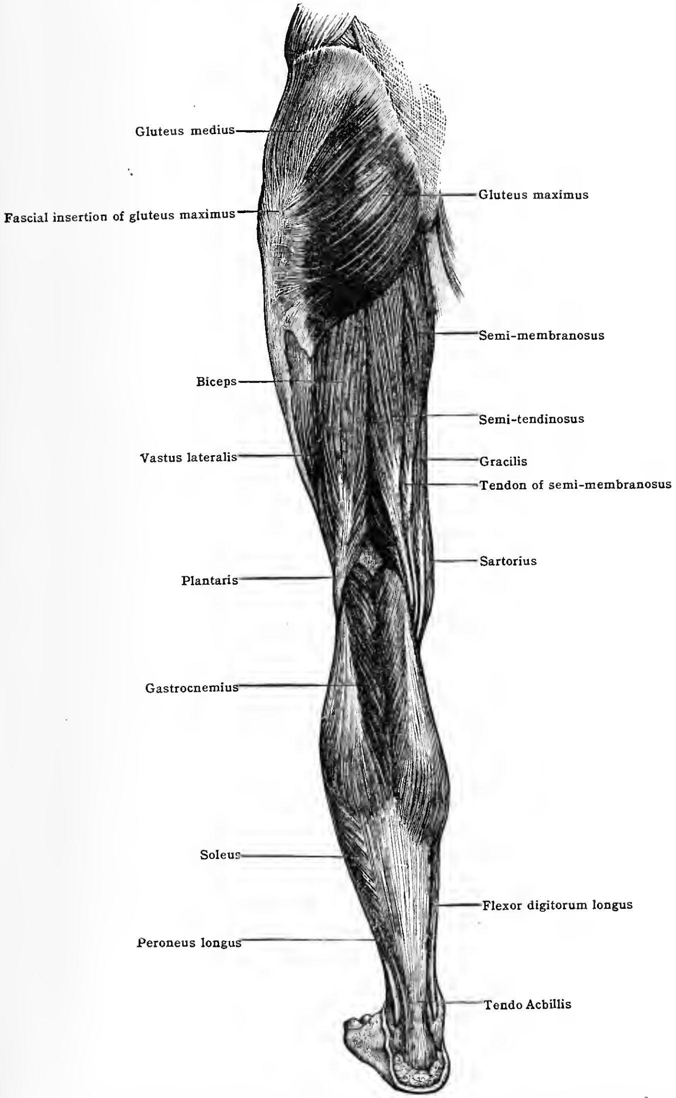
Relations.—It is covered by the pectineal fascia, lies between the ilio-psoas and the adductor longus muscles, and crosses the obturator externus and adductor brevis muscles, The medial circumflex artery runs between it and the ilio-psoas, the deep femoral artery between it and the adductor longus.

Variations.—The extent of the division of the pectineus into superficial and deep portions varies considerably. It may also be divided into a lateral and a medial division. Often the pectineus is fused with the adductor longus. It may receive an accessory fasciculus from the capsule of the hip-joint, the iliacus muscle, the obturator externus, or the adductor brevis muscles, or the small trochanter. It may send a fasciculus to the sartorius.

The adductor longus (fig. 411).—*Origin.*—From the medial corner of the superior ramus of the pubis by a strong tendon which extends for some distance on the medial border of the muscle.

Structure and insertion.—From this tendon the fibre-bundles diverge toward their insertion.

FIG. 413.—SUPERFICIAL MUSCLES OF THE BACK OF THE THIGH AND LEG.



This takes place between two lamellæ of a short tendon attached to the middle third of the linea aspera. The tendon is usually fused to the medial intermuscular septum and sends an expansion to the long tendon of the adductor magnus.

Nerve-supply.—A branch from the anterior division of the main obturator trunk gives off several twigs which enter the middle third of the deep surface of the muscle. Occasionally a small branch from the femoral (anterior crural) nerve enters the muscle. This is probably sensory in nature.

Action.—To adduct and flex the thigh, and rotate it medialward.

Relations.—The sartorius, the vastus medialis, and the femoral vessels lie antero-lateral to it. Behind it lie the adductor brevis and adductor magnus muscles. Between these and the longus run the profunda vessels. Its lateral border touches the pectineus above, but is separated from it toward the insertion.

Variations.—It may be fused with the other adductors, including the pectineus. It may be doubled. The femoral insertion may extend to the medial epicondyle.

The adductor brevis (fig. 412).—*Origin.*—From the medial part of the outer surface of the inferior ramus of the pubis directly, and by means of short tendinous processes or a short flat tendon.

Structure and insertion.—From their origin the fibre-bundles diverge into a sheet which is inserted by short tendinous bands into the distal two-thirds of the pectineal line and the upper third of the linea aspera. The muscle is more or less completely divided into two fasciculi near its insertion. The place of division is near where the intertrochanteric line curves away from the linea aspera.

Nerve-supply.—Usually from the anterior but also sometimes from the posterior branch of the main obturator trunk. The rami enter the middle third of the muscle near the proximal border.

Action.—It is chiefly an adductor and to a less extent a flexor and a lateral rotator of the thigh.

Relations.—In front lie the pectineus and adductor longus; behind, the obturator externus quadratus femoris and adductor magnus. It is crossed by the profunda artery. The first perforating artery passes usually between the two fasciculi of the insertion.

Variations.—It may be fused with other members of the group. It may be divided completely into two fasciculi, rarely into three.

The **adductor magnus** (figs. 409, 412).—The *origin* of this muscle begins on the inferior ramus of the pubis posterior to the origins of the adductor brevis and gracilis muscles. From here it extends backward along the inferior margin of the ventro-lateral surface of the ischium to the tuberosity. The muscle in passing from this curved origin to its extensive femoral insertion presents posteriorly a longitudinal groove in which rest the hamstring muscles. The adductor magnus is composed of three superimposed fasciculi, of which the first is frequently fairly distinct and is called the **adductor minimus,** while the other two are normally fused, but are occasionally distinct.

The **superior fasciculus** (**adductor minimus**) *arises* directly from the inferior rami of the pubis and ischium. From here the fibres diverge to form a thin sheet *inserted* by tendinous bands to the medial side of the gluteal ridge and the superior part of the linea aspera. The **middle fasciculus** *arises* directly from the inferior margin of the ventro-lateral surface of the inferior ramus and the tuber of the ischium, and from a tendon which descends along the dorso-medial margin of the muscle from the tuber ischii. The fibre-bundles diverge to be *inserted* between the lamellæ of a narrow flat tendon attached to the distal three-fourths of the linea aspera. This tendon is pierced by the perforating vessels. The **inferior fasciculus** *arises* dorsal to and in common with the middle fasciculus. The fibre-bundles converge toward a strong tendon which begins in the distal third of the thigh and is *inserted* into a tubercle at the distal end of the medial supracondylar ridge.

Nerve-supply.—The chief nerve-supply is from the posterior ramus of the obturator. This enters by one or more branches the proximal portion of the ventral surface of the muscle about midway between its pubic and femoral attachments. It also receives a branch from the sciatic which enters the dorsal surface of the muscle in the middle third of the thigh. To the adductor minimus a branch may be sent from the nerve to the quadratus femoris.

Action.—It is the strongest of the adductors. The superior and middle fasciculi rotate the thigh medialward and flex it; the inferior rotate it lateralward when the thigh is extended, but medialward when the thigh is flexed. The latter also extend the thigh.

Relations.—In front are the pectineus, the short and long adductor and the vastus medialis muscles, and the profunda artery. Behind lie the hamstring muscles and the gluteus maximus. Medially lies the gracilis muscle. The femoral and perforating arteries pass through its attachment to the shaft of the femur.

Variations.—The divisions of the muscle may be more or less distinct. It may be partly fused or exchange fasciculi with neighbouring muscles—the semimembranosus, quadratus femoris, adductor brevis, and adductor longus.

Bursæ

B. m. pectinei.—A small bursa frequently present between this muscle and the ilio-psoas and small trochanter. **B. anserina.**—A fairly large bursa which lies between the tendons of the sartorius, gracilis, and semitendinosus muscles and the tibial collateral ligament of the knee-joint. (See also B. M. Sartorii Propria, p. 471.)

3. The Posterior (Hamstring) Group

(Figs. 408, 413)

The muscles of this group are the semitendinosus, semimembranosus, and biceps. They flex the leg and extend and adduct the thigh. The semitendinosus and semimembranosus rotate the thigh and the leg medialward; the biceps, lateralward. The semitendinosus and the long head of the biceps constitute a superficial layer; the semimembranosus and the short head of the biceps a deep layer. The **semitendinosus** and the **long head of the biceps** arise by a common tendon from the tuber of the ischium. The somewhat fusiform semitendinosus gives rise to a tendon in the lower half of the thigh. The tendon curves forward behind the knee to be inserted under that of the sartorius into the medial side of the tibia. The penniform **short head of the biceps** arises from the linea aspera in the lower part of the thigh, and is inserted, together with the fusiform long head, into a tendon that passes over the lateral side of the knee and is attached to the head of the fibula. The **semimembranosus** arises from the tuber ischii through a long, flat, triangular tendon. The belly of the muscle increases in thickness toward the knee. It is inserted by a strong tendon on the back of the medial condyle of the tibia. From the tendons of all the hamstring muscles expansions are sent into the crural fascia.

The muscles of this group are all supplied by the tibial portion of the sciatic, except the short head of the biceps, which is supplied from the peroneal portion.

The femoral head of the biceps is characteristic of the anthropoid apes and man. In many mammals its place is taken by a slender muscle, the **tenuissimus**, which extends from the caudal vertebræ, the sacro-tuberous (great sacro-sciatic) ligament, or the gluteal fascia to the fascia of the back of the leg. In some forms this muscle is broad instead of slender. According to Testut, the long head of the biceps may be looked upon as arising by two fasciculi, one primitively attached to the posterior part of the ilium, the other to the caudal vertebræ or coccyx. The sacro-tuberous (great sacro-sciatic) ligament represents the reduced upper portion of this muscle. In the fœtus the origin of the muscle extends higher on the sacro-tuberous ligament than in the adult. In many of the lower mammals the origins of the semimembranosus and semitendinosus take place in part from the sacro-caudal vertebræ.

In the mammals below man the insertion of the biceps, gracilis, and semitendinosus takes place chiefly into the fascia of the back of the leg, and extends more distally than in man. This insertion of these flexor muscles is associated with a permanent position of flexion of the leg at the knee. In the human embryo likewise these muscles are inserted more distally than in the adult. In the lower primates the semimembranosus is chiefly a medial rotator of the leg.

Biceps femoris (Figs. 408, 413).—**Long head.**—*Origin.*—From a tendon common to it and the semitendinosus. This tendon arises from the more medial of the two facets on the back of the tuber of the ischium and from the sacro-tuberous (great sacro-sciatic) ligament. It is continued for a third of the distance to the knee as a septum between the biceps and the semitendinosus, and for a short distance as an aponeurotic sheath on the deep surface of the biceps.

Structure and insertion.—The fibre-bundles begin to arise from the tendon some distance from the ischium. They form a thick fusiform belly which is inserted into the deep surface of a tendon that begins laterally on the back of the muscle about the middle of the thigh. The insertion of the fibre-bundles of the long head continues on the medial margin of the deep surface of the tendon nearly as far as the lateral condyle of the femur.

Short head.—*Origin.*—By short tendinous fibres from the lateral lip of the linea aspera of the femur from the middle of the shaft to the bifurcation of this line, the proximal two-thirds of the supracondylar ridge, and the lateral intermuscular septum.

Structure and insertion.—The fibre-bundles take a nearly parallel course, to be inserted on the deep surface of the common tendon of insertion. The most distal fibres are inserted nearly to the skeletal attachment of the tendon. The tendon is inserted into the superior extremity of the head of the fibula, into the lateral condyle of the tibia, and into the fascia of the leg.

Nerve-supply.—Commonly two branches are given to the long head of the biceps. One of these branches is given off proximal to the ischium, and enters the proximal third of the deep surface of the muscle. The other is given off more distally and usually enters the middle third. Either or both branches may be doubled or the two may be combined for some distance in a common trunk. The nerve-fibres arise usually from the first, second, and third sacral nerves. The branch to the short head arises from the peroneal (external popliteal) portion of the sciatic nerve about the middle of the thigh. It enters the posterior surface near the lateral margin of the muscle, and passes distally across the muscle bundles about midway between the tendons of origin and insertion. The nerve-fibres come chiefly from the fifth lumbar, first and second sacral nerves.

Action.—To extend and adduct the thigh and flex the leg. The short head acts only on the leg. The long head acts as a lateral rotator of the thigh, and of the leg when flexed.

Relations.—The upper extremity of the muscle is covered by the gluteus maximus. Below this the long head and tendon of insertion lie beneath the fascia lata and overlie the short head. Ventral to the muscle lie the tendon of origin of the semimembranosus, the adductor magnus and vastus lateralis muscles, and the lateral head of the gastrocnemius. The medial border is in contact with the semitendinosus and semimembranosus. Distally it forms the upper lateral border of the popliteal space. The sciatic nerve runs between it and the adductor magnus.

Variations.—The short head is rarely absent. It may be more isolated from the long head than usual, and at times has a separate tendon of insertion. It may itself be divided into two distinct laminæ. Its origin may take place higher up on the femur than usual or from the fascia lata. Variations of this sort suggest the tenuissimus muscle of some of the lower mammals (see above). The long head of the biceps may receive accessory fasciculi from the coccyx, sacrum, sacro-tuberous (great sacro-sciatic) ligament, tuber of the ischium, or the deep surface of the gluteus maximus. These fasciculi suggest the iliac and sacro-coccygeal origin of the muscle found in lower vertebrates (see above). Inferiorly, a muscle fasciculus may take the place of the fibrous prolongations from the tendon of the biceps into the sural fascia (the **tensores fasciæ suralis**). This may extend to the tendon of Achilles. The long head may have a tendinous inscription similar to that of the semitendinosus.

The **semitendinosus** (figs. 408, 413).—*Origin.*—Partly from a medio-dorsal facet on the distal margin of the tuber of the ischium by direct implantation of the fibre-bundles, and partly from the medial surface of the tendon common to it and the long head of the biceps.

Structure and insertion.—The fibre-bundles spread out to form a flat, fusiform belly which, about the middle of the thigh, again contracts toward the tendon of insertion. This begins on the medial margin and dorsal surface of the muscle, becomes free from the muscle slightly above the medial condyle of the femur, passes behind this and curves forward to be inserted by a triangular expansion into the proximal part of the medial surface of the tibia behind and distal to the insertion of the gracilis. An aponeurotic expansion is continued into the fascia of the leg. About the middle of the muscle a narrow irregular tendinous inscription more or less completely divides the belly into proximal and distal divisions.

Nerve-supply.—To the muscle two nerves are commonly given. One arises from the sciatic nerve or directly from the plexus, proximal to the tuber of the ischium, sometimes in company with a branch to the long head of the biceps. It enters the middle third of the deep surface of the proximal portion of the muscle. The other branch arises from the sciatic nerve, usually distal to the ischial tuber, sometimes in common with a nerve to the biceps or the semimembranosus. It enters about the middle of the deep surface of the distal half of the muscle. Either or both branches may be represented by two nerves. The nerve fibres of the first branch arise chiefly from the first and second sacral nerves, those of the second from the fifth lumbar and first sacral nerves.

Action.—To extend and adduct the thigh and rotate it medialward and to flex the leg, and with knee flexed, to rotate the leg medialward.

Relations.—It is covered by the gluteus maximus and fascia lata; on the lateral side lies the biceps; and in front, the semimembranosus and adductor magnus.

Variations.—It may be completely separated from the biceps at its origin. It may be fused with neighbouring muscles. There may be two tendinous inscriptions. It may have a femoral head (a condition characteristic of many birds). A muscle fasciculus may extend from the body of the muscle to the fascia of the back of the leg.

The **semimembranosus** (fig. 408).—*Origin.*—By a long, flat tendon which lies beneath the proximal half of the semitendinosus, and which arises from the more lateral of the two facets on the back of the tuber of the ischium, between the tendons of the biceps and the quadratus femoris. The tendon is at first adherent to the tendon of the adductor magnus in front and to that of the biceps and semitendinosus behind. It descends to the middle of the muscle.

Structure and insertion.—From both surfaces of the medial side and distal extremity of the tendon of origin fibre-bundles arise which take an oblique course to their insertion on the aponeurosis of the tendon of insertion. This appears on the deep surface and medial margin of the muscle opposite the end of the tendon of origin and descends on the medial side and deep surface of the muscle. Near the back of the medial condyle of the femur the insertion of muscle-fibres ceases and the tendon is inserted directly on the back of the medial condyle of the tibia, and by aponeurotic expansions into the capsule of the joint, into the lateral condyle of the femur, into the tibial collateral ligament, and into the fascia of the popliteus muscle.

Nerve-supply.—By several branches from the sciatic nerve, which usually arise from a common trunk in company with the branches to the adductor magnus. These branches enter the deep surface of the muscle about midway between the origin and insertion of the constituent fibre-bundles.

Action.—To flex the leg and rotate it medialward and to extend and adduct the thigh and rotate it medialward.

Relations.—It is covered by the gluteus maximus, the long head of the biceps, the semitendinosus, and the fascia lata. It lies dorsal to the quadratus femoris, the adductor magnus, and the knee-joint.

Variations.—It may be fused with the semitendinosus or the adductor magnus. It may be doubled. Its tendons may have a more extensive attachment than usual. The extent of the belly of the muscle varies considerably. A muscle fasciculus may be sent into the popliteal space. An extra head may arise from the ischial spine.

Bursæ

B. m. bicipitis femoris superior.—A fair-sized bursa which frequently lies between the tendon of origin of the long head of the biceps and semitendinosus and the tendon of the semimembranosus and the ischial tuber. **B. m. bicipitis femoris inferior.**—A small bursa which separates the tendon of insertion from the fibular collateral ligament of the knee-joint. **B. m. bicipitis gastrocnemialis.**—A bursa infrequently found between the tendon of the biceps and the tendons of origin of the lateral head of the gastrocnemius and the plantaris muscles. **B. m. semimembranosus.**—This is a large double bursa constantly present. One part extends between the semimembranosus, the medial head of the gastrocnemius, and the knee-joint. With the cavity of the joint it frequently communicates. The other part extends between the tendon of the semimembranosus and the medial condyle of the tibia.

C. MUSCULATURE OF THE LEG

(Figs. 413–422)

The musculature of the leg arises in part from the distal end of the femur, but in the main from the tibia and fibula. The muscle-bellies are best developed in the proximal half of the leg, where they give rise to the 'calf' behind and to less well-marked ventral and lateral protrusions. Toward the ankle the muscle-bellies give way to tendons which attach the muscles of the leg to the skeleton of the foot.

The musculature is divisible into an anterior, a lateral and a posterior group of muscles. The anterior and lateral groups are separated from one another by an intermuscular septum. The antero-lateral groups are separated from the posterior group by the tibia and fibula, the interosseous membrane, and by an intermuscular septum which extends from the lateral margin of the shaft of the fibula to the fascia enveloping the leg. Medially the separation is well marked by the broad medial surface of the tibia. Laterally the line of division is not so clearly marked externally. In the proximal part of the leg the dorsal musculature protrudes somewhat ventrally; in the distal part the lateral musculature passes dorsal to the lower end of the fibula. The posterior group is divided by a transverse septum into superficial and deep divisions.

While in the forearm the extensor-supinator muscles extend proximally on the radial side of the arm to the humerus, and the flexor-pronator muscles on the ulnar side, in the leg both of the corresponding sets of muscles extend primitively on the fibular side of the leg to the femur. In the higher vertebrates the superficial layer of the flexor musculature of the leg takes origin from both sides of the distal extremity of the femur, and the origin of the extensor musculature ceases to extend to the femur. The crural musculature is primitively inserted into the bones of the leg, the tarsus, and the aponeuroses of the foot. On the extensor side of the leg the musculature ultimately becomes attached wholly to the foot by means of tendons differentiated, in part at least, from the dorsal aponeurosis. The lateral portion of the extensor musculature, which primitively extends from the femur to the fibula, in the higher vertebrates extends from the fibula to the tarsus and metatarsus (peroneal musculature). On the flexor side of the leg the more superficial musculature maintains a tarsal attachment through the tendon of Achilles. The deeper musculature in part extends from the femur and fibula to the tibia, in part arises from the fibula and tibia, and is inserted into the metatarsus and the digits through tendons differentiated from the plantar aponeuroses. The musculature of the sole of the foot is highly developed in five-toed vertebrates, but in those which walk on the toes, and especially in hoofed animals, it is very greatly reduced.

FASCIÆ OF THE LEG

The **tela subcutanea** of the leg contains a considerable amount of fat where it overlies the muscles, but less where it overlies the bones and joints. Subcutaneous bursæ are found over the tuberosity of the tibia (**b. subcutanea tuberositatis tibiæ**) and over each of the malleoli (**b. subcutanea malleoli medialis et lateralis**). Over the dorsum of the foot the tela contains comparatively little fat, but on the sole of the foot and plantar surface of the toes it contains much fat interposed between dense fibrous tissue. The **b. subcutanea calcanea** lies beneath the tuber calcanei.

The **crural fascia,** or external layer of fascia of the leg, extends from the knee to the ankle. It forms an enveloping cone-like sheath for the muscles and is adherent to the periosteum of the medial surface of the tibia. It is formed of transverse, oblique, and longitudinal fibres and is thickest in front.

Ventrally the fascia of the thigh, to which the tendons of the quadriceps, sartorius, gracilis, semitendinosus, and biceps muscles and the ilio-tibial band are closely united, becomes attached with these tendons to the tibia and fibula. From these attachments, therefore, the fascia of the front of the leg may be said to arise. Into it extend processes from the tendons mentioned. Dorsally the fascia of the thigh is continued uninterruptedly into that of the leg. Distally the crural fascia is attached to the two malleoli and to the posterior surface of the calcaneus.

In the proximal part of the leg in front the underlying muscles in part take origin from the fascia; in other places the fascia is separated from the underlying muscles by loose tissue.

From the fascia two main intermuscular septa arise. One, the **anterior intermuscular septum,** extends between the extensor digitorum longus and peroneal muscles to the anterior crest of the fibula; the other, the **posterior intermuscular septum,** between the peroneal muscles and the soleus to the lateral crest of the fibula. These septa separate compartments for the anterior, lateral, and posterior groups of muscles.

As the heads of the gastrocnemius pass over the back of the knee they are held in place by a special deep lamina of the fascia lata, which distally becomes fused with the crural fascia (fig. 414 A).

Fig. 414, A–F.—Transverse Sections through the Left Leg in the Regions shown in the Diagram.

d In the diagram indicates the region through which passes section D, fig. 410 (p. 465); *a′*, *b′*, *c′*, *d′*, the regions through which pass sections A, B, C, D, fig. 417 (p. 488).

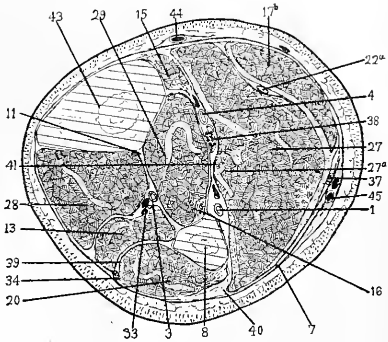
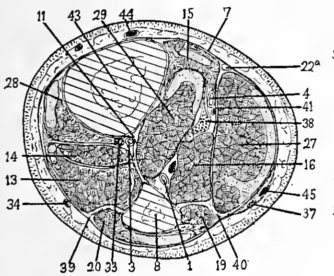
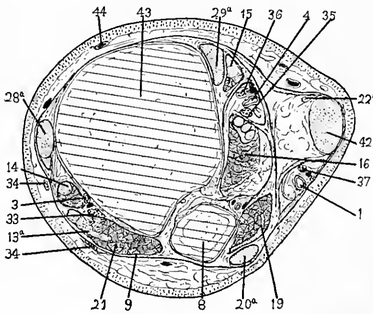
C



D



E



F

The semimembranosus has a special fascial investment which, on the back of the knee becomes bound on each side of the muscle and its tendon to the capsule of the joint. This fascia extends into a transverse septal membrane which is continued over the deep muscles of the back of the leg to the ankle. It is united on one side to the tibia, on the other to the fibula. Proximally the fibres are continued into it from the tendon of the semimembranosus. Over the back of the tibia the septum is interrupted by the attachment of the soleus to the popliteal line. Beyond the tibial origin of the soleus it is fused on the medial side of the flexor digitorum longus to the crural fascia.

In addition to the two intermuscular septa and the longitudinal transverse septum, other septa serve to separate the individual muscles of the different groups.

Above the ankle the fascia is enforced by bands of tissue so that ligaments are formed which serve to retain in position the various tendons which pass from the leg into the foot.

The **transverse crural ligament** (upper part of anterior annular ligament) (fig. 415) lies on the front of the lower part of the leg above the ankle. It is composed of fascia strengthened by transverse bundles which pass from the medial side of the tibia to the ventral margin of the fibula. From its deep surface a strong, broad septum descends to the tibia and divides the underlying space into two osteo-fibrous canals, a medial for the tibialis anterior and a lateral for the long extensor muscles. The lateral compartment is further subdivided by a slightly marked septum into a medial division for the extensor hallucis longus and a lateral for the extensor digitorum longus and the peroneus tertius.

The **cruciate ligament** (lower part of anterior annular ligament) (fig. 415) serves to hold the tendons of the anterior muscle group in place as they pass to the dorsum of the foot. In part it is formed by a dense fibrous band lying in the fascia over the ankle, in part of a ligament which passes from the bones of the ankle to the deep surface of this band. The superficial band is V-shaped. It arises from the lateral surface of the body of the calcaneus and passes across the dorsum of the foot, one arm of the V going to the medial malleolus, the other to the side of the foot, where it terminates in the fascia over the first cuneiform bone. The apex of the V lies over the tendons of the extensor digitorum longus and peroneus tertius muscles. The distal arm extends over the tendons of the extensor hallucis longus and tibialis anterior muscles. The proximal arm passes over the tendon of the extensor hallucis longus and then divides into two layers, between which the tendon of the tibialis anterior passes. The deeper ligament mentioned above arises from deep within the tarsal sinus, some of its fibres even from the sustentaculum tali. It then passes forward and medially beneath the long extensor tendons, and divides into two parts, one of which curves about the medial margin of the tendon of the extensor digitorum longus, the other about the extensor hallucis longus tendon to the under surface of the proximal arm of the V-shaped band.

The **peroneal retinacula** are strengthened regions in the fascia which serve to hold the tendons of the peroneal muscles in place. The **superior** extends from the lateral malleolus into the fascia on the back of the leg, and to the lateral surface of the calcaneus. The **inferior** overlies the tendons on the lateral surface of the calcaneus, and is attached to this bone on each side of them. Between the tendons it sends a septum to the bone. It is connected with the superficial layer of the cruciate ligament.

The **laciniate ligament** (internal annular) (fig. 416) is found on the medial side of the ankle. Here the fascia is strengthened by fibre-bands which form a well-marked ligament that holds in place the tendons of the deep dorsal cruro-pedal muscles. This ligament extends from the dorsal and distal margins of the medial malleolus to the calcaneus. It is closely bound to the tibia and the talo-tibial (tibio-astragaloid) ligament until the tendon of the tibialis posterior is reached. It passes over this and becomes bound to the bony structures on the posterior margin of the tendon. From this attachment two layers, a deep and a superficial, extend backward. The superficial layer extends to the tuber calcanei, and is connected superiorly with the crural fascia. The deep layer, which represents a continuation distally of the transverse septum, extends over the tendons of the flexor digitorum longus and flexor hallucis longus to the medial surface of the calcaneus, and is closely united to the underlying bone on each side of these tendons, thus giving rise to osteo-fibrous canals.

MUSCLES

1. Muscles of thf Front of the Leg

(Figs. 415, 418)

The anterior musculature of the leg consists of four muscles, the tibialis anterior, extensor digitorum longus, peroneus tertius, and extensor hallucis longus. The **tibialis anterior** has a quadrangular prismatic belly which arises from the lateral side of the tibia and adjacent interosseous membrane in the proximal half of the leg. The tendon passes over the front of the tibia to the first metatarsal. The **extensor digitorum longus** is a transversely flattened, fusiform muscle, which arises from the superior extremity of the tibia, the anterior crest of the fibula, and the adjacent interosseous membrane, and gives rise to a tendon which passes over the front of the distal extremity of the tibia and sends tendons to the two terminal phalanges of the four more lateral toes. The **peroneus tertius** represents a more or less completely differentiated portion of the preceding muscle. Its tendon passes laterally through the same osteo-fibrous canal in the same synovial sheath and terminates on the fifth metatarsal. The **extensor hallucis longus** is a narrow muscle which arises from the distal half of the medial surface of the fibula and the interosseous membrane. Its tendon extends over the ankle to the great toe. The tendons of these muscles are held in place by the transverse and cruciate ligaments described above.

All the muscles of this group flex the foot. The extensors extend the toes; the peroneus tertius and the extensor digitorum longus evert the foot. The nerve supply is from the deep peroneal (anterior tibial) nerve.

The tibialis anterior is represented in the arm probably by the brachio-radialis and the two radial extensors; the extensor digitorum longus by the extensor digitorum communis and extensor digiti quinti proprius; and the extensor hallucis longus by the extensor pollicis longus. Two abnormal muscles not infrequently found, the abductor hallucis longus and extensor primi internodii hallucis, represent probably the corresponding normal muscles of the hand.

The tibialis anterior (fig. 415).—*Origin.*—From the distal surface of the lateral condyle of the tibia, and the lateral surface of the proximal half of the shaft of the tibia, the adjacent interosseous membrane, the overlying fascia near the condyle (tuberosity) of the tibia, and the intermuscular septum between it and the extensor digitorum longus.

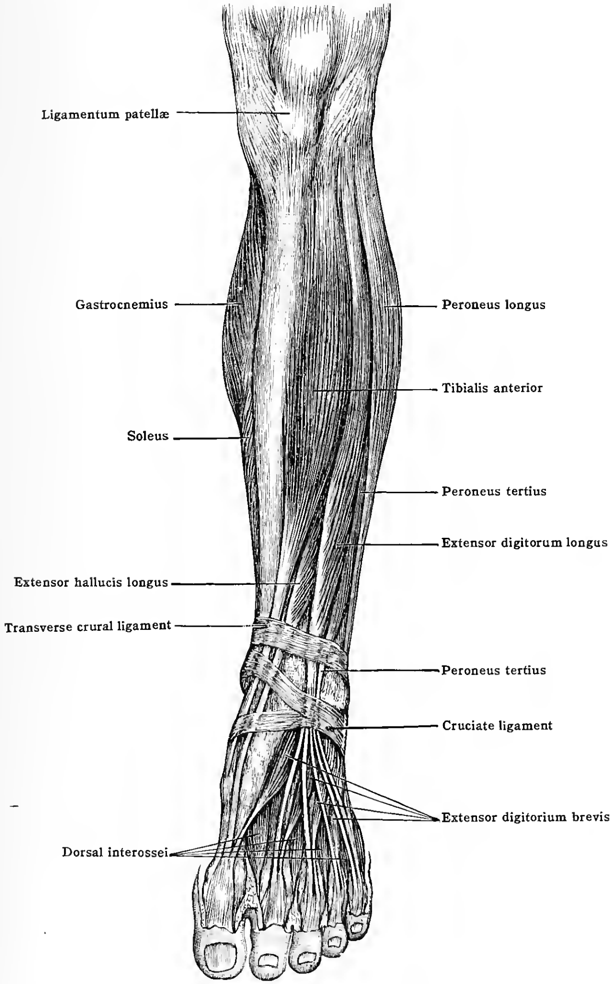
Structure.—Bipenniform. The fibre-bundles converge upon a flat tendon which begins high in the muscle and emerges on the anterior margin of the muscle about the middle of the leg. On the deep surface the implantation of fibre-bundles continues to the transverse crural (anterior annular) ligament.

Insertion.—The tendon passes over the front of the tibia to the medial side of the foot, where it is inserted into the medial surface of the first cuneiform and the base of the first metatarsal.

Nerve-supply.—As a rule, a branch from the common peroneal (external popliteal) nerve enters the proximal portion of the muscle by several twigs, and another from the deep peroneal (anterior tibial) enters near the middle of the belly on the lateral edge.

Relations.—In the proximal half of the leg the extensor digitorum longus lies lateral to it; and between the two muscles, the anterior tibial artery and vein. It is covered by the crural fascia and rests on the interosseous membrane. Distally it lies over the extensor hallucis longus. The tendon passes in special compartments beneath the transverse and the cruciate (anterior annular) ligaments.

FIG. 415.—THE MUSCLES OF THE FRONT OF THE LEG.



The extensor digitorum longus (fig. 415).—*Origin.*—From the lateral condyle of the tibia, the anterior crest (surface) of the fibula, the intermuscular membrane between it and the tibialis anterior, the lateral margin of the interosseous membrane, the septum between it and the peroneus longus, and the fascia of the leg near the tibial origin.

Structure.—Penniform. The fibre-bundles converge upon the posterior surface of a tendon which begins at the middle of the leg. The implantation of fibres continues nearly to the ankle. Usually at the distal margin of the transverse (anterior annular) ligament the tendon divides into two parts which pass between the two layers of the cruciate (lower part of anterior annular) ligament, and then each divides again into two parts, thus giving rise to four slips, one for each of the four lateral toes.

Insertion.—Each tendon on the dorsal surface of the toe to which it goes divides into three fasciculi: an intermediate, which is attached to the dorsum of the base of the second phalanx; and two lateral, which converge to the dorsum of the base of the third phalanx. The margins of the tendon are also bound by fibrous tissue to the sides of the back of the first phalanx.

Nerve-supply.—Most frequently two branches of the deep peroneal (anterior tibial) enter the deep surface of the muscle, one near its tibial origin, one about the centre of the belly.

Relations.—In the proximal half of the leg it lies on the interosseous membrane, and beneath the fascia of the leg, and adjoins medially the tibialis anterior, laterally the peroneus longus. Distally it lies over the extensor hallucis longus and adjoins laterally the peroneus brevis. The tendon passes beneath the transverse crural and the superficial layer of the cruciate (anterior annular) ligaments and over the extensor digitorum brevis muscle. The superficial peroneal (musculo-cutaneous) nerve runs in the septum between it and the peroneal muscles; the anterior tibial artery and deep peroneal nerve pass beneath the head of the muscle, and then between it and the tibialis anterior.

The peroneus tertius (fig. 415).—*Origin*.—From the distal third of the medial surface of the fibula, the neighbouring interosseous membrane, and the anterior intermuscular septum.

Structure.—It is essentially a fasciculus of the extensor digitorum longus, from which it is seldom completely differentiated. The fibre-bundles descend obliquely forward to be inserted in a penniform manner on a tendon which runs along the lateral margin of the tendons of the extensor digitorum. The attachment of fibre-bundles continues to the cruciate ligament (lower part of anterior annular ligament).

Insertion.—On the base of the fifth metatarsal and often also on the base of the fourth.

Nerve-supply.—The more distal nerve to the extensor digitorum continues into this muscle.

Relations.—It lies lateral to the extensor digitorum longus. Its tendon passes into the foot beneath the transverse crural and the superficial layer of the cruciate ligament in the same compartments with those of the extensor longus.

The extensor hallucis longus (fig. 415).—*Origin*.—From the middle two-fourths of the medial surface of the fibula near the interosseous crest, and from the distal half of the interosseous membrane.

Structure.—Penniform. The fibre-bundles are attached as far as the cruciate ligament to the back and sides of a tendon which begins on the antero-medial margin of the distal third of the muscle.

Insertion.—On the base of the second phalanx of the big toe. On the back of the first phalanx the margins of the tendon are attached to the bone by bands of fibres.

Nerve-supply.—As a rule, a branch from the deep peroneal (anterior tibial) nerve enters the deep surface of the muscle near the junction of the upper and middle thirds, and passes distally across the middle of the obliquely running muscle fibre-bundles.

Relations.—It lies on the distal half of the interosseous membrane, partly covered by the extensor digitorum longus and the tibialis anterior muscles. Its tendon passes over the front of the distal extremity of the tibia and the medial side of the dorsum of the foot and is held in place by the transverse and cruciate ligaments and by a strengthening band in the fascia over the base of the first metatarsal. In the distal part of the leg the anterior tibial artery and the deep peroneal (anterior tibial) nerve pass beneath the muscle to enter the foot on the lateral side of its tendon.

Actions.—The muscles of this group all flex the ankle. The tibialis anterior and extensor hallucis longus evert the foot at the talo-calcaneo-navicular joints, and invert it at the talo-navicular, calcaneo-cuboid joints. In certain positions the tibialis anterior may, however, invert the foot at these joints. The peroneus tertius and the long extensor evert the foot. The force of the extensor hallucis longus is exerted powerfully on the first phalanx and weakly on the second. The short muscles of the big toe aid in extending the second phalanx. The extensor digitorum longus extends the first phalanx of each toe powerfully, but exerts less force on the second and third. The lumbrical muscles assist in extending the last two phalanges.

Variations.—The origin of the tibialis anterior may extend to the femur. Its tendon of insertion may give accessory slips to the cuneiforms, metatarsals, and phalanges. More rarely its belly is divided into two portions, one of which sends a tendon to the first cuneiform and one to the first metatarsal. A slip, the **tensor fasciæ dorsalis pedis** (Wood), may pass to the dorsal fascia of the foot. Another, the **tibio-astragalus anticus** (Gruber), to the talus (astragalus) or calcaneus. The bellies or the tendons of the extensor hallucis and extensor digitorum may be more or less completely fused, or tendon slips may pass from the tendon of one muscle to that of the other. Tendon slips may pass to the metatarsal bones or from the tendon of one toe to that of a neighbouring toe. The tendon to each toe may be doubled. The belly of the extensor digitorum longus may be more or less completely subdivided to correspond with the tendons to individual toes. The peroneus tertius is frequently fused with the long extensor. It may be doubled. More often its tendon may bifurcate or trifurcate and be inserted into the extensor tendons of the fifth toe or into the fourth or third metatarsal. It is absent in about 8.5 per cent. of bodies (Le Double).

Abnormal Muscles.—The **abductor hallucis longus** is rarely found as a completely independent muscle. It usually arises as a fasciculus of the extensor digitorum longus, extensor hallucis longus, or the tibialis anterior. It is inserted into the base of the first metatarsal. The **extensor primi internodii hallucis** (extensor hallucis brevis) has an origin similar to that of the long abductor above described. It is inserted into the dorsum of the base of the first phalanx of the big toe. It is not to be confounded with that portion of the extensor digitorum brevis connected with the great toe and also sometimes called the extensor hallucis brevis.

Bursæ

B. subtendinea m. tibialis anterioris.—A small bursa between the medial surface of the first cuneiform bone and the tendon of the tibialis anterior. **B. subtendinea m. extensoris hallucis longi.**—A small bursa beneath the tendon near the tarso-metatarsal articulation. It may communicate with the synovial sheath of the tendon. **B. sinus tarsi.**—A large bursa in the sinus tarsi and on the lateral surface of the neck of the talus (astragalus) beneath the tendons of the extensor digitorum longus and the fibrous bands between the talo-calcaneal and the cruciate ligaments. It extends back to the talo-crural, forward to the talo-navicular joint, and may communicate with the joint cavity of the latter.

Synovial Tendon-sheaths

Vagina tendinis m. tibialis anterioris.—This sheath surrounds the tendon from above the transverse crural ligament to the talo-navicular joint. **Vagina tendinis m. extensoris hallucis longi.**—The sheath begins above the proximal arm of the cruciate ligament, and ends near the tarso-metatarsal joint beneath a band-like thickening of the dorsal fascia of the foot. **Vagina tendinum m. extensoris digitorum longi.**—This sheath surrounds the tendons of the long digital extensor and the peroneus tertius from above the cruciate ligament to the middle of the third cuneiform bone.

2. Lateral Musculature of the Leg

(Figs. 416, 422)

The lateral muscles consist of the peroneus longus and the peroneus brevis. They extend and evert the foot. The thick prismatic belly of the **peroneus longus** arises from the proximal half of the lateral surface of the fibula and from neighbouring structures, while the smaller belly of the **peroneus brevis** arises from the middle third of the lateral surface of this bone. The peroneus longus partly covers the peroneus brevis. The tendons of the two muscles pass behind the lateral malleolus, held in place by special retinacula (p. 480). There the tendon of the peroneus longus lies at first lateral to and then crosses behind that of the peroneus brevis and curves about the lateral side of the calcaneus and across the sole of the foot closely applied to the cuboid and to the tarso-metatarsal articulations, and terminates on the base of the first metatarsal. The tendon of the peroneus brevis terminates on the lateral side of the foot at the base of the fifth metatarsal. The nerve supply is from the superficial peroneal (musculo-cutaneous) nerve.

The two muscles are probably represented in the arm by the extensor carpi ulnaris. In some of the lower animals the head of the peroneus longus extends to the femur. The fibular collateral ligament of the knee-joint probably represents in man the femoral head of the peroneus longus.

The peroneus longus (figs. 416, 422).—*Origin.*—Anterior head: tendinous from the anterior tibio-fibular ligament, the neighbouring part of the lateral condyle of the tibia, and the head of the fibula; fleshy from the proximal third of the anterior intermuscular septum and the crural fascia near the tibia. Posterior head: fleshy from the proximal half of the lateral surface of the shaft of the fibula and from the posterior intermuscular septum.

Structure.—Bipenniform. The fibre-bundles converge upon a tendon which begins high in the muscle. The constituent fibre-bundles of the anterior head are long and take a nearly vertical course. The fibre-bundles of the posterior head take a more oblique course and their attachment extends more distally on the tendon. The tendon emerges on the surface of the muscle in the distal half of the leg. The fibre-bundles of the posterior head extend to within a few centimetres of the lateral malleolus. The tendon passes through the retro-malleolar groove, passes across the lateral face of the calcaneus, to and through the peroneal groove of the cuboid, and crosses the second and third tarso-metatarsal joints. Where the tendon enters the groove in the cuboid it contains a fibro-cartilaginous nodule which may become a sesamoid bone.

Insertion.—On the inferior surface of the first cuneiform and on the supero-lateral border and base of the first metatarsal. From the region of the fibro-cartilaginous nodule above mentioned a fibrous slip is usually sent to the base of the fifth metatarsal.

Nerve-supply.—Most commonly the peroneal (external popliteal) nerve before dividing gives off two branches. One of these enters the deep surface of the middle third of the anterior head, the other passes across the middle third of the constituent bundles of the posterior head. The latter branch may arise from the superficial peroneal (musculo-cutaneous) nerve, and it may extend to supply the peroneus brevis.

The peroneus brevis (fig. 416).—*Origin.*—From the middle third of the lateral surface of the fibula; (2) from the septa which separate it from the anterior and posterior groups of muscles.

Structure.—Penniform. The fibre-bundles converge upon a tendon which begins high in the muscle and becomes visible on the lateral surface of the distal half of the belly. Behind the lateral malleolus the tendon becomes free, then passes forward below the malleolus and across the calcaneus and cuboid.

Insertion.—Into the tip of the tuberosity of the fifth metatarsal.

Nerve-supply.—The nerve arises from the superficial peroneal (musculo-cutaneous) nerve, or from a branch to the peroneus longus. It enters the proximal margin of the muscle and passes distally across its constituent fibre-bundles.

Relations.—The peroneal muscles in the leg are contained in a compartment bounded by the anterior and posterior intermuscular septa, by the fibula, and by the fascia of the leg. The peroneus longus to a considerable degree overlies the peroneus brevis. Beneath the upper part of the peroneus longus the peroneal (external popliteal) nerve bifurcates into its two chief branches. The deep peroneal (anterior tibial) nerve passes medially beneath the anterior head of the muscle. The superficial peroneal (musculo-cutaneous) nerve extends in the interval between the areas of the attachment of the two heads of the peroneus longus, and along the anterior margin of the peroneus brevis to the anterior intermuscular septum, through which it passes to its superficial distribution. The tendon of the peroneus longus at first lies lateral to and slightly overlaps that of the peroneus brevis. Toward the tip of the malleolus it lies almost directly posterior to this tendon. On the lateral surface of the calcaneus the tendon of the brevis lies superior to that of the longus, from which it is separated by a bony spine, the processus trochlearis of the calcaneus. The tendon of the longus is separated from the deep surface of the abductor of the little toe, and is held in place in the groove in the cuboid by the long plantar ligament.

Action.—The peroneus brevis everts the foot. The peroneus longus extends, abducts, and everts the foot, and supports the arch of the foot. The peroneus brevis also extends the foot when this is greatly flexed.

Variations.—The two peroneal muscles may be more or less fused. The origin of the peroneus longus may extend to the femur. The two heads of origin may be fused. Its tendon of insertion may send slips to the second, third, and rarely to the fourth and fifth metatarsals. The tendon may be united to that of the tibialis posterior (12 out of 45 bodies—Picou). Sesamoid cartilages or bones are occasionally found in the retro-malleolar and calcaneal portions of the tendon. The tendon of the peroneus brevis may send a slip to the second or third phalanx or to the head of the metatarsal of the fifth toe, to its extensor tendon, or to the cuboid. It may also send a fasciculus to the fourth metatarsal or the extensor tendon of the fourth toe.

Accessory peroneals.—Poirier considers these all varieties of a muscle which in its simplest form arises from the distal fourth of the fibula and is inserted by a tendon into the fifth toe. A corresponding muscle is normally found in many of the monkeys (**peroneus digiti quinti**). In man in one form or another it is a frequent anomaly. It may be so fused with the peroneus brevis that only its tendon of insertion is apparent. It may appear as a special muscle fasciculus of the peroneus longus or brevis. It may be merely a tendinous band, or it may be tendinous at origin and insertion, with an intermediate belly. Instead of being attached to the fifth toe, it may be inserted into the fifth metatarsal, the cuboid, the tendon of the peroneus longus, the calcaneus, lateral malleolus, or posterior talo-fibular ligament.

Synovial Tendon-sheaths

Vagina tendinum peroneorum communis.—There is a double sheath for the tendons of the peroneal muscles as they pass back of the lateral malleolus. From this region of union the sheath sends processes along each tendon proximally above the malleolus and distally over the lateral surface of the calcaneus. This process on the tendon of the peroneus longus often communicates with the following sheath. **Vagina tendinis m. peronæi longi plantaris.**—This sheath begins in the peroneal groove of the cuboid and ends near the medial border of the long plantar ligament.

3. Musculature of the Back of the Leg

a. Superficial Group (fig. 413)

To this group belong the gastrocnemius, soleus, and plantaris muscles. They extend the foot and flex the leg. The two ovoid heads of the **gastrocnemius** arise one on each side from above the condyles of the femur, extend about to the middle of the back of the leg, and are inserted into the posterior surface of the tendon of Achilles, and through this into the back of the calcaneus. The broad, flat, ovoid **soleus** arises beneath the gastrocnemius from the tibia and fibula, and is inserted into the deep surface of the tendon of Achilles as far as the ankle. The two heads of the gastrocnemius and the soleus constitute the **triceps suræ.** The **plantaris** is a slender muscle which passes along the medial margin of the lateral head of the gastrocnemius and beneath the medial head, where it gives rise to a slender tendon that runs between the gastrocnemius and soleus and along the medial margin of the tendon of Achilles to the fatty fibrous tissue of the heel. The nerve-supply is from the tibial nerve.

The muscles of this group have a common embryonic origin, and are first differentiated on the fibular side of the leg, whence they extend over the posterior tibial vessels and nerve to their medial attachments. The gastrocnemius corresponds with the flexor carpi radialis and ulnaris, the plantaris with the palmaris longus, the soleus with a portion of the flexor digitorum sublimis of the forearm. In many of the monkeys and in the prosimians the plantaris is much more developed than in man.

The gastrocnemius (fig. 413).—**Medial head.**—*Origin.*—From a facet on the back of the medial condyle of the femur above the articular surface, from an area on the back of the femur superior and lateral to this, and from the femoral margin of the capsule of the knee-joint. **Lateral head.**—*Origin.*—From a facet on the proximal portion of the postero-lateral surface of the lateral condyle of the femur and from a rough area situated more medially and at a greater distance from the joint.

Structure and insertion.—The heads of the gastrocnemius are similar in structure. From the condylar facets there descend aponeurotic bands, one on the medial margin and the medial side of the posterior surface of the medial head, the other on the lateral margin and the lateral side of the posterior surface of the lateral head. These bands descend about two-thirds of the way down the muscle. In the tendon of the lateral head a sesamoid bone is frequently found. The fibre-bundles of the muscle pass obliquely from the supracondylar areas of origin and from the deep surface of the aponeurosis on each side to the tendon of insertion. This tendon begins as a septum between the two heads, and as a lamina on the deep surface of each head. The septum and laminæ soon fuse with the broad aponeurosis which covers the dorsal surface of the soleus. The attachment of fibre-bundles continues to about the middle of the back of the leg. The attachment of the medial head extends more distally than that of the lateral head. As a rule, the medial head is also the broader and thicker of the two.

The soleus.—*Origin.*—(1) By a fibular head from the back of the head and the proximal third of the posterior surface of the shaft of the fibula, and from the intermuscular septum between it and the peroneus longus; and (2) by a tibial head from the transverse septum over the distal margin of the popliteus, from the popliteal line, and from the middle third of the medial border of the tibia.

Structure and insertion.—From the fibular and tibial origins arise broad aponeuroses which unite proximally on the deep surface of the muscle so as to form a fibrous arch over the posterior tibial vessels and nerves. Distally they diverge and become more narrow, but the fibular aponeurosis is continued on the fibular side and the tibial aponeurosis on the tibial side of the muscle as far as the distal quarter of the leg. The main portion of the belly of the muscle is formed by fibre-bundles which arise from the posterior surface of these aponeuroses and pass obliquely to be inserted in a bipenniform manner on the deep surface of the tendon of Achilles. This tendon begins as a broad aponeurosis which covers the greater part of the posterior surface of the muscle, and gradually converges into a heavy fibrous band that is inserted into the calcaneus. The bundles of fibres of the tendon take a slightly spiral course. Those on the posterior surface run from the medial margin toward the lateral surface of the calcaneus; those on the anterior surface in a reverse direction. The attachment of the fibre-bundles continues to within a short distance of the heel. A few of the fibre-bundles arise directly from the fibula and the posterior intermuscular septum. On the deep surface of the belly of the muscle there is an **accessory fasciculus** which is formed by fibre-bundles that spring on each side from the anterior surface of the aponeuroses of origin of the muscle and have a bipenniform insertion on each side of a thin, oblique tendinous lamina which inferiorly becomes united to the deep surface of the tendon of Achilles.

The plantaris (fig. 413).—This muscle *arises* from the distal part of the lateral line of bifurcation of the linea aspera, in close association with the lateral head of the gastrocnemius. The fibre-bundles give rise to a flat, short, fusiform belly, and are united to a narrow tendon which extends along the medial edge of the tendon of Achilles to the lateral part of the dorsal surface of the calcaneus, where it *terminates* in the neighbouring fibrous tissue.

Nerve-supply.—From the tibial (internal popliteal) part of the sciatic nerve in the popliteal space nerves arise for each head of the gastrocnemius. Each nerve enters the middle third of the deep surface of the head near the proximal margin. The nerve-supply for the soleus is from two sources. One nerve arises in the popliteal space, often in company with the nerve to the lateral head of the gastrocnemius. It enters the posterior surface of the muscle near the proximal border and divides into two branches, one for each head of the muscle. The tibial (posterior tibial) nerve gives rise to a branch which, about half-way down the leg, enters the deep surface of the muscle and furnishes branches for the deep portion of the muscle on each side. The nerve-supply of the plantaris is by a branch from the tibial (internal popliteal) portion of the sciatic. This arises in the popliteal space and enters the deep surface of the muscle.

Relations.—The semimembranosus winds about the medial margin of the medial head of the gastrocnemius to its deep surface. The biceps passes to the lateral side of the lateral head of the gastrocnemius, and the plantaris along its medial margin. The semimembranosus and biceps above, the medial head of the gastrocnemius and the plantaris below, bound the popliteal space. The peroneal (external popliteal) nerve passes from the popliteal space obliquely across the plantaris and the lateral head of the gastrocnemius. The medial sural (short saphenous) nerve and the small saphenous vein pass between the heads of the gastrocnemius to the surface and thence to the lateral side of the ankle. From the peroneal (external popliteal) nerve in the popliteal space the lateral sural (communicans peronei) nerve extends distally over the calf. The (posterior) tibial nerve and posterior tibial artery and vein run between the two heads of the gastrocnemius, and then beneath the soleus to the medial side of the ankle. In the region of the tendon of Achilles a considerable space filled with fatty tissue intervenes between the tendon and the transverse septum.

Action.—The contraction of the triceps suræ produces extension, adduction, and inversion of the foot. The gastrocnemius is also a flexor of the leg. The plantaris has no known function in man. In some animals it is an extensor of the plantar fascia.

Variations.—There is considerable variation in the extent of the separation of the different parts of the triceps suræ. The tendons of the three heads may be separate nearly to the heel. Either or both heads of the gastrocnemius or the soleus may be doubled. A slip from the biceps or semimembranosus, from the linea aspera, or popliteal space may join the triceps and give rise to a quadriceps suræ. On the other hand, one of the heads of the gastrocnemius or the tibial head of the soleus may be missing. A supernumerary fasciculus may extend from the deep surface of the soleus to the calcaneus. The plantaris is exceedingly variable in origin, structure, and insertion. The origin may be from the capsule of the knee-joint, the fascia of the leg, or from the tibia. Its tendon may terminate at almost any part of its course in neighbouring structures. It may be represented by a fibrous band. It is absent in about 7 per cent. of instances (Le Double).

Bursæ

B. m. gastrocnemii lateralis.—A bursa is often found between the tendon of the lateral head of the gastrocnemius and the capsule of the joint. It may communicate with the joint cavity. **B. m. gastrocnemii medialis.**—A bursa usually lies between the tendon of origin of the medial head of the gastrocnemius, the condyle of the humerus, and the capsule of the joint. Another bursa (b. m. semimembranosi) extends between the semimembranosus and the medial head of the gastrocnemius muscle. The two bursæ frequently communicate with one another and with the joint. **B. tendinis calcanei.**—This lies between the tendon of Achilles and the upper part of the back of the calcaneus. Between the back of the tendon and the crural fascia another bursa is frequently present.

b. Deep Group

The deep posterior musculature is separated from the superficial by the transverse septum described above (p. 479). The muscles covered by this septal fascia are the **popliteus,** the **flexor digitorum longus,** the **flexor hallucis longus,** and the **tibialis posterior.** An intermuscular septum between the popliteus and the tibialis posterior, and the attachment of the soleus to the popliteal line on the back of the tibia serve to separate the popliteus from the other deep posterior muscles which lie distal to this region and send tendons into the sole of the foot. The deep posterior musculature may thus be considered as divided into a proximal femoro-tibial and a distal cruro-pedal group. Both sets of muscles are supplied by branches of the tibial nerve.

Femoro-tibial Muscle

The popliteus (fig. 416).—A triangular muscle which *arises* from an ovoid facet at the inferior extremity of the groove on the outer side of the lateral condyle of the femur and is *inserted* into the proximal lip of the popliteal line of the tibia and the surface of the shaft of the tibia proximal to this. It rotates the leg medialward and flexes it.

Structure.—From the origin a broad tendon glides over the condyle within the capsule of the joint, then over the lateral fibro-cartilage and through a groove on the back of the tibio-fibular articulation. From both surfaces of this tendon, fibre-bundles diverge toward the area of insertion. The tendon is more or less intimately united to several structures with which it comes in contact about the joint. Rarely it contains a sesamoid bone. The fibres of insertion terminate in part in the fascia covering the muscle. The popliteus is homologous with the pronator teres of the arm, or, according to some investigators, with the deep portion of that muscle.

Nerve-supply.—A nerve which arises either independently or in conjunction with that to the posterior tibial muscle enters the popliteus near the middle of its distal edge. Sometimes a branch from the chief nerve to the knee-joint enters the proximal edge of the muscle.

Action.—To flex and rotate the leg medially.

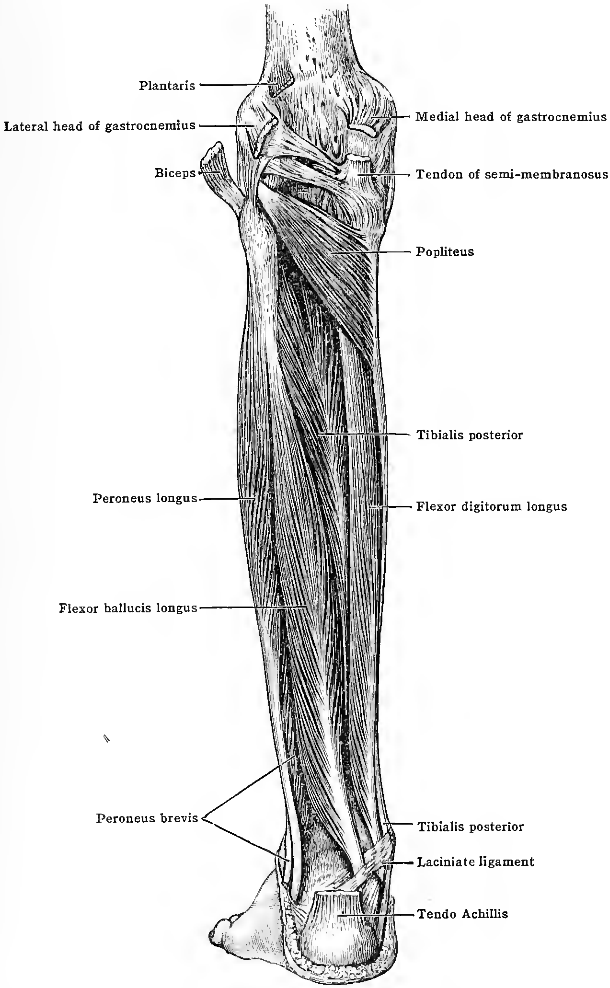
Relations.—The popliteus lies within a compartment bounded by the transverse septum, the capsules of the knee and superior tibio-fibular joints, the back of the tibia, and a septum extending to the popliteal line (see above). On the transverse septum run the popliteal vessels and the tibial nerve. The proximal margin of the soleus overlaps the distal margin of the popliteus. The synovial membrane of the knee-joint sends a prolongation between its tendon and the back of the lateral condyle of the tibia.

Variations.—It is rarely absent. An accessory head may arise from the medial side of the lateral condyle or from some neighbouring structure. The **fibulo-tibialis** (peroneo-tibialis) is a small muscle found by Gruber in one body in seven. It arises from the medial side of the head of the fibula and is inserted into the posterior surface of the tibia beneath the popliteus.

Cruro-pedal Muscles (figs. 416, 420)

Of the three muscles of this group, the **flexor digitorum longus** lies on the tibial side of the leg, the **flexor hallucis longus** on the fibular side, and the **tibialis posterior** upon the interosseous membrane, partly covered by the other two muscles, beneath the former of which it crosses, distally, to the tibial side of the leg. Septa separate the flexor muscles from the tibialis. The tendons of the three muscles pass behind the medial malleolus, held in place by the transverse septum and the deep layer of the laciniate (internal annular) ligament. They lie

FIG. 416.—THE DEEP MUSCLES OF THE BACK OF THE LEG.



in compartments divided by septa which descend to the tibia. The compartment for the tibialis posterior is the most medial. It is partly overlapped by that for the flexor digitorum. At the ankle the tendon of the tibialis passes above, the tendon of the flexor digitorum medial to, and that of the flexor hallucis below, the sustentaculum tali, each in a separate osteo-fibrous canal bounded

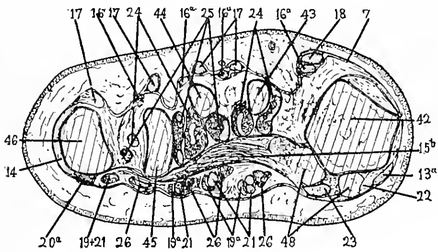
C



D

externally by the laciniate (internal annular) ligament. In the sole the tendon of the long flexor of the big toe passes under (deeper than) the tendon of the flexor digitorum, to which it gives a slip, and is inserted into the terminal phalanx of the big toe. The tendon of the long flexor of the toes passes obliquely across the sole, is joined by the quadratus plantæ (flexor accessorius), and gives rise to a tendon for the terminal phalanx of each of the four lateral toes. From these tendons the lumbrical muscles arise. The tibialis posterior has an extensive insertion on the plantar surface of the tarsus.

The long flexors act chiefly on the toes. Together with the tibialis posterior they invert and extend the foot.

The long flexors of the toes probably represent the flexor profundus and the flexor pollicis longus of the forearm. The tendons of the deep flexors of the forearm do not, however, cross like those of the long flexors of the toes. In the lower mammals there is much variation in the toes to which the tibial and fibular flexors are distributed. The tibialis posterior has no certain representative in the forearm. The rare ulno-carpeus may represent it.

The flexor digitorum longus (figs. 416, 420).—*Origin.*—From the popliteal line, the medial side of the second quarter of the dorsal surface of the tibia, the fibrous septum between the muscle and the tibialis posterior, and the fascia covering its proximal extremity.

Structure and insertion.—From these areas of origin the fibre-bundles run obliquely to be inserted in a penniform manner on a tendon which begins in the proximal quarter of the muscle as a narrow septum, and more distally becomes a strong band on the medial margin. The insertion of the fibre-bundles continues nearly to the medial malleolus. From here the tendon passes behind the medial malleolus, dorso-lateral to the tendon of the tibialis posterior, crosses the posterior talo-tibial ligament, and passes along the medial margin of the sustentaculum tali into the sole of the foot. Here it crosses the tendon of the flexor hallucis longus, from which it receives a tendinous slip, and divides into four parts, which pass to the second to the fifth toes. Each tendon is bound to the phalanges of the toe to which it passes by a fibrous sheath. Superficial to it in the sheath lies a tendon of the flexor digitorum brevis, which the flexor longus tendon perforates as it passes to the base of the terminal phalanx. The tendon is connected, like those of the fingers, by vincula tendinum, to the phalanges of the toes.

Nerve-supply.—From the tibial (posterior tibial) nerve a branch arises, often in company with nerves to some other or others of the muscles of this group. The nerve divides into two branches, one of which passes to the lateral side of the muscle, where it extends along near the middle of the fibre-bundles of that side, while the other branch passes along near the middle of the fibre-bundles of the medial side of the muscle.

Relations.—In the proximal half of the leg it lies on the tibia, in the distal half on the posterior tibial muscle. Between it and the flexor hallucis lie the posterior tibial vessels and nerve. Near the ankle the plantar vessels and nerves cross the tendon of the muscle, separated from it by the deep layer of the laciniate (internal annular) ligament. In the upper two-thirds of its extent it is covered by the triceps suræ. In the lower third of the leg it emerges medial to the soleus and the tendon of Achilles. The relations of its tendon at the ankle have been described above. The tendon lies beneath the origin of the abductor hallucis muscle and in the sole is covered by the flexor digitorum brevis, crosses the tendon of the long flexor and the oblique adductor of the big toe and the interosseous muscles, is joined by the quadratus plantæ (flexor accessorius), and gives origin to the lumbrical muscles.

The flexor hallucis longus (figs. 416, 420).—*Origin.*—From the distal two-thirds of the posterior surface of the fibula, the septa between it and the tibialis posterior and peroneal muscles, and the fascia above its proximal extremity.

Structure and insertion.—The fibre-bundles converge upon a tendon which begins in the second quarter of the muscle, within its substance, and emerges upon the postero-medial margin in its distal half. The insertion of the fibre-bundles continues to the end of the tibia. From here the tendon passes over the dorsal talo-tibial (tibio-astragaloid) ligament, and through the groove on the posterior surface of the talus and the under surface of the sustentaculum tali, where it lies on the fibular side of the tendon of the flexor digitorum longus. It then crosses the deep surface of this tendon, to which it gives a slip, passes over the plantar surface of the medial head of the flexor hallucis brevis, and between the sesamoid bones of this muscle into the osteo-fibrous canal on the plantar surface of the big toe. It is inserted into the base of the terminal phalanx of the big toe.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) nerve, often in company with the nerve to the flexor digitorum longus or the other muscles of the group. It runs along the deep surface of the muscle and sends twigs into the middle third of its constituent fibre-bundles. Sometimes two nerves are furnished to the muscle.

Relations.—It lies on the fibular side of the distal two-thirds of the leg. Proximally it diverges from the preceding muscle so as to disclose the tibialis posterior, which is more deeply situated. Between it and the tibialis posterior lie the peroneal vessels. Distally its tibial margin approaches the flexor digitorum longus, but between them lie the posterior tibial vessels and nerve. Lateral to it lie the peroneal muscles. It is covered in the leg by the soleus. In the distal part of the leg its tendon lies medial to the tendon of Achilles. On entering the foot the tendon crosses beneath the abductor hallucis muscle and the lateral plantar vessels and nerve. The other relations of the tendon have been described above.

The tibialis posterior (figs. 416, 422).—*Origin.*—From—(1) the lateral half of the distal margin of the popliteal line and the middle third of the posterior surface of the tibia; (2) the medial side of the head and of that part of the body of the fibula next the interosseous membrane in the proximal two-thirds; (3) from the whole of the proximal and the lateral portion of the distal part of the posterior surface of the interosseous membrane; and (4) from the septa between its proximal portion and the long flexor muscles.

Structure.—From this extensive area of origin the fibre-bundles converge upon a tendon which is at first deep seated within the muscle-belly, but about the middle of the leg emerges on the medial margin of the muscle. The fibular portion of the muscle is much more extensive than the tibial. The proximal fibres take a nearly perpendicular, the most distal (from the fibula) a nearly transverse, course. The insertion of fibres stops a little proximal to the medial malleolus. The tendon then extends to the medial side of the tendon of the long flexor of the toes, passes through the groove on the back of the malleolus, across the medial talo-tibial (tibio-astragaloid) ligament, and above the sustentaculum tali to the sole.

Insertion.—The tendon divides into two chief divisions, a deep and a superficial. (1) The deep portion becomes attached chiefly to the tubercle of the navicular bone, and usually in part also to the first cuneiform. (2) The superficial spreads out to be attached chiefly to the third cuneiform and the base of the fourth metatarsal, but also in part to the second cuneiform, to the capsule of the naviculo-cuneiform joint, to the sulcus of the cuboid, and usually also to the origin of the short flexor of the big toe and the base of the second metatarsal. Slips may, however, also be given to other structures. A sesamoid bone is usually found in the tendon either near the calcaneo-navicular ligament or the navicular bone.

Nerve-supply.—The nerve arises from the tibial (posterior tibial) in company often with branches to the other muscles of the group. It enters the posterior surface of the muscle in its proximal third, and gives off one or two branches for the tibial fasciculus. The main trunk descends across the middle third of the fasciculi arising from the fibula.

Relations.—The muscle covers the posterior surface of the interosseous membrane, and extends distally over the posterior surface of the tibia beneath the flexor digitorum longus. It is covered proximally by the soleus, distally by the two long digital flexors. The posterior tibial and peroneal arteries and the tibial (posterior tibial) nerve run upon its posterior surface. The tendon in the sole is under cover of the origin of the plantar muscles of the big toe.

Action.—The tibialis posterior adducts the foot and slightly inverts it. The flexor digitorum longus flexes the terminal phalanx on the second and the second on the first, and at the height of its contraction the first on the metatarsals. It also rotates medially to some extent the ends of the fourth and fifth toes, and inverts the foot. The flexor hallucis longus flexes the second phalanx of the big toe on the first, and, less energetically, the first on the metatarsal. It also inverts the foot. All three muscles extend the foot. The flexor hallucis is the strongest of the three in this respect.

Variations.—The muscles of the group may be more or less fused with one another or be united by fasciculi. This is especially common between the two flexors of the toes. The individual muscles vary in development. The flexor digitorum longus may be more or less divided into separate fasciculi for the individual toes. The slip from the flexor hallucis longus to the flexor digitorum longus varies greatly in extent, but usually passes mainly to the second and third toes, more rarely to the second, third, and fourth, and very rarely to the fifth. In most of the apes the tibial flexor (flexor digitorum) sends tendons to the second and fifth, the fibular flexor (flexor hallucis) to the first, third, and fourth toes. This condition is also sometimes found in man. A slip may pass from the tendon of the flexor digitorum to that of the flexor hallucis longus. There may be a sesamoid bone in the tendon of the flexor hallucis longus as it passes over the talus (astragalus) and calcaneus. The tibialis posterior may be doubled. Aberrant fasciculi may arise from various regions on the back of the leg and join any one of the three muscles of the group.

Abnormal muscles.—**The soleus accessorius.**—Arises by a tendon from the head of the fibula beneath the soleus. It is usually a slender muscle inserted into the medial surface of calcaneus. **The tibialis secundus** (tensor of capsule of ankle-joint).—A small muscle which arises from the tibia beneath the flexor digitorum and is inserted into the capsule of the ankle-joint. **The fibulo-calcaneus medialis** (peroneo-calcaneus internus of MacAlister, flexor accessorius long. dig. long., etc.).—A fasciculus which arises from the lower third of the body of the fibula and gives rise to a tendon which passes beneath the laciniate ligament to the quadratus plantæ or to the tendon of the flexor digitorum longus.

Bursæ

B. subtendinea m. tibialis posterioris.—A small bursa between the navicular fibro-cartilage and the tendon.

Synovial Tendon-sheaths

Vagina m. flexoris digitorum longi.—The tendon is surrounded by a synovial sheath from the back of the medial malleolus to where it crosses the tendon of the flexor hallucis longus below the navicular bone. It may communicate with the sheath of the tibialis anterior or with that of the flexor hallucis longus. **Vaginæ tendinum digitales.**—The tendons of the long flexor, together with those of the short flexor, are surrounded by synovial sheaths from the heads of the metatarsals to the insertions of the tendons. In structure these resemble those of the fingers. **Vagina m. flexoris hallucis longi.**—The tendon is surrounded by a sheath from the back of the medial malleolus to the crossing of the tendon of the flexor digitorum longus. Another sheath surrounds the tendon from the middle of the first metatarsal to its insertion. **Vagina m. tibialis posterioris.**—The tendon is surrounded by a synovial sheath extending from a region proximal to the medial malleolus to the insertion of the tendon.

D. MUSCULATURE OF THE FOOT

On the dorsum of the foot there is a muscle not represented in the hand, the extensor digitorum brevis (fig. 418). In the sole of the foot there is a highly developed musculature which may be subdivided into the flexor digitorum brevis (fig. 419); the muscles connected with the long extensor of the toes, quadratus plantæ and lumbricales (fig. 420); the intrinsic muscles of the great toe, (figs. 419, 421); the intrinsic muscles of the little toe (figs. 419, 421); and the interosseous muscles (fig. 422). These muscles abduct and adduct the toes, flex them at the metacarpophalangeal joints and flex and extend them at the first row of interphalangeal joints. On the second row of interphalangeal joints they seem to exert relatively little action. All the movements, excepting flexion, are weak in most individuals. The extensor digitorum brevis is innervated by the deep peroneal (anterior tibial) nerve. The muscles of the sole of the foot are all innervated by the lateral (external) plantar, except the flexor digitorum brevis, the most medial of the lumbrical muscles, and the abductor and flexor brevis of the great toe, which are innervated by the medial (internal) plantar.

FASCIÆ

Tela subcutanea.—Over the dorsum of the foot the tela subcutanea contains little fat. On the sole of the foot and the plantar surface of the toes it contains much fat embedded in dense fibrous tissue.

Muscle fasciæ.—Over the dorsum of the foot a fascial membrane extends from the cruciate ligament mentioned above to the toes, where it is continued as fibrous sheaths for the extensor tendons. Laterally and medially it is continued into the plantar fascia. Where it overlies skeletal structures it becomes adherent to them. In the main this fascial sheet is thin. Over the base of the first metatarsal it is strengthened by a band which runs from the medial side of this bone over the extensor tendons of the big toe to the base of the second metatarsal. The extensor digitorum brevis is covered by an adherent fascial sheet. The dorsal surface of each dorsal interosseous muscle is likewise covered by an adherent membrane.

The **plantar surface** of the foot is invested by a fascia in which three distinct regions may be observed, a central, a lateral, and a medial. The central region is greatly thickened by bands of fibrous tissue, the **plantar aponeurosis,** which diverge toward the toes from the medial half of the tuber calcanei. These bands become distinct from one another as the toes are approached, and each finally terminates partly in the skin over the head of the corresponding metatarsal and in the digital sheath of the flexor tendons. Some of the fibres are continued into the transverse capitular ligaments, the others extend through near the metatarsophalangeal articulation to the dorsum of the foot. Broader, thicker bands go to the three middle toes than to the big and little toes. At the margins of this central area some fibres radiate into the fascia of the lateral and medial area, some extend laterally into the skin, and some sink into the intermuscular septa described below. Near the toes well-marked transverse bundles of fibres may be seen between the digital bands. The central area of the plantar fascia is not densely adherent to the skin.

The digital sheaths of the flexor tendons of the toes correspond essentially with those previously described (p. 387) for the fingers.

The **medial plantar fascia** is thin and adherent to the skin. It extends between the central plantar and the dorsal fascia over the intrinsic muscles of the big toe. The **lateral plantar fascia** is thick and well developed near the heel, thin as the little toe is approached. A dense band, the **calcaneo-metatarsal ligament,** strengthens it between the calcaneus and the tuberosity of the fifth metatarsal.

At the junction of the lateral with the central region of the plantar fascia the **lateral intermuscular septum** sinks in to be attached to the first cuneiform, the navicular and the tendon of the posterior tibial. A similar **medial intermuscular septum** sinks in between the medial and central regions of the plantar fascia and is attached to the long plantar ligament, the tendon sheath of the peroneus longus and the base of the fifth metatarsal. The fascia of each of these regions in considerable part extends into these septa instead of becoming continuous across them.

The sole is thus divided into three great fascial compartments by these septa, a lateral, a central, and a medial. In the lateral lie the intrinsic pedal muscles of the little toe; in the medial, the abductor and the flexor brevis of the big toe and the distal end of the tendon of the flexor hallucis longus. The central compartment is subdivided by transverse septa into several sub-compartments. In the most superficial compartment lies the flexor digitorum brevis; in the second, the tendons of the flexor digitorum longus and its associated muscles, the quadratus plantæ (flexor accessorius) and the lumbrical muscles; in the third, the adductor muscles of the big toe; and in the fourth, the interosseous muscles.

The first two sub-compartments are most clearly marked in the region of the tarsus. Distally they become merged by the disappearance of the intervening transverse septum, and longitudinally subdivided by fibrous septa which serve to make a complete sheath over each digit for the flexor tendons. The sheath over the adductor muscle of the big toe is a thin membrane continued laterally from the medial intermuscular septum. Where the two heads of the adductor muscle advance upon their tendon of insertion, the medial septum has no skeletal attachment, so that the adductor sub-compartment of the middle fascial compartment communicates freely with the medial compartment. Over the cuneiform bones the tendon of the flexor hallucis longus passes from the long flexor region of the middle compartment into the medial compartment. Here the medial intermuscular septum divides into two layers, which form a sheath for the tendon as it passes to the plantar surface of the flexor hallucis brevis.

MUSCLES

1. Muscle of the Dorsum of the Foot

The extensor digitorum brevis (fig. 418).—This muscle is broad and thin, lies beneath the tendons of the long extensor muscle on the tarsus, lateral to the navicular and the head of the talus, and sends tendons to the four more medial toes. It arises from the calcaneus. Its nerve-supply is from the deep peroneal.

Origin.—From the lateral and superior surfaces of the body of the calcaneus and from the apex of the cruciate ligament.

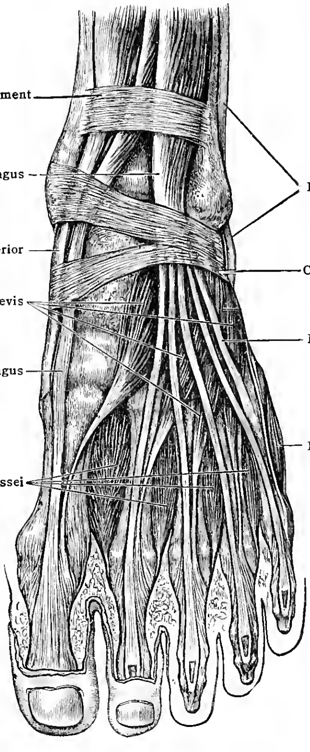
Structure and insertion.—The fibre-bundles arise directly from the ligament, and by short tendinous bands from the bone. As they extend distally they become grouped into four bellies. Those of the most medial and largest belly, the **extensor hallucis brevis,** become inserted in a bipenniform manner on the lateral and medial margins of a tendon which begins opposite the cuboid. The insertion of fibre-bundles continues to the base of the first metatarsal. The insertion of the fibre-bundles of the other bellies, which are seldom so distinctly isolated as the first, takes place in a penniform manner into their respective tendons, but the exact mode of attachment is subject to great individual variations. The tendon of the first digit is inserted mainly into the middle of the back of the base of the first phalanx, but it is often also united to the tendon of the long extensor. The other three tendons are fused with the lateral margins of the corresponding tendons of the long extensor near the bases of the three middle digits. They also usually give slips to the bases of the first phalanges of the corresponding toes.

Nerve-supply.—The deep peroneal (anterior tibial) nerve, which, accompanied by the anterior tibial artery, passes beneath the medial belly of the muscle, gives off a branch which passes transversely across the middle of the deep surface of the muscle and sends twigs into it.

Relations.—It lies on the lateral side of the tarsus, beneath the long extensor tendons of the toes. The relations of its tendons have been described above.

Action.—It aids the long extensors in extending the first phalanx of each of the four medial digits. It has but a limited action on the second and third phalanges. It serves also to pull the ends of the toes to which its tendons go toward the little toe.

FIG. 418.—THE MUSCLE OF THE DORSUM OF THE FOOT.



Variations.—The muscle shows great variation in development. Rarely the whole muscle, more frequently one or more of its digital divisions, may be missing. On the other hand, it may be more highly developed than usual. Accessory fasciculi vary greatly in origin and termination. Most frequently their tendons go to a metacarpo-phalangeal articulation or to the second or the fifth toe.

2. MUSCLES OF THE SOLE OF THE FOOT

a. FLEXOR DIGITORUM BREVIS (fig. 419)

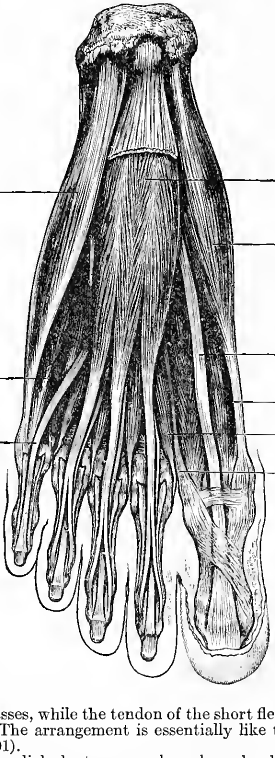
The **flexor digitorum brevis,** the most superficially placed of the plantar muscles, lies in the mid-plantar region beneath the plantar fascia and over the tendons of the long flexor of the toes and its associated muscles. It arises from the calcaneus, and has a flat, elongated belly, which toward the middle of the sole is prolonged into four processes, each of which has a special tendon that is inserted into the second phalanx of one of the four lateral toes. The tendons of the muscle correspond to those of the flexor sublimis in the palm. The belly of the flexor sublimis is supposed to be represented by the soleus. The nerve supply is from the medial (internal) plantar.

Origin.—From (1) the medial process of the tuber calcanei; (2) the posterior third of the plantar aponeurosis; and (3) the medial and lateral intermuscular septa.

Structure.—The constituent fibre-bundles pass distally in a compact mass. The tendons of insertion begin within the muscle substance, and as the fibre-bundles become inserted on them, the separate fasciculi become more and more distinct. The fasciculi for the second and third toes are larger and arise more superficially than those for the fourth and fifth toes. The fasciculus for the fifth toe is often very small, and its tendon takes an oblique course to the insertion.

Insertion.—The tendons of the short flexor pass superficial to those of the long flexor into the osteo-fibrous canals on the flexor surface of the digits. Upon the first phalanx of each toe the tendon of the short flexor divides and forms an opening (chiasma tendinis) through which

Fig. 419.—First Layer of the Muscles of the Sole



the tendon of the long flexor passes, while the tendon of the short flexor becomes attached to the base of the second phalanx. The arrangement is essentially like that described at length for the flexors of the fingers (p. 401).

Nerve-supply.—From the medial plantar nerve by a branch which enters the middle third of the deep surface near the medial margin of the muscle.

Action.—It is a strong flexor of the second row of phalanges.

Relations.—The short flexor is separated from the abductors of the big toe and little toe by strong intermuscular septa (p. 492), and from the long flexor tendons and the quadratus plantæ (flexor accessorius) by a transverse septum in which the lateral plantar vessels and nerve cross the foot. In its distal two-thirds it is separated from the plantar fascia by loose tissue.

Variations.—The muscle shows a tendency toward reduction, one or more of its fasciculi being frequently absent, and occasionally the whole muscle. The fasciculus for the fifth toe is absent in about 20 per cent. of bodies (Le Double). When a fasciculus is absent, its tendon is usually replaced by an accessory tendon from the long flexor. The muscle or its tendons may be more or less fused to the tendons of the flexor digitorum longus.

b. Muscles Attached to the Tendons of the Flexor Digitorum Longus (fig. 420)

The muscles belonging in this group are the **quadratus plantæ** (flexor accessorius), a flat, quadrangular, bicipital muscle which runs from the medial and plantar surface of the body of the calcaneus to the dorso-lateral margin and deep surface of the long flexor tendon; and the **lumbricales**, four slender bipinnate muscles which run from the medial sides of the digital slips of the tendon to the medial sides of the four more lateral toes. The quadratus aids the long flexor muscle; the lumbricales extend the last two phalanges and flex the first phalanx of each of the digits to which they pass. The lumbrical muscles correspond to those of the hand. The quadratus is not there represented. The nerve-supply is from the lateral (external) plantar nerve except that for the first lumbrical muscle which gets its supply from the medial (internal) plantar.

The quadratus plantæ (flexor accessorius) (fig. 420).—This muscle *arises* by two heads. The *lateral head* springs by an elongated tendon from the calcaneus in front of the lateral process of the tuber, and from the lateral margin of the long plantar ligament. The *medial head* arises directly from the medial surface of the body of the calcaneus as far back as the medial process of the tuber calcanei, and from neighbouring ligaments.

Structure and insertion.—The two heads are separated at their origin by a short triangular space. They soon fuse to form a single belly, but the fibre-bundles of each head in the main are separately inserted. Those from the lateral head diverge to be attached to the lateral margin of the flexor tendon. Those from the medial head are inserted on a tendon that begins on the medial margin and deep surface of this head, becomes broader, and is inserted as a flat aponeurosis on the deep surface of the flexor tendon. There are great individual variations in the structure of this muscle. The fibres of either part may be inserted with those of the other part.

Nerve-supply.—From a branch of the lateral plantar nerve which passes obliquely across the superficial surface of the muscle parallel with the tendon of the flexor digitorum longus.

Relations.—The muscle lies in a fascial compartment with the long flexor tendons. This compartment is bounded on each side by intermuscular septa, deeply by the tarsus, and plantarward by a septum which intervenes between it and the flexor digitorum brevis, and in which the lateral plantar nerve and vessels cross to the lateral side of the foot.

Action.—It assists the long flexor tendon in flexing the toes. It makes the direction of traction on the toes parallel with the long axis of the foot.

Variations.—It is frequently reduced in size. The lateral head is not infrequently missing, the medial head or the whole muscle much more rarely. The mode of attachment to the tendon varies. It may be inserted in part or wholly into the long flexor of the great toe. It may receive, in about one body in twenty (Wood), an accessory slip of origin from the fibula, one of the muscles of the leg, the fascia of the leg or foot, or the medial surface of the calcaneus, etc.

The lumbricales.—The three lateral muscles *arise* from the contiguous sides of the digital tendon-slips of the flexor digitorum longus in the angles of division. The first lumbrical arises on the medial margin of the tendon to the second toe. The fibre-bundles of each muscle converge on both sides of a tendon which becomes free near the metatarso-phalangeal joint and is *attached* to the medial side of the first phalanx of the toe to which the muscle belongs. A tendinous expansion is sent into the aponeurosis of the extensor muscle.

Nerve-supply.—The three lateral lumbrical muscles are most frequently supplied by branches of the deep ramus of the lateral plantar nerve, the medial by the first common plantar digital branch of the medial plantar nerve. The latter nerve may supply the two more medial muscles or the more medial muscles may receive a double supply. The branches of the lateral plantar nerve enter the deep surfaces of the muscles in the middle third. The branches of the medial plantar enter the medial borders of the muscles near the junction of the proximal and middle thirds.

Relations.—The lumbrical muscles lie in a plane with the long flexor tendons deeper than the flexor brevis tendons and superficial to the adductor hallucis. The deep branches of the lateral plantar nerve and vessels pass across their deep surface; superficial branches of both plantar nerves across the superficial surface.

Action.—To extend the last two phalanges of the toes and to flex the first.

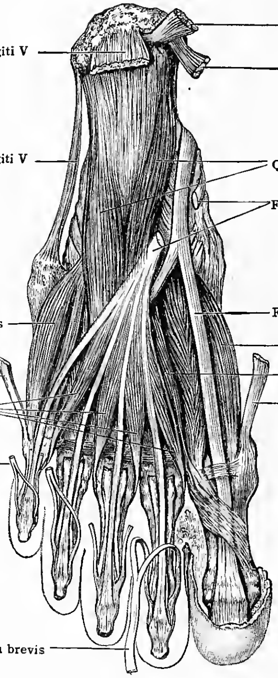
Variations.—One or more of the muscles may be absent. Sometimes a muscle is doubled. This is more frequently the case with the third and fourth muscles. The first may arise wholly from the tendon of the posterior tibial muscle or from this and the long flexor of the big toe. The third lumbrical may arise from the flexor digitorum brevis. The second and fourth lumbricals may be inserted into the tendons of the flexor digitorum brevis.

c. Intrinsic Muscles of the Great Toe (figs. 419–421)

These muscles are the abductor, flexor brevis, and adductor. Of the three muscles, the first two lie in the medial fascial compartment, while the last lies in the middle compartment covered by the flexor digitorum longus and its associated muscles.

The **abductor hallucis** (fig. 419), the largest and most superficial of these muscles, lies on the border of the sole medial to the short flexor muscle. It passes from the calcaneus across the tendons of the long flexor muscles, and is inserted into the medial side of the base of the first phalanx of the great toe and into the medial side of the long extensor tendon. It is partly fused to the medial belly of the flexor hallucis brevis. The **flexor hallucis brevis** (fig. 421) is a bicaudal muscle which lies over the first metatarsal. It arises in the region of the cuneiform bones and is inserted on each side of the base of the first phalanx. Between

FIG. 420.—SECOND LAYER OF THE MUSCLES OF THE SOLE.



its two bellies and insertions runs the tendon of the long flexor of the great toe. Proximally and medially the flexor brevis is crossed by the abductor hallucis. Its tendons are fused with those of the abductor and the oblique head of the adductor. The **adductor hallucis** (fig. 421) is composed of two distinct heads, an oblique and a transverse. The oblique head extends from the long plantar ligament under cover of the tendons of the flexor digitorum longus and the lumbrical muscles to the lateral side of the base of the first phalanx of the great toe. Its tendon of insertion is joined by the transverse head, which arises from the capsules of the third to the fifth metatarso-phalangeal joints. Beneath the adductor lie the more medial interosseous muscles.

These muscles perform not only the functions indicated by their names, but also extend the second phalanx. They correspond fairly well with those of the thumb. The opponens is not normally present in the foot. The nerve supply for the adductor is from the lateral (external) plantar nerve; that for the other muscles is from the medial (internal) plantar.

The abductor hallucis (fig. 419).—*Origin.*—From (1) the medial process of the tuber calcanei; (2) the deep surface of the neighbouring plantar fascia; (3) the laciniate (internal annular) ligament; (4) the septum between the muscle and the flexor digitorum brevis; and (5) a fibrous arch which extends on the deep surface of the muscle over the plantar vessels and nerves and the long flexor tendons from the calcaneus to the navicular bone.

Structure.—From the medial process of the tuber calcanei a tendinous band passes to the deep, lateral side of the muscle. Numerous tendinous bands arise from the other areas of origin. The fibre-bundles arise from these tendons and directly from the fibrous arch. They are attached in a penniform manner to numerous tendinous slips which extend far up in the muscle. These slips become gradually fused into a tendon which appears on the superficial plantar aspect of the muscle. Opposite the distal half of the first metatarsal bone the tendon leaves the belly of the muscle and becomes closely bound to the medial belly of the flexor hallucis brevis.

Fig. 421.—Third Layer of the Muscles of the Sole.

Insertion.—In conjunction with the tendon of the medial belly of the flexor brevis into the base of the first phalanx. It usually sends an expansion to the extensor tendon.

Nerve-supply.—A branch from the medial plantar nerve usually enters near the middle of the lateral border of the muscle.

Relations.—It is covered by the plantar fascia and is separated from the muscles of the median compartment by the medial intermuscular septum. It crosses the tendons of the tibialis anterior, tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the plantar vessels and nerves.

The flexor hallucis brevis (fig. 421).—*Origin.*—From a tendon attached to the first (internal), second and third cuneiform bones. The more lateral of its fibres are continued into the plantar calcaneo-cuboid ligament and the more medial into the expansion of the tendon of the posterior tibial muscle.

Structure and insertion.—The fibre-bundles give rise to two bellies, a medial and a lateral. Those of the medial belly pass obliquely medially to be inserted into the tendon of the abductor hallucis, and by a short tendon fused with this into the medial side of the plantar surface of the base of the first phalanx. This tendon contains a sesamoid bone. Those of the lateral converge upon the tendon of the oblique head of the adductor, and the two muscles are inserted by a common tendon, which contains a sesamoid bone, into the lateral side of the plantar surface of the base of the first phalanx.

Nerve-supply.—A branch from the medial plantar (or first plantar digital) nerve divides over the plantar surface of the muscle and gives a twig to each belly near the middle third. Rarely the lateral belly may receive a branch from the lateral plantar nerve.

Relations.—The abductor hallucis covers it medially; the tendon of the flexor hallucis longus passes between its two heads. Branches of the medial plantar vessels and nerve lie on its superficial surface.

The adductor hallucis (fig. 421).—The **oblique head.**—*Origin.*—From (1) the tuberosity of the cuboid and the sheath over the tendon of the peroneus longus muscle; (2) the plantar calcaneo-cuboid ligament; (3) the third cuneiform; (4) the bases of the second and third metatarsals and (5) a fibrous arch which extends from the plantar calcaneo-cuboid ligament to the interosseous fascia.

Structure and insertion.—From short tendon-slips the fibre-bundles pass forward to form a thick, fusiform belly which is attached in a bipenniform manner to a flat tendon. The tendon begins about the middle of the plantar surface of the muscle and is inserted in common with that of the flexor brevis into the lateral side of the plantar surface of the base of the first phalanx, and by a slip into the aponeurosis of the long extensor muscle on the back of the big toe.

Nerve-supply.—A branch from the deep ramus of the lateral plantar nerve enters the middle third of the lateral border of the muscle on its deep surface.

The **transverse head** *arises* from the joint-capsules of the third, fourth, and fifth metatarso-phalangeal joints and from the transverse capitular ligaments.

Structure and insertion.—Of the three fasciculi, that to the little toe lies nearest the heel, that to the middle toe the most distally. The fibre-bundles take a nearly parallel course to be attached to tendon-slips which are fused into a common tendon that splits and passes on each side of the tendon of the oblique head and is inserted into the sheath of the tendon of the long flexor of the great toe (Leboucq).

Nerve-supply.—A branch from the deep ramus of the lateral plantar nerve enters the middle third of the deep surface of the muscle.

Relations.—The adductor hallucis is crossed superficially by the tendons of the flexor digitorum longus and by the lumbrical muscles. On its deep surface lie the interosseous muscles, and the deep plantar vessels and nerves.

Action.—The actions of the muscles of this group are indicated by the names of the individual muscles. The abductor and the oblique head of the adductor are also flexors of the first phalanx. All the muscles of the group aid in extending the second phalanx. The transverse head of the adductor serves to draw together the heads of the metatarsals after they have been separated by the weight of the body during the tread.

Variations.—The extent of fusion of the abductor and adductor with the two heads of the short flexor varies considerably. The abductor may receive an accessory fasciculus from the medial border of the foot. Either the adductor or the flexor brevis may send a tendon to the base of the first phalanx or to the short flexor tendon of the second toe. The adductor shows frequent variations in relation to its metatarsal attachments, owing to the fact that originally a fasciculus from the body of the second (and third) metatarsal was probably normally present and the transverse head was more developed (Leboucq). The **opponens hallucis** is a fasciculus occasionally found which extends from the short flexor or the medial intermuscular septum to the body of the first metatarsal. This muscle is normal in some monkeys. An **adductor digiti secundi** has been seen to arise from various sources and become attached to the lateral side of the plantar surface of the base of the first phalanx of the second toe. This muscle may be fused with the oblique adductor. A corresponding muscle is found normally in some apes, and in some of the lower animals there is a special adductor for each toe.

d. Intrinsic Muscles of the Little Toe (figs. 419–421)

In this group belong three muscles, an abductor, a flexor and an opponens. The largest of these, the **abductor digiti quinti** (fig. 419), extends superficially over the lateral margin of the foot from the lateral side of the tuber calcanei to the base of the little toe. The **flexor digiti quinti brevis** (fig. 421) is a small, flat muscle which lies on the plantar surface of the fifth metatarsal. The **opponens** is a small muscle lying lateral to this. The two, which are often fused, arise from the cuboid. The flexor brevis is inserted into the plantar side of the base of the first phalanx of the little toe. The opponens is inserted into the lateral surface of the metatarsal. The abductor corresponds with the abductor of the little finger. The opponens and flexor brevis correspond probably with the deep part of the opponens of the little finger. The nerve supply is from the lateral plantar nerve.

The abductor digiti quinti (fig. 419).—*Origin.*—From (1) the lateral process of the tuber calcanei and the lateral and plantar surface of the body of the bone in front of this; (2) the lateral intermuscular septum; (3) the deep surface of the lateral plantar fascia, including the fibrous band extending from the calcaneus to the lateral side of the base of the fifth metatarsal bone.

Structure.—The fibre-bundles run obliquely to a flat tendon of insertion. This begins within the muscle near the calcaneo-cuboid joint, soon emerges on the medial side of the deep surface, and becomes free near the metatarso-phalangeal joint. Considerable individual variation in structure is found.

Insertion.—On the lateral surface of the first phalanx of the little toe and the metatarso-phalangeal capsule. Often a slip is sent to the extensor tendon. While usually the muscle glides over the tuberosity of the fifth metatarsal, it frequently sends a second fasciculus to be attached to this bone (**abductor ossis metatarsi quinti**). A special fasciculus from the tuberosity often constitutes the lateral margin of the muscle.

Nerve-supply.—The nerve arises from the lateral plantar. It may be distributed either near the deep or the superficial surface of the muscle. The former appears to be the case when the muscle is slightly developed. The chief intramuscular branches then extend across the middle third of the constituent fibre-bundles near the deep surface. In case the calcaneo-metatarsal bundles are well developed, the nerve enters the proximal margin of the muscle and its chief branches extend across the middle third of the more superficial muscle-bundles, finally terminating in the distal margin of the muscle.

Relations.—It is ensheathed by the plantar fascia and the lateral intermuscular septum. It lies superficial to the quadratus plantæ (flexor accessorius), the opponens and flexor brevis of the little toe, the long plantar ligament, and the tendon of the peroneus longus muscle.

The flexor digiti quinti brevis (fig. 421).—*Origin.*—From the sheath of the peroneus longus, the tuberosity of the cuboid, and (3) the base of the fifth metatarsal.

Structure and insertion.—The fibre-bundles take a nearly parallel course, although the belly is slightly fusiform. They are attached by short tendinous bands to the base of the first phalanx of the little toe, the capsule of the corresponding joint, and the aponeurosis on the dorsal surface of the toe.

Nerve-supply.—A branch of the superficial ramus of the lateral plantar nerve sends twigs to the middle third of the plantar surface of this and the following muscle.

Relations.—It is covered medially by the plantar fascia, laterally by the abductor of the fifth toe. Medially it lies superficial to the third plantar interosseous muscle.

The opponens digiti quinti.—This muscle *arises* from the sheath of the peroneus longus and the tuberosity of the cuboid by a slender tendon which passes over the tuberosity of the fifth metatarsal and gives rise to fibre-bundles which are *inserted* on the lateral surface of the fifth metatarsal.

Nerve-supply.—From branches of the nerve to the flexor brevis.

Relations.—It is covered by the abductor of the fifth toe.

Actions.—The abductor and flexor brevis abduct the little toe and flex the first phalanx. They act as extensors of the second phalanx. The opponens serves to draw the little toe medially in a plantar direction.

Variations.—The muscles of this group may be more or less completely fused. The abductor, in addition to the variations mentioned above, may send tendons to the third and fourth metatarsals. The opponens is frequently missing. The **abductor accessorius digiti quinti** is a rare muscle which arises from the lateral process of the tuber of the calcaneus and is inserted into the lateral surface of the base of the first phalanx of the little toe.

e. The Interosseous Muscles (fig. 422)

Two groups of interosseous muscles are recognised, a dorsal and a plantar. The dorsal are the larger and fill the interspaces. The first two are inserted into each side of the base of the first phalanx of the second toe; the third and fourth into the lateral sides of the bases of the first phalanges of the third and fourth toes. The plantar interossei lie on the medial side of the ventral surfaces of the third, fourth, and fifth metatarsals, and are inserted each on the medial side of the base of the first phalanx of the corresponding toe. In the hand the axis about which the interosseous muscles are arranged passes through the middle finger, in the foot through the second toe. The nerve-supply is from the lateral plantar nerve.

The interossei dorsales.—Each of the three lateral dorsal interosseous muscles *arises* from —(1) the sides of the shaft and the plantar surface of the bases of the metatarsal bones bounding the space in which it lies; (2) from the fascia covering it dorsally; and (3) from fibrous prolongations from the long plantar ligament. The first has a similar origin except that it is attached medially to the base of the first metatarsal and to a fibrous arch extending from the base to the head.

Structure.—The component fibre-bundles of each muscle are inserted bipinnately on a tendon which begins high in the muscle and becomes free near the metatarso-phalangeal joint.

Insertion.—The first and second on each side of the base of the first phalanx of the second toe. The third and fourth on the lateral side of the bases of the proximal phalanges of the third and fourth toes. Each tendon is adherent to the capsule of the neighbouring joint. They send no well marked processes to the extensor tendons, as do those of the hand.

The interossei plantares.—Each plantar interosseus *arises*—(1) from the proximal third of the medial plantar surface of the shaft and from the base of the metatarsal on which it lies; and (2) from expansions of the long plantar ligament.

Structure and insertion.—The obliquely placed fibre-bundles are longer than those of the dorsal interossei, and are inserted in a tendon which lies near the medial border of the muscle, becomes free near the metatarso-phalangeal joint, and is inserted into a tubercle on the medial side of the base of the first phalanx of the digit to which it goes.

Nerve-supply.—From the deep branch of the lateral plantar nerve several rami are given off for the interossei. The nerve of each muscle enters the plantar surface in the proximal third. The interosseous muscles of the fourth interspace, however, are usually supplied by a branch from the superficial ramus of the lateral plantar nerve.

Relations.—The interosseous muscles are covered on the plantar surface by a thin fascia on which the deep branches of the lateral plantar nerve and vessels run. The first dorsal interosseous adjoins medially the flexor hallucis brevis and laterally on the plantar surface of the second metatarsal, adjoins the second dorsal interosseous. Dorsal and plantar interossei then alternate across the plantar surface of the foot until the fifth metatarsal is reached. Here the third plantar interosseous adjoins the flexor brevis of the little toe.

Fig. 422.—Fourth Layer of the Muscles of the Sole.

Action.—The chief axis of the foot may be taken to extend through the second toe. The dorsal interosseous muscles abduct—pull the digits to which they are attached away from this axis; the plantar interosseous muscles adduct—pull the digits toward the axis. The interossei all flex the first row of phalanges.

Variations.—The second dorsal interosseous may have no attachment to the third metatarsal.

Bursæ

B. intermetatarsophalangeæ.—Four bursæ between the neighbouring sides of the heads of the metatarsal bones and dorsal to the transverse capitular ligaments. **B. mm. lumbricalium.**—Between the ends of the tendons of the lumbrical muscles and the transverse capitular ligaments. The three medial are more constant than the lateral.

For other bursæ in the foot, see pp. 483 and 491.

MUSCLES GROUPED ACCORDING TO FUNCTION

The exact functions of many of the muscles have not yet been decisively determined. Anatomical studies, the construction of mechanical models, the electrical stimulation of the musculature, and observation of the muscular activities of normal individuals and of individuals in whom given muscles or sets of muscles are absent or paralysed, have all proved valuable methods of investigation, but each method has its drawbacks, and knowledge of the part actually played by individual muscles in the normal activities of the body is as yet merely approximate. Owing to the influence of gravity, the relations of other muscles to the skeleton, and similar factors, a given muscle may perform functions which would not be deduced from a simple study of the relations of the muscle to the skeleton. Thus the iliacus serves to flex not only the hip, but also the knee, and the hamstring muscles may flex the hip while flexing the knee. The functions ascribed to various muscles in the following tables, although an attempt has been made to base them upon the more recent work on the action of the muscles, must be taken to be merely approximately correct. So far as possible the muscles are given in order of their power in effecting the various movements. In this we have utilized chiefly the work of R. Fick: "Anatomie und Mechanik der Gelenke unter Berücksichtigung der bewegenden Muskeln" in von Bardeleben's Handbuch der Anatomie des Menschen.

In this table have been included not only the voluntary muscles described in the preceding section, but also several described in other parts of the book.

1. Facial muscles.
   These serve essentially to contract the various visceral orifices of the head or to retract the tissue surrounding them.
   Ear.
      Retractors: auricularis anterior, superior, and posterior.
   Orbit.
      (*a*) Retractor: Epicranius (occipito-frontalis). The levator palpebræ superioris, innervated by the third cranial nerve, serves to raise the upper lid of the eye.
      (*b*) Contractors: orbicularis oculi, corrugator, and procerus.
   Nasal orifice.
      (*a*) Dilators: angular head of the quadratus labii superioris, transverse portion of the nasalis, and the dilatores naris.
      (*b*) Contractors: pars alaris of the nasalis and the depressor septi nasi.
   Oral orifice.
      (*a*) Retractors:
         Upward: zygomaticus, quadratus labii superioris, caninus.
         Lateralward: zygomaticus, risorius, platysma, triangularis, buccinator.
         Downward: triangularis, quadratus labii inferioris, platysma.
      (*b*) Contractors: orbicularis oris, compressor labii, incisivus labii inferioris and superioris.
      (*c*) Protractors of the lips: incisivus labii inferioris and superioris, mentalis.
2. Muscles acting on the eyeball (see Section on Eye).
   To adduct the pupil: rectus medialis.
   To abduct the pupil: rectus lateralis.
   To direct the pupil upward: rectus superior, in association with the obliquus inferior.
   To direct the pupil downward: rectus inferior, in association with the obliquus superior.
3. Muscles acting on the lower jaw.
   (*a*) To raise it: masseter, temporal, internal pterygoid.
   (*b*) To lower it: external pterygoid, digastric, mylo-hyoid, genio-hyoid, and the infrahyoid muscles. The weight of the jaw also plays a part in this movement.
   (*c*) To protract it: external pterygoid, internal pterygoid, masseter and the anterior part of the temporal.
   (*d*) To retract it: the inferior dorsal portion of the temporal and the digastric.
   (*e*) To produce lateral movements: the external pterygoid acting on one side rotates the chin and carries the jaw toward the opposite side. The rotation may be aided by the digastric of the opposite side. The masseter draws it slightly toward the side on which the muscle lies. This action of the masseter is counterbalanced by the internal pterygoid (Riegner).
4. Muscles acting on the hyoid bone.
   (*a*) To elevate it: digastric, stylo-hyoid, stylo-glossus, mylo-hyoid, genio-hyoid, genio-glossus, hyo-glossus, and the middle constrictor of the pharynx.
   (*b*) To depress it: thyreo-hyoid, sterno-hyoid, omohyoid, sterno-thyreoid.
   (*c*) To protract it: genio-glossus (inferior portion), genio-hyoid, anterior belly of digastric, and the mylo-hyoid.
   (*d*) To retract it: posterior belly of digastric, stylo-hyoid, and the middle constrictor of the pharynx.
5. Muscles acting on the larynx (see Section IX).
   (*a*) To elevate it: thyreo-hyoid, stylo-pharyngeus, pharyngo-palatinus, the inferior constrictor of the pharynx, and the elevators of the hyoid bone.
   (*b*) To depress it: sterno-thyreoid, sterno-hyoid, and omo-hyoid.
   (*c*) To approximate the vocal cords: crico-arytenoideus lateralis; vocalis; thyreo-arytenoideus, arytenoideus transversus.
   (*d*) To make the vocal cord tense: crico-thyreoideus.
   (*e*) To widen the rima glottidis: crico-arytenoideus posterior.
   (*f*) To shorten and thicken the vocal cords: thyreo-arytenoideus (externus), vocalis.

(*g*) To constrict the aditus and vestibule of the larynx: aryepiglotticus, thyreo-arytenoideus.
(*h*) To widen the aditus and vestibule of the larynx: thyreo-epiglottideus

6. Muscles acting on the tongue (see Section IX).
(*a*) To elevate it: stylo-glossus (especially along the sides), glosso-palatinus, glosso-pharyngeus, and the elevators of the hyoid bone.
(*b*) To depress it: genio-glossus (in the centre), hyoglossus (at the sides), chondroglossus, and the depressors of the hyoid bone.
(c) To protrude it: genio-glossus (middle and inferior portions).
(*d*) To retract it: genio-glossus (anterior portion), stylo-glossus, chondroglossus.
(*e*) To shorten it and make it bulge upwards: longitudinalis superior and inferior.
(*f*) To narrow it and make it bulge upwards: transversus linguæ.
(g) To flatten it: verticalis linguæ.
When the muscles work symmetrically, these movements are symmetrical; when they do not work symmetrically, the tongue is moved from side to side, rotated, etc.

7. Muscles acting on the palate and pharynx (see Section IX).
(*a*) To narrow the pharyngeal opening of the tuba auditiva (Eustachian tube): levator veli palatini.
(*b*) To widen the isthmus of the tuba: levator veli palatini.
(*c*) To open the tube: tensor veli palatini, pharyngo-palatinus.
(*d*) To raise and shorten the uvula: m. uvulæ.
(e) To depress the soft palate: glosso-palatinus, pharyngo-palatinus.
(*f*) To make tense the soft palate: tensor veli palatini.
(*g*) To lift the soft palate: levator veli palatini.
(*h*) To approximate the glosso-palatine arches (anterior pillars of the fauces): glosso-palatinus.
(*i*) To approximate the pharyngo-palatine arches (posterior pillars of the fauces): pharyngo-palatinus, superior constrictor of the pharynx.
(*j*) To constrict the pharynx: superior, middle, and inferior constrictors.
(*k*) To widen the pharynx: stylo-pharyngeus and the muscles which protract the hyoid bone.
(*l*) To elevate the pharynx: stylo-pharyngeus, pharyngo-palatinus.

8. Muscles acting on the head.
(*a*) To flex it: the supra- and infrahyoid muscles, rectus capitis anterior, longus capitis, rectus capitis lateralis.
(*b*) To extend it: sterno-cleido-mastoid, trapezius, splenius capitis, longissimus capitis, semispinalis capitis, obliquus capitis superior, rectus capitis posterior major and minor. When the hyoid bone and lower jaw are fixed by contraction of the hyomandibular and infrahyoid muscles, the posterior belly of the digastric aids the extensors of the head in opening the mouth.
(*c*) To bend it laterally: sterno-cleido-mastoid, rectus capitis lateralis, splenius capitis, longissimus capitis, semispinalis capitis, obliquus capitis superior.
(*d*) To rotate it: sterno-cleido-mastoid, trapezius, splenius capitis, longissimus capitis, semispinalis capitis, obliquus capitis superior and inferior, rectus capitis posterior major.

9. Muscles acting on the spinal column.
(*a*) To flex it: sterno-cleido-mastoid, longus colli, longus capitis, psoas major and minor, scaleni, rectus abdominis, obliquus abdominis externus and internus, the crura of the diaphragm, levator ani, and the coccygeus.
(*b*) To extend it: splenius capitis, splenius cervicis, spinalis, sacro-spinalis, semispinalis dorsi, cervicis and capitis, multifidus, rotatores, interspinales, intertransversarii, levatores costarum, quadratus lumborum.
(*c*) To bent it laterally and extend it: quadratus lumborum, splenius, iliocostalis, longissimus dorsi, cervicis and capitis, semispinales, multifidus, rotatores, levatores costarum, intertransversarii.
(*d*) To bend it laterally and flex it: scalene, sterno-cleido-mastoid, obliquus abdominis externus and internus, intercostales, psoas major and minor.
When the arm and shoulder girdle are fixed the trapezius, levator scapulæ, latissimus dorsi and rhomboids aid abduction.
(*e*) To rotate it to the right: r. internal oblique, l. external oblique, r. splenius, l. sterno-cleido-mastoid, r. longissimus capitis, r. ilio-costalis, l. semispinalis, l. multifidus, l. rotatores (except the lumbar), longus colli (r. above, l. below), l. serratus anterior and rhomboids, r. levatores costarum.

10. Muscles of respiration.

Quiet inspiration: the external intercostals, intercartilaginons parts of internal intercostals, diaphragm.

Enforced inspiration: in addition to the muscles mentioned above, the scaleni, sterno-cleido-mastoid, serratus posterior snperior and inferior, rhomboids, serratus anterior, latissimus dorsi, subclavius, pectoralis major and minor, and the extensors of the spinal column, the trapezius and the levator scapuli.

Quiet expiration: interosseous parts of internal intercostals, subcostales, and transversus thoracis.

Enforced expiration: in addition to the muscles mentioned above, the abdominal muscles, ilio-costalis lumborum and dorsi, longissimus dorsi, and the quadratus lumbornm.

The chief muscles of respiration are the intercostals; the diaphragm plays a minor part (Fick).

11. Muscles acting on the abdomen.

(*a*) Constriction of the abdominal cavity: obliquus abdominis externus and internus, the transversus and rectus abdominis, and the diaphragm, levator ani, and coccygeus.

(*b*) Reduction of pressure in the abdominal cavity: the mnscles of inspiration, with the exception of the diaphragm, serve to lessen the compression of the abdominal viscera.

12. Action of the muscles of the perineal region.

(*a*) To close anal canal: sphincter ani externus.

(*b*) To constrict the anal portion of the rectum: levator ani (pubo-coccygeal portion).

(*c*) To constrict the bulbus urethræ and the corpus cavernosum urethræ (corpus spongiosum): bulbo-cavernosus.

(*d*) To elevate the prostate gland: levator ani.

(*e*) To constrict the vagina: bulbo-cavernosus, levator ani (pubo-coccygeal portion), constrictor vaginæ.

(*f*) To cause erection of penis and clitoris: ischio-cavernosus, bulbo-cavernosus, and sphincter urethræ membranaceæ.

(*g*) To compress the urethra and the bulbo-urethral (Cowper's) or the great vestibular (Bartholin's) gland: sphincter urethræ membranaceæ and the transversus perinei profnndus.

(*h*) To snpport and lift the pelvic floor: levator ani, coccygeus, transversus perinei profundus and superficialis.

13. Muscles acting on the shoulder-girdle.

The two joints acted upon are the sterno-clavicular and the acromio-clavicular. The movements produced consist in lifting and lowering the scapula, carrying it forward and backward and rotating it.

(*a*) Elevation: trapezius (upper portion), levator scapulæ, sterno-cleido-mastoid, rhomboidei, pectoralis major (upper sternal part), serratus anterior (middle portion), omo-hyoid.

(*b*) Depression: trapezius (lower portion), pectoralis major (lower portion), pectoralis minor, subclavins, latissimus dorsi, serratus anterior (lower part). The weight of the limb is likewise a factor.

(*c*) Forward movement: serratns anterior, pectorales major and minor.

(*d*) Backward movement: trapezius, rhomboidei, latissimus dorsi.

(*e*) Rotation:

Associated with abduction of the arm: serratus anterior (inferior portion), trapezius.

Associated with adduction of the arm: rhomboidei, pectoralis major (pectoral portion), latissimus dorsi, pectoralis minor, levator scapulæ.

14. Muscles acting on the arm at the shoulder-joint.

(*a*) To flex it,

When the arm is at the side: pectoralis major (upper part), deltoid (anterior part), short head of biceps, coracobrachialis, infraspinatus, long head of biceps, teres minor, subscapularis (upper part), supraspinatns.

When the arm is abducted 60°: pectoralis major, deltoid, subscapularis, short head of biceps, coracobrachialis, long head of biceps, infraspinatus, supraspinatus.

The movement is aided by the trapezius and the serratus anterior.

(*b*) To extend it,

When the arm is at the side: latissimus dorsi, deltoid (posterior part), teres major, subscapularis (lower part), triceps.

When the arm is abducted 60°: latissimus dorsi, deltoid, teres major, triceps, teres minor.

The upper and middle portions of the trapezius and the levator scapnlæ play an important part in extension of the arm.

(*c*) To abdnct it,

When the arm is at the side: deltoid, supraspinatus, long head of biceps, subscapularis, infraspinatus (upper part).

When the arm is abducted 60°: deltoid, supraspinatus, infraspinatus (upper part), long head of biceps, short head of biceps.

The subscapularis is an adductor when the arm is abducted. The inferior part of the serratus anterior and the trapezius are important in abduction of the arm.

(*d*) To adduct it,

When the arm is at the side: pectoralis major, latissimus dorsi, deltoid (posterior and anterior parts), teres major, triceps, coracobrachialis, short head of biceps, teres minor, infraspinatus.

When the arm is abducted: pectoralis major, latissimus dorsi, teres major, triceps, subscapularis, deltoid (dorsal and ventral parts), coracobrachialis.

(*e*) To rotate it lateralward (supinate),

When the arm is at the side: infraspinatus (upper part), the dorsal part of the deltoid, teres minor, supraspinatus.

When the arm is abducted 60°: teres minor, infraspinatus, deltoid (dorsal part), coracobrachialis.

(*f*) To rotate it medialward (pronate).

With the arm at the side: latissimus dorsi, pectoralis major, subscapularis, deltoid (ventral part), long head of biceps, teres major, short head of biceps.

With the arm abducted 60°: latissimus dorsi, pectoralis major, subscapularis, teres major, deltoid (ventral part).

When the arms are raised high the power of rotation at the shoulder becomes slight.

15. Muscles acting on the forearm at the elbow-joint (arranged according to R. Fick).

(*a*) Flexion at elbow.

Forearm supinated: brachialis, long head of biceps, short head of biceps, brachio-radialis, pronator teres, extensor carpi radialis longus, flexor carpi radialis, extensor carpi radialis brevis, palmaris longus.

Forearm in mid-position or pronated: brachialis, long head of biceps, short head of biceps, brachio-radialis, extensor carpi radialis longus, pronator teres, flexor carpi radialis, extensor carpi radialis brevis, palmaris longus.

(*b*) Extension at elbow: triceps (lateral, medial, and long heads), anconeus.

(*c*) Pronation of forearm.

Forearm extended: flexor carpi radialis, pronator teres, pronator quadratus, palmaris longus.

Forearm at right angles: pronator teres, flexor carpi radialis, brachio-radialis, pronator quadratus, extensor carpi radialis longus, palmaris longus.

Forearm flexed: pronator teres, brachio-radialis, flexor carpi radialis, pronator quadratus, extensor carpi radialis longus, palmaris longus.

(*d*) Supination.

Forearm extended: short head of biceps, supinator, long head of biceps, brachio-radialis, extensor carpi radialis longus, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, extensor indicis proprius.

Forearm at right angles: short head of biceps, long head of biceps, supinator, abductor pollicis longus, extensor pollicis brevis, brachio-radialis (in pronation), extensor pollicis longus, extensor indicis proprius.

Forearm flexed: short head of biceps, long head of biceps, supinator, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, extensor indicis proprius.

16. Muscles acting on the hand at the wrist (arranged according to R. Fick).

(*a*) To flex it: flexor digitorum sublimis, flexor digitorum profundus, flexor carpi ulnaris, flexor pollicis longus, flexor carpi radialis, abductor pollicis longus, palmaris longus.

(*b*) To extend it: extensor digitorum communis, extensor carpi ulnaris, extensor carpi radialis longus and brevis, extensor indicis proprius, extensor pollicis longus.

(*c*) Radial abduction: extensor carpi radialis longus, extensor carpi radialis brevis, abductor pollicis longus, flexor carpi radialis, extensor indicis proprius, extensor pollicis longus, extensor pollicis brevis.

(*d*) Ulnar abduction: extensor carpi ulnaris, flexor carpi ulnaris.

17. Muscles acting on the palm:

(*a*) To flex the ulnar side: opponens, long and short flexors of the little finger.

(*b*) To extend the ulnar side: extensor carpi ulnaris, extensor digiti quinti.

(*c*) To adduct the ulnar side: third volar interosseous.

(*d*) To abduct the ulnar side: abductor digiti quinti.

For action on the radial side see "muscles acting on the thumb." Movements of the second, third and fourth metacarpals are produced by the long flexors and the dorsal interosseous muscles.

18. Muscles acting on the thumb.

(*a*) To oppose the thumb: adductor, opponens, flexor brevis, flexor longus, adductor brevis.

(*b*) To repose the thumb: long abductor, short extensor.

(*c*) To flex all joints: flexor pollicis longus; the carpo-metacarpal and metacarpo-phalangeal joints; flexor brevis, the adductors, abductor brevis; the carpo-metacarpal joints: opponens pollicis, abductor longus.
(*d*) To extend: all joints, extensor pollicis longus; the carpo-metacarpal and metacarpo-phalangeal joints, extensor pollicis brevis; the interphalangeal joint, abductor brevis, flexor brevis.
(*e*) To adduct: the adductor, flexor brevis, opponens, first dorsal interosseous, extensor longus.
(*f*) To abduct: the long and short abductors.

19. Muscles acting on the fingers.
(*a*) To flex: all the joints, flexor digitorum profundus; all but the last, flexor digitorum sublimis; the metacarpo-phalangeal joint only, flexor digiti quinti brevis, the lumbricales, and interossei.
(*b*) To extend the fingers: extensor digitorum communis, extensor indicis proprius, extensor digiti quinti proprius; to extend the two interphalangeal joints: the lumbricales, interossei, and frequently the flexor digiti quinti brevis.
(*c*) To abduct from the axis passing through the centre of the middle finger: dorsal interossei, first two lumbricales, abductor digiti quinti, the long extensor of the fingers.
(*d*) To adduct toward this axis: volar interossei, last two lumbricales, opponens and flexor digiti quinti brevis.

20. Muscles acting on the pelvis.
(*a*) To flex it: rectus abdominis, obliquus abdominis externus and internus, psoas major and minor.
(*b*) To extend it: sacro-spinalis, multifidus, latissimus dorsi and quadratus lumborum.
(*c*) To bend it laterally and rotate it: abdominal muscles, quadratus lumborum, psoas muscles, and latissimus dorsi acting on one side.

21. Muscles acting on the thigh at the hip-joint (arranged according to R. Fick).
(*a*) To flex it: ilio-psoas, rectus femoris, adductor longus, adductor brevis, obturator externus, tensor fasciæ latæ, pectineus, sartorius, gluteus minimus, adductor magnus (upper part), gracilis, quadratus femoris.
(*b*) To extend it: gluteus maximus, adductor magnus (posterior lower part), biceps, semitendinosus, semimembranosus, gluteus medius, piriformis, obturator internus.
(*c*) To adduct it: adductor magnus, gluteus maximus, adductor brevis, adductor longus, quadratus femoris, obturator externus, gracilis, adductor magnus (upper part), pectineus, biceps, semitendinosus, obturator internus and gemelli, semimembranosus.
(*d*) To abduct it: gluteus medius and minimus, the piriformis, rectus femoris, tensor fasciæ latæ, sartorius; and when the hip is flexed, the gluteus maximus, obturator internus, and gemelli.
(*e*) To rotate it medialward: gluteus medius (anterior portion), gluteus minimus, ilio-psoas, adductor magnus (upper part), pectineus, adductor longus, semitendinosus, semimembranosus, tensor fasciæ latæ.
(*f*) To rotate it lateralward: gluteus maximus, quadratus femoris, obturator internus, piriformis, rectus femoris, adductor brevis, adductor magnus (lower part), biceps, sartorius, obturator externus gracilis, gluteus medius (posterior part).

22. Muscles acting on the leg at the knee-joint (arranged according to R. Fick).
(*a*) To flex it: semimembranosus, semitendinosus, biceps, gastrocnemius, gracilis, sartorius, popliteus.
(*b*) To extend it: quadriceps femoris (the tensor fasciæ latæ and gluteus maximus through the ilio-tibial band keep the extended leg fixed).
(*c*) To rotate it medialward (when flexed): semimembranosus, semitendinosus, sartorius, popliteus, gracilis.
(*d*) To rotate it lateralward (when flexed): biceps, tensor fasciæ latæ.

23. Muscles acting on the foot at the ankle-joint (arranged according to R. Fick).
(*a*) To flex it: tibialis anterior, extensor digitorum longus, peroneus tertius, extensor hallucis longus.
(*b*) To extend it: gastrocnemius, soleus, flexor hallucis longus, peroneus longus, tibialis posterior, flexor digitorum longus, peroneus brevis.
(*c*) To invert the foot at the inferior articulation of the talus (art. talo-calcanea and talo-calcaneo-navicularis): gastrocnemius, soleus, tibialis posterior, flexor hallucis longus, flexor digitorum longus, tibialis anterior.
(*d*) To evert the foot at the inferior articulation of the talus: peroneus longus, peroneus brevis, extensor digitorum longus, peroneus tertius, extensor hallucis longus, tibialis anterior.
(*e*) To invert the foot at Chopart's (talo-navicular-calcaneo-cuboid) joint: tibialis anterior, tibialis posterior, flexor digitorum longus, flexor hallucis longus, extensor hallucis longus.
(*f*) To evert the foot at Chopart's joint: peroneus longus, peroneus brevis, extensor digitorum longus, peroneus tertius.

24. Muscles acting on the toes (arranged according to R. Fick).

(*a*) To flex: all the joints, flexor hallucis longus, quadratus plantæ, and flexor digitorum longus; the first interphalangeal and the metatarso-phalangeal joints of the four lateral toes, flexor digitorum brevis; the metacarpo-phalangeal joints, the lumbricales, interossei, abductor hallucis, adductor hallucis (oblique head), flexor hallucis brevis, abductor digiti quinti, flexor digiti quinti brevis.

(*b*) To extend: all joints, extensor digitorum longus, extensor hallucis longus, extensor digitorum brevis; the interphalangeal joints, the lumbricales, and the adductors and abductors of the big and little toes.

(*c*) To abduct from an axis passing through the second toe; abductor hallucis, dorsal interossei, abductor digiti quinti, first lumbrical.

(*d*) To adduct toward this axis: adductores hallucis, plantar interossei, three more lateral lumbricals.

(*e*) To draw together the ends of the metatarsals: the transverse head of the adductor of the big toe.

SECTION V

THE BLOOD-VASCULAR SYSTEM

REVISED FOR THE FIFTH EDITION

BY H. D. SENIOR, M.B., F.R.C.S.

PROFESSOR OF ANATOMY, NEW YORK UNIVERSITY

THE organs of circulation consist of a system of tubes or vessels which during life are filled with fluid constantly moving in one direction. The major portion of the system is concerned with the continuous distribution of blood throughout the body and is called the **hæmal or blood-vascular** system. A circumscribed part of the hæmal circulation is differentiated into a rhythmically contracting propulsory organ called the heart. The minor portion of the system is called the **lymphatic system.** The lymphatic vessels convey fluid, the lymph, from the tissues to the hæmal system.

The essential functions of the blood-vascular system are performed by the smallest of all the blood-vessels, the **capillaries** [vasa capillaria], which form a network pervading practically all the tissues of the body. Blood is carried to and from the capillaries by larger vessels called the **arteries** and **veins** respectively. The heart receives blood from the veins and propels it, in turn, into the arteries.

One of the primary functions of the blood is the transmission of oxygen from the atmosphere to the tissues. In order to do this the blood must of necessity pass through the respiratory organ before being delivered to the body at large. In gill-breathing vertebrates, the blood, having received oxygen in its passage through the gills, passes on directly to the tissues. The entire circuit is here accomplished by a single continuous chain of vessels in which capillaries occur twice, once in the gills and again in the organs and tissues in general. In man, as in other higher vertebrates, lungs assume the function of the gills. Having received oxygen in the lungs the blood is returned again to the heart before being redistributed throughout the body. There are thus in man two separate circuits or systems of blood-vessels, one traversing the lungs and a second ramifying throughout the body. The former is known as the **pulmonary** circulation; the latter as the **systemic.** Each has its own arteries, capillaries and veins; the heart is common to both. From the time of birth the heart is longitudinally divided into right and left halves, each of which contains its own independent stream of blood. The blood entering the left side of the heart has issued from the pulmonary circulation and is driven into the systemic; that in the right side, having traversed the systemic circuit, is returned again to the lungs.

The heart and blood-vessels have a continuous lining of flattened cells called endothelium; the hæmal system is, therefore, a closed circuit.* The main thickness of the heart, arteries and veins consists of additional tissue developed around the endothelial lining. It is due to this tissue that the blood is continuously delivered to and withdrawn from the capillaries under suitable pressure and velocity. The heart is mainly composed of rhythmically contracting muscle and its valves are so arranged that the contained blood is driven intermittently in one direction only. The walls of the largest arteries are formed to a great extent of elastic tissue, and, being constantly under tension from within, are instrumental in converting the stream, intermittently received from the heart, into a continuous flow. The walls of the medium sized to smallest arteries are mainly muscular. The smallest arteries are microscopic in size and known as **arterioles** [arteriolæ]. The muscular arteries are capable of general or local alterations of calibre regulated by the nervous system; they are thus largely concerned in the maintenance of the blood pressure and in the regulation of the volume of blood entering given localities under varying conditions. The veins have much thinner walls than the arteries; the blood in them is under low tension upon which they exercise little or no control.

When an artery divides, the combined calibre of its branches is greater than that of the vessel itself. Since the arteries divide repeatedly the bed of the blood-stream increases in proportion as the vessels diminish in size. The rate of increase, slow at first, becomes enormous in the arterioles. Conversely, the bed of flow undergoes contraction as the heart is approached from the venous side. The velocity of flow in the capillaries must necessarily be much lower

* In the spleen and bone marrow the blood-channels intermediate between the arteries and veins are possible exceptions to this statement, but the essential conditions here are still imperfectly understood.

than in the great arteries and veins. From the relative slowness of the blood flow in the systemic capillaries, it has been estimated that their total bed is eight hundred times greater than the bed of the main arterial stem.

Variations in the course and arrangement of the adult arteries and veins, originally studied by the surgeon for utilitarian purposes only, now furnish one of the most stimulating fields for anatomical research. Text-books can provide, at best, catalogues of the arrangement commonly found in the adult body and of the most ordinary variations. That no text-book description can fit any individual case in all particulars, and that unusual distribution of vessels does not necessarily shorten life are among the earliest lessons learned in the anatomical laboratory. The adult vascular pattern is derived from a symmetrical arrangement in the early embryo of which scarcely a trace remains. The intervening changes are so numerous and profound that the general uniformity of vascular distribution in different individuals is more remarkable than the occurrence of occasional wide variations from the usual type.

In early stages of development all vessels have a similar structure; they consist, in fact, of a single layer of endothelium. Some vessels, however, are larger than others; these act as arteries or veins (according to the direction of flow) while the smaller channels perform the office of capillaries. The early principal vessels do not necessarily persist, for many of these dwindle or are lost. New channels are meanwhile in continuous process of formation and some of these may, in turn, become main channels. It thus follows that the main vessels of the adult must be looked upon rather as selected channels through a plexus of possible pathways, than as separate entities which must necessarily conform to given rules of distribution and branching.

In time, no doubt, most of the commoner variations from the usual adult type will receive a rational explanation; at present enough has been done to indicate the value of the embryological method. The list of variations in the arteries and veins respectively is preceded by a brief account of the morphogenesis of these vessels.

In the case of the heart anomalies frequently result in early death, so that subjects of developmental irregularities are seldom seen in the anatomical laboratory. The anomalies usually consist in improper development of the septa which normally divide the heart and main arterial trunk into their pulmonary and systemic halves. A short account of the morphogenesis of the heart is appended to the description of the adult organ.

In the following section the heart and pericardium will first be considered followed by the arteries and veins.

A. THE HEART AND PERICARDIUM

1. THE HEART

The **heart** [cor] is a hollow organ principally composed of muscle, the **myocardium.** It is lined internally by **endocardium** which is continuous with the intima of the blood-vessels. Externally, it is covered by the **epicardium,** a serous membrane continuous with the serous lining of the pericardium. The form of the heart, when removed from the body without previous hardening, is that of a fairly regular truncated cone. The **base** [basis cordis] is poorly circumscribed but corresponds, in a general way, to the area occupied by the roots of the great vessels and the portion of the heart-wall between them. The base of the heart is held in position* chiefly by the great vessels, which are attached to the pericardium; the remainder of the organ is capable of free movement within the pericardial cavity.

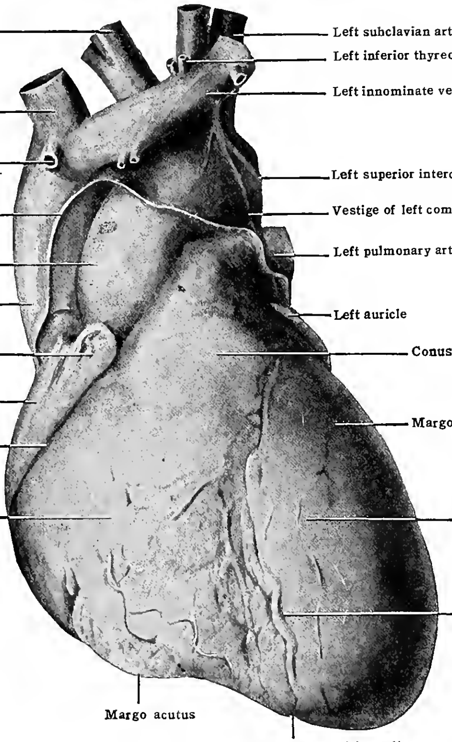
The interior of the heart is longitudinally divided, into right and left cavities, by a septum passing from base to apex. Each cavity is subdivided into an **atrium** [atrium cordis] and a **ventricle** [ventriculus cordis], the former receiving the ultimate venous trunks and the latter giving rise to the main arteries. Thus the left atrium receives the four pulmonary veins, and the right atrium the superior and inferior vena cava and the coronary sinus; the aorta issues from the left ventricle and the pulmonary artery from the right. The ventricles, which constitute the major portion of the heart, may be recognised by their very thick walls. The atria have thinner walls and are less capacious than the ventricles; projecting from each is a diverticulum or **auricle** [auricula cordis]. The auricles (which receive their name from their resemblance to dog's ears) partially embrace the roots of the pulmonary artery and aorta.

Orientation of the heart.—The apex of the heart [apex cordis] points forward, to the left and downward. The base is directed backward, to the right and upward. The longitudinal axis of the heart forms an angle of about 40° with the horizontal plane and also with the median sagittal plane of the body.

* Not necessarily fixed, for during systole the base performs a greater excursion than does the apex.

The long axis of the heart is therefore slightly more horizontal than vertical, and slightly more antero-posterior than transverse. The atria are posterior to rather than above the ventricles. To arrive approximately at the longitudinal axis, it is necessary to select the central point of the base. By cutting the vessels short in several hearts, hardened by formalin before removal, a point immediately to the left of the left lower pulmonary vein was selected in determining the data above given. A steel pin was passed through this point to the apex cordis, and the angles controlled by frontal and transverse sections of the thorax. Mention of angular measurements of the axis of the heart could be found only in the text-books of Testut and Luschka; the former gives 40° to the horizontal plane, the latter 60° to the mid-sagittal. Luschka's angle appear to be too large; but further investigation in this direction is desirable.

FIG. 423.—STERNO-COSTAL SURFACE OF THE HEART.



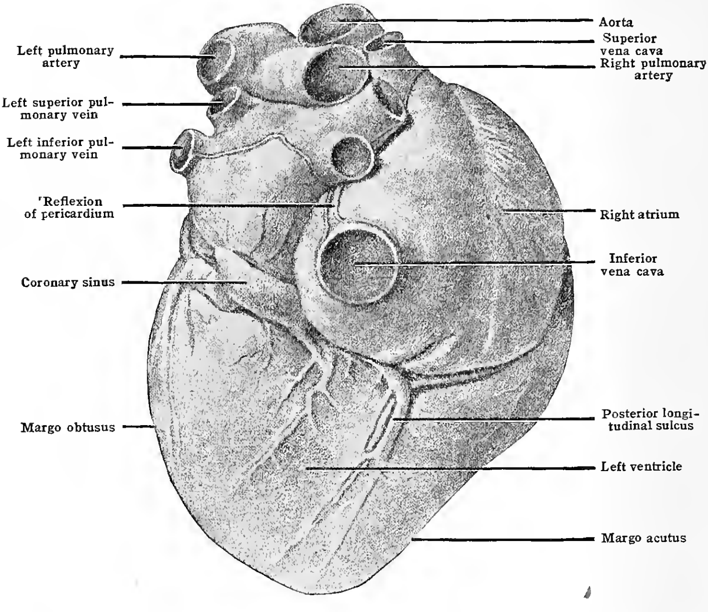
Size and weight.—In the adult the heart measures about 12.5 cm. (5 in.) from base to apex, 8.7 cm. ($3\frac{1}{2}$ in.) across where it is broadest, and 6.2 cm. ($2\frac{1}{2}$ in.) at its thickest portion. In the male its weight averages about 312 gm. (eleven ounces), and in the female about 255 gm. (nine ounces). It increases both in size and weight up to advanced life, the increase being most marked up to the age of twenty-nine years. The proportion of heart-weight to body-weight is about 1:205 in the adult.

EXTERIOR OF THE HEART

In hearts which have been hardened by injection before removal from the body, the regularity of the heart-cone is disturbed by a well-marked triangular facet, imparted by contact with the diaphragm. This facet is the **diaphragmatic surface** [facies diaphragmatica], which is directed downward and slightly backward (fig. 424). It ends abruptly along a sharp margin extending from the apex toward the right. This margin is the **margo acutus** (fig. 423); it separates the diaphragmatic surface from the sternocostal surface. The other margin of the diaphragmatic surface is more rounded and shades gradually into the very wide margo obtusus (fig. 423), which passes almost insensibly into the sternocostal surface. The convex **sternocostal** surface [facies sternocostalis] (fig. 423), directed forward and somewhat upward and to the right, is triangular and bounded below by the margo acutus. To the left it goes over into the margo obtusus along a line extending from the apex of the heart to the root of the pulmonary artery. The **margo obtusus** corresponds to the rounded left side of the left ventricle.

The interventricular sulcus is a slightly marked groove indicating the separation of the ventricles upon the exterior of the heart. It lodges coronary blood-vessels and a moderate quantity of fat which can be seen through the epicardium.

Fig. 424.—Base and Diaphragmatic Surface of the Heart. (After His.)



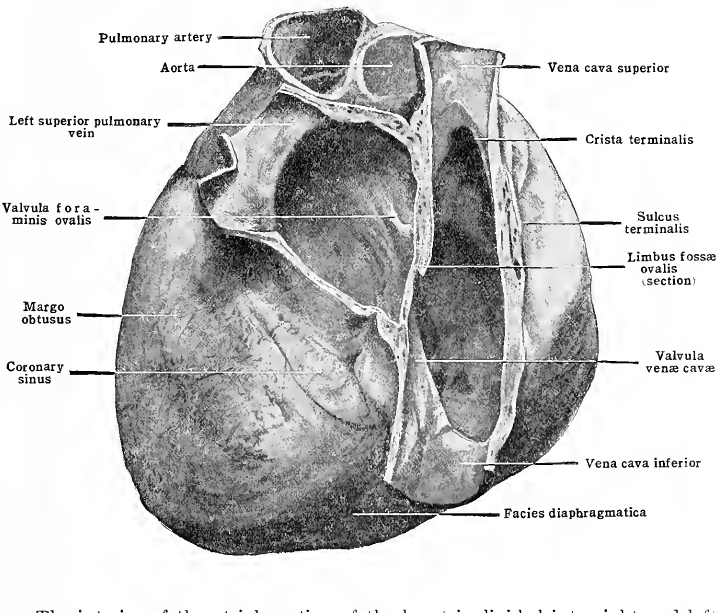
The anterior part of this groove, **sulcus longitudinalis anterior,** beginning posteriorly, runs obliquely over the upper part of the margo obtusus on to the sternocostal surface. Crossing the margo acutus to the right of the apex, it is continuous with the **sulcus longitudinalis posterior** upon the diaphragmatic surface. The diaphragmatic surface is formed about equally by the right and left ventricles, and the sterno-costal surface mainly by the right. Where the longitudinal sulcus crosses the margo acutus it produces a slight notch, the **incisura (apicis) cordis.**

The atria are separated externally from the ventricles by the **sulcus coronarius.** This is a horseshoe-shaped groove well marked below and laterally, and interrupted above by the roots of the pulmonary artery and aorta. It lodges the coronary sinus, smaller coronary vessels and fat.

ATRIAL PORTION

The **atrial portion of the heart** is situated behind, and slightly to the right of and above, the ventricular portion. The separation between the right and left atrium is not indicated behind except in distended hearts (such as that shown in fig. 424); in these it is marked by a slight groove connecting the left sides of the superior and inferior venæ cavæ. In front, the auricles are separated by the deep notch which lodges the aorta and pulmonary artery. A slight groove on the back of the right atrium which connects the right sides of the superior and inferior venæ cavæ, is the **sulcus terminalis** (figs. 424, 425). This represents the right limit of what was, in the embryo, the sinus venosus. It also indicates that the embryonic sinus venosus has become an integral part of the adult right atrium. The superior and inferior cavæ have each a nearly vertical direction and join the posterior part of the right atrium above and below, respectively. The coronary sinus runs downward, backward and to the right to join the lower part of the right atrium anterior to the inferior vena cava. The four pulmonary veins run nearly transversely and somewhat forward into the right and left sides of the left atrium.

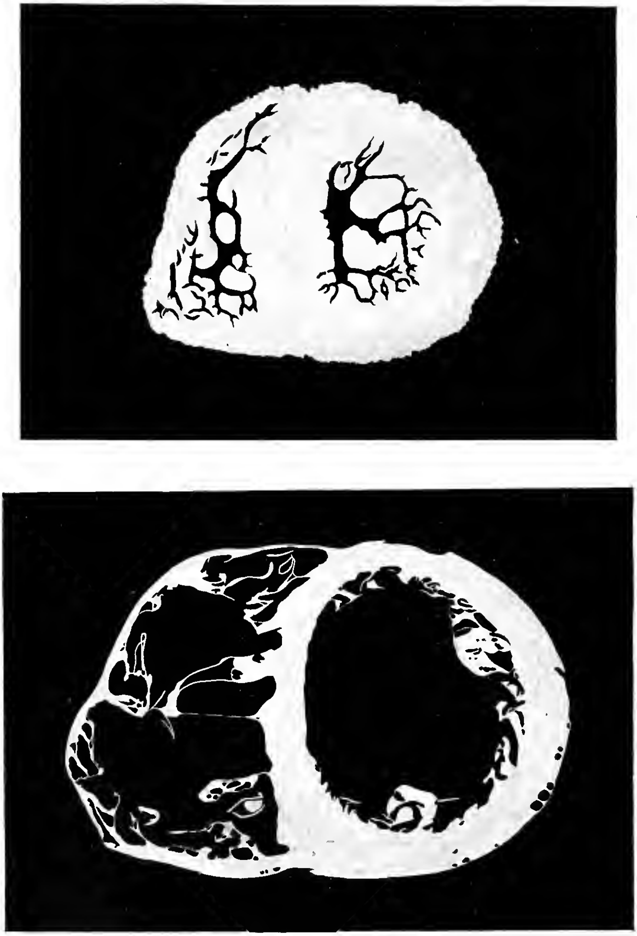
Fig. 425.—Atria Opened Posteriorly to show the Septum Atriorum.



The interior of the atrial portion of the heart is divided into right and left cavities by the **septum atriorum.** This septum is a composite structure, having been developed (see morphogenesis of the heart) in two independent parts, each forming an incomplete septum in itself. The two incomplete septa, however, partly overlap one another so that, by the lateral fusion at the time of birth, they together produce the impervious structure of the adult heart (fig. 425). Of these septa, the first to be formed is the **membranous septum** [pars membranacea septi atriorum]. Later there is formed to the right of this the muscular septum, the margin of which forms, in the adult atrium, the greater part of the **limbus fossæ ovalis.** The margin of the membranous septum is recognizable as a fold of endocardium on the septal wall of the left atrium; it is called the **valvula foraminis ovalis.**

Posteriorly into the **right atrium** [atrium dextrum (fig. 425)], above and below, respectively, open the superior and the inferior vena cava. Upon the septal wall, immediately above the inferior cava is the **fossa ovalis,** a depression of

FIG. 426.—SECTION OF THE VENTRICLES IN SYSTOLE AND DIASTOLE. (After Krehl.)

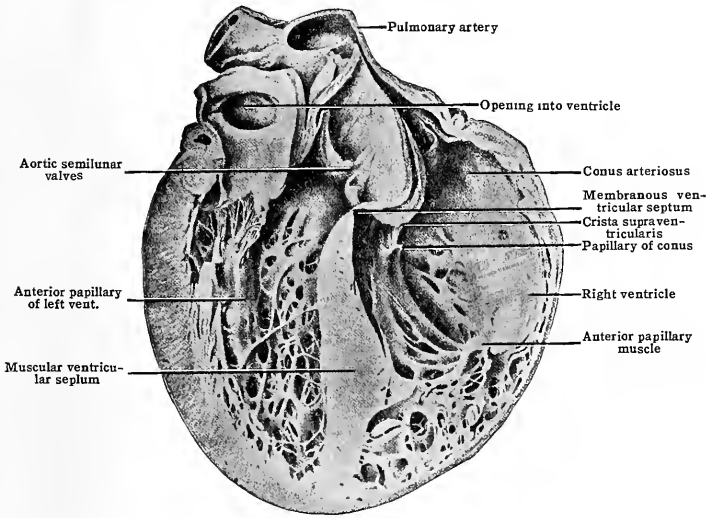


which the floor is formed by the membranous septum. Surrounding the fossa ovalis except below (indeed producing the fossa) is the limbus fossæ ovalis which is continuous anteriorly and below with the **valvula venæ cavæ** (inferioris Eustachii). Just anterior to the fossa ovalis is the orifice of the coronary sinus guarded by the **valvula sinus coronarii** (Thebesii) (fig. 428). Leading from the front of the atrium forward and slightly downward and to the left is the **ostium venosum** (right atrio-ventricular orifice) guarded by the tricuspid valve. Above and behind this is the auricle, the exterior of which is in contact medially with the root of the aorta. To the right of the superior and inferior caval orifices there is a vertical ridge, the **crista terminalis,** which corresponds to the sulcus terminalis on the exterior (figs. 425, 428).

The portion of the atrium medial to the crista is smooth and is called the **sinus venarum;** in the embryo it is separated from the atrial cavity proper by the right and left sinus valves. The crista terminalis marks the original line of attachment of the right sinus valve. The valve itself has disappeared, except at the lower part where it persists as the caval and coronary valves. These valves vary in size considerably in different specimens, and are frequently netlike from numerous perforations.

The conversion of a portion of a single valve into two separate valves, which meet at an acute angle, is brought about by an attachment between the sinus valve and an embryonic structure called the sinus-septum. This septum is a ridge dividing the right horn of the sinus venosus from the transverse portion of the sinus (the coronary of the adult); it probably con-

Fig. 427.—The Interior of the Ventricles, Anterior Half. (After His.)



tributes somewhat to the formation of both the coronary and caval valves. The left sinus valve usually disappears by blending with the septum atriorum on which it unites with the limbus fossæ ovalis; it occasionally remains partially separate in the adult.

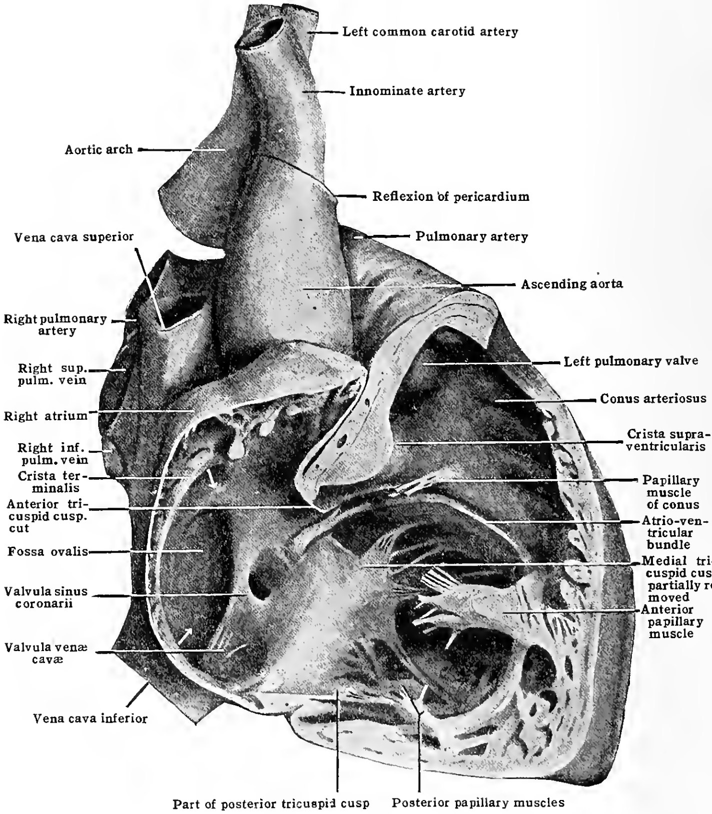
The interior of the right auricle and of the portion of the atrium lateral to the crista terminalis is thrown into ridges (**musculi pectinati**) by prominent bands of the atrial myocardium. The musculi pectinati end abruptly by joining the crista. The orifice of the superior cava has no valve and is directed downward and somewhat forward; below it, on the posterior wall of the atrium, there has been described a tubercle or ridge, the **tuberculum intervenosum** (Loweri).

Apart from the posterior circumference of the superior cava itself and the limbus fossæ ovalis, the human heart appears to contain nothing in this region that could be described as a tubercle. With regard to the segregation of the streams entering the fœtal right atrium from the superior and inferior cavæ, respectively, in which the tubercle of Lower has been supposed to participate, it is to be noted that the fossa ovalis is just above (almost within) the inferior caval orifice. Also that the caval opening and the fossal ovalis (containing the fœtal foramen ovale) are, in hearts well hardened before removal, situated in a distinct diverticulum to the left of the remainder of the atrium. Between this diverticulum and the atrium proper, the caval valve and the limbus fossæ ovalis form a prominent flange, better marked in the fœtus than the adult. Opening into the right atrium, particularly upon the septal and right lateral walls, are numerous *foramina venarum minimarum* (Thebesii).

The **left atrium** [a. sinistrum] (fig. 425) is to the left and somewhat posterior to the right. It is behind the root of the aorta and its auricle is to the left of the

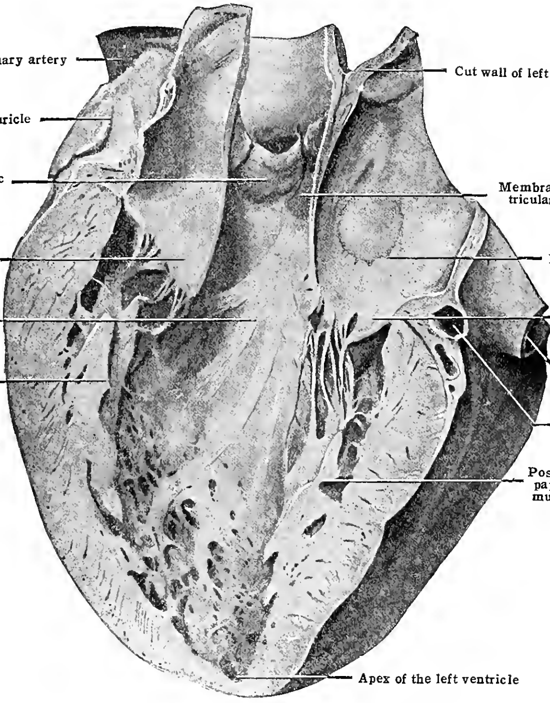
FIG. 428.—INTERIOR OF THE RIGHT ATRIUM AND VENTRICLE.

The atrio-ventricular bundle is dissected out.



pulmonary root. Opening into it posteriorly on the right and left sides, respectively, are the right and left upper and lower pulmonary veins. The valvula foraminis ovalis forms a more or less distinct crescentic ridge on the septal wall (fig. 425). This may not be attached to the limbus fossæ ovalis, in which case there is a communication between the two atria. Absence of lateral adhesion between the two septa atriorum does not necessarily lead to admixture of arterial and venous blood during life. The left **ostium venosum** (atrio-ventricular orifice) guarded by the mitral valve leads from the anterior part of the atrium forward and slightly downward and to the left. The interior of the left atrium is smooth except in the auricle, in which musculi pectinati are well marked.

Fig. 429.—Left Ventricle and Part of the Atrium.
The aorta is opened through the anterior cusp of the mitral valve. The plainly visible left limb of the atrio-ventricular bundle has been accentuated.



ATRIO-VENTRICULAR VALVES

The **atrio-ventricular valves** (figs. 427, 428, 429, 431) are attached around the venous ostia of the ventricles in such a way as to open freely into the ventricles, but to prevent regurgitation of the blood into the atria during ventricular systole. Each valve is continuous along its line of attachment, but its free edge is notched so as to produce an irregular margin; some of the notches are so deep as to partially divide the valve into cusps. The right atrio-ventricular valve is commonly divided by three deep notches into three cusps; this valve is therefore called the **tricuspid** [valvula tricuspidalis]. The left is similarly divided into two cusps and is called the **bicuspid** [v. bicuspidalis] or **mitral**. The depth of the notches, however, is very variable and there may be an increase or (more rarely) a diminution in the number of cusps; the addition of small subsidiary cusps is quite common. Each valve cusp is tied down to the **papillary muscles** [mm. papillares] of the ventricle by **chordæ tendineæ**. The latter are fibrous cords, generally branched, of varying thickness. The thinnest cords are attached to the free margin of the cusp; those of intermediate thickness to the ventricular surface a few millimetres from the margin, and the thickest to the ventricular surface near the attached margin. The valves are smooth and glistening on the atrial aspect, but rough and fasciculated, from the attachment of the chordæ, on the ventricular. The cusps of the *mitral valve* are called *anterior* and *posterior;* those of the *tricuspid, anterior, posterior* and *medial.* Each cusp receives chordæ from more than one papillary muscle and each papillary muscle sends chordæ to more than one cusp. The chordæ tendineæ of the mitral valve are thicker than those of the tricuspid (figs. 428, 429).

VENTRICULAR PORTION

The **ventricles** form the greater portion of the heart. In the adult the relation of the ventricles to one another is as follows. The left [ventriculus sinister] has the form of a narrow cone, the apex of which is the apex of the heart. The right ventricle [ventriculus dexter] is crescentic in section and appears to be partially wrapped around the right or lower wall of the left ventricle which forms the septum ventriculorum (fig. 426). The **left ventricle** forms the margo obtusus of the heart, about half the diaphragmatic surface, and a slight part of the sterno-costal surface. The **right ventricle** forms about half the diaphragmatic surface and the major part of the sterno-costal surface; it takes no share in the formation of the apex of the heart.

The **interventricular septum** [septum ventriculorum] is thick and muscular except for a small area near the root of the aorta which is membranous [septum membranaceum ventriculorum]. The latter can be seen from the left ventricle in the angle between the attached edges of the right and posterior aortic valves (fig. 429). The membranous septum is partly concealed from the right heart by the medial cusp of the tricuspid valve which is attached to it near its upper part. The portion of the membranous septum above the medial tricuspid cusp is therefore atrio-ventricular, i. e., between the right atrium and left ventricle.

The membranous septum is the extreme lower part of the independent septum (s. aorticum) which divides the aortic root from the pulmonary artery and conus arteriosus (and partially subdivides, also, the right ventricle by separating the conus arteriosus from the remainder of the ventricle). The relation of the part of the aortic septum between the conus arteriosus and aortic root to the septum ventriculorum is beautifully shown by His, in fig. 427.

The greater part of the interior of the ventricles is thrown into ridges by myocardial bundles of large size. These fasciculi [**trabeculæ cordis**] either stand out in relief only, or, by being undermined, form bands covered except at either end by endothelium. A careful examination of the endocardium of fresh hearts will reveal a plexiform network of **Purkinje fibres.** These fibres, belonging to the atrio-ventricular conducting system, become very obvious when the endocardium has been exposed to the air long enough to become partially dry.

The wall of the **right ventricle** [ventriculus dexter] (figs. 427, 428) is much thicker than that of the atria, but less so than that of the left ventricle. The upper and anterior part of the right ventricle is in relation posteriorly with the root of the aorta. This portion of the ventricle is called the **conus arteriosus** and is separated from the remainder of the right ventricle by a muscular spur which extends from the back of the conus to the right venous ostium. The spur is the **crista supraventricularis;** its relation to the partition between the conus and aorta, and to the septum membranaceum, shows that it is the free edge of the embryonic aortic septum (see morphogenesis of the heart).

Two papillary muscles in the right ventricle are constant in position, the large **anterior papillary muscle,** and the small **papillary muscle of the conus** (Luschka). The anterior papillary is situated on the sterno-costal wall, near the junction of this with the septal wall. The papillary of the conus is placed just below the septal end of the crista supraventricularis. The **posterior papillary muscles** form an irregular group springing from the diaphragmatic wall. Some chordæ tendineæ stretch directly from the septal wall (with or without small muscular elevations at their bases) to the medial cusp of the tricuspid valve. The chordæ tendineæ from the anterior papillary go to the anterior and posterior cusps; those from the conus papillary to the medial and anterior, and those from the posterior papillary muscles to the medial and posterior cusps of the tricuspid valve, respectively.

There is frequently a band of myocardium extending from the septal wall of the right ventricle to the anterior papillary muscle near its middle. This is the **moderator band,** which contains a part of the right limb of the atrio-ventricular bundle. If the moderator band joins the anterior papillary near its base, as it frequently does, it is difficult to distinguish it from the ordinary trabeculæ in this situation.

The term moderator band was originally applied to this bridge or band of muscle under the impression that it prevented overdistention of the ventricle. Subsequent discovery of the conducting system of the heart makes it plain that there is always a band conducting the right limb of the atrio-ventricular bundle from the septum to the anterior papillary muscle. Whether the band is isolated from the other trabeculæ, and therefore readily recognizable, appears to depend somewhat upon the relation of the base of the papillary muscle to the septum ventriculorum.

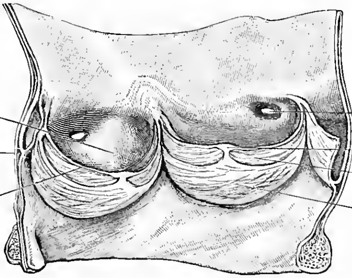
The wall of the **left ventricle** [ventriculus sinister] (figs. 427, 429) is very thick except at the extreme apex, and at the membranous septum. In the left ventricle are two large papillary muscles, generally known as **anterior** and **posterior**; both send chordæ tendineæ to each cusp of the mitral valve. On the septal wall of the ventricle the left limb of the atrio-ventricular bundle can usually be seen as a broad, flattened band beneath the endocardium. The band appears just below the septum membranaceum and divides into strands which go to the two papillary muscles. The strands in many places bridge across part of the ventricle to reach the papillary muscles covered only by tubes of endocardium.

These bridging strands connecting the papillary muscles with the septum ventriculorum, which were formerly called "false chordæ tendineæ," are exactly comparable to the moderator band of the right ventricle which occasionally consists of atrio-ventricular bundle and endocardium only.

SEMILUNAR VALVES

The **semilunar valves** [valvulæ semilunares] guard the arterial ostia of the ventricles. The aortic ostium is directed upward and slightly forward and to the right; the pulmonary backward and slightly upward and to the left. Each valve, of which there are three to each ostium, is a pocket-like fold of endocardium strengthened by fibrous tissue (fig. 430). The free edge of each valve is directed away from the ventricle, so that excess of pressure within the great vessels brings

Fig. 430.—Interior View of the Aortic Semilunar Valves.



the three valves of either ostium into mutual apposition. In the middle of the free edge of each valve there is a small fibro-cartilaginous **nodule**; radiating from this toward the entire fundus, and along the extreme free edge of the valve, are fibrous thickenings. On either side of the nodule, between the thicker margin and fundus, the valve is thin over a crescentic area called the **lunula**.

The aortic valves are called the right, left, and posterior; the pulmonary valves, the right, left, and anterior.* The aortic semilunar valves are stronger than the pulmonary; opposite them there are three dilatations in the aortic wall, the aortic

* The BNA names of the aortic and pulmonary valves are not based upon their relative positions in the body. From transverse sections through the thorax (see any good atlas) it may be seen that one aortic valve is anterior, one pulmonary valve posterior, and the other aortic and pulmonary valves are right and left. If the removed heart is held so that the ventricles are on the right and left of the septum, respectively, the valves take the positions indicated by the BNA. The names given by the BNA to the valves, although conventional (like many other terms of orientation applied to parts of the heart), are convenient, particularly from a developmental standpoint.

sinuses [**sinus aortæ**] or sinuses of Valsalva. From the right and left sinuses the right and left coronary arteries, respectively, arise.

After ventricular systole the increased pressure in the great vessels distends the valves with blood. The noduli meet in the centre and the lunulæ, coming into mutual contact, produce a tri-radiate line of contact between the valves.

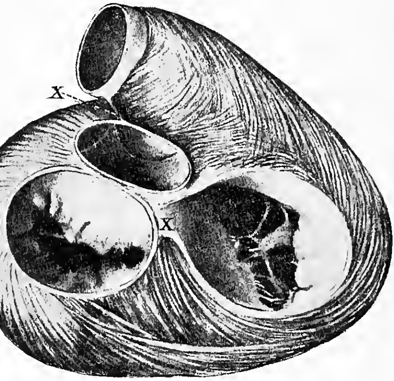
ARCHITECTURE OF THE MYOCARDIUM

In the adult heart the myocardium of the atria is separate from that of the ventricles. There is, between the atria and ventricles, a fibrous partition, the upper and lower surfaces of which give attachment to the muscle fibres of these cavities, respectively.

The **fibrous partition** (fig. 431) is thickest in the triangle formed by the meeting of the aortic, and right and left atrio-ventricular ostia. This interval is filled by a mass of fibrous tissue, which in the angles between the aortic and the left atrio-ventricular ostium forms two thickened triangular masses, the **trigona fibrosa.** The fibrous mass is continued to the pulmonary ostium as the **tendon of the conus.** Below the point of junction of the trigona and the tendon of the conus these structures blend with the septum membranaceum ventriculorum. The septum membranaceum, tendon of the conus, and part of the trigona are derived from the aortic septum (pp. 516, 527). The trigona give off laterally, on either side, atrio-ventricular rings which encircle the venous ostia and give attachment to the atrio-ventricular valves. There are also weak

Fig. 431.—Base of a Well Developed Heart showing the Course of the Superficial Muscle Fibres.

From X to X′ around the front of the aorta indicates the course of the aortic septum. (Mall, $\frac{3}{4}$ nat. size.)



rings surrounding the pulmonary and aortic orifices; the aortic and left atrio-ventricular rings being partly confluent. The rings surrounding the arterial and venous ostia are the **annuli fibrosi.**

The **atrial musculature** is attached to the trigona and atrio-ventricular rings only. The superficial fibres are attached to both rings and either encircle both atria in one loop, or enter the septum and form a figure 8. The deeper fibres are attached to one ring and encircle one atrium only; some fibres encircle only the auricle.

The **ventricular musculature** is very complex and consists of numerous superimposed layers distinguished from one another by the direction taken by the muscle fibres. In a general way, the fibres of the deepest layer have a direction crossing those upon the surface of the same area at a right angle. The intervening layers of fibres pass through all stages of obliquity.

Recent work upon the origin and distribution of the ventricular fibres has resulted in the recognition of a certain uniformity of behavior, thus:—

1. All fibres arise from, and are inserted into, the fibrous partition at the base. The attachment may be directly to the trigona or annuli, or indirectly to them by means of the chordæ tendineæ and atrio-ventricular valves.

2. The more superficial fibres (fig. 432) tend to encircle the entire heart, passing over the longitudinal sulci. If they enter the septum they do so by passing into the vortex or whorl at the apex of the left ventricle. These fibres have always a definite direction upon the surface, i. e., from right to left upon the sterno-costal surface and from left to right on the diaphragmatic (fig. 431).

3. The deeper fibres all enter the septum in a direction oblique or perpendicular to its longitudinal axis. In addition they completely encircle one or both ventricles forming, in the latter case, double loops (fig. 433).

During systole, as a result of this arrangement:—(1) The papillary muscles and the longitudinal and antero-posterior axes of the ventricles are simultaneously shortened. (2) There is a movement of torsion or "wringing" which reduces the ventricular cavities to their minimum dimensions.

Conducting system.—Although the ordinary myocardium of the atria is distinct from that of the ventricles there is, at one place, a connection between them. This connection is by means of a small band of muscle which differs histologically from ordinary heart muscle. It is known as the **atrio-ventricular bundle,** and serves to transmit the atrial rhythm of contraction to the ventricles.

The atrio-ventricular bundle begins in the septal wall of the atrium a short distance in front of the coronary orifices (fig. 428). It has an expanded free end, the **atrio-ventricular node,** from which branches pass to be quickly lost in the atrial myocardium. The bundle passes forward covered by endocardium and by one or two millimetres of myocardium, and passes beneath the medial cusp of the tricuspid valve. In passing from the atrium to the ventricle, the bundle skirts the lower margin of the septum membranaceum. Immediately in front of the septum membranaceum it divides into a left and right limb, of which the former pierces the muscular interventricular septum. The right limb now passes beneath the crista supraventricularis and above the papillary muscle of the conus, giving off branches to the latter and to other small papillaries on the septum (fig. 428). Bending somewhat toward the apex, it enters the moderator band which conducts it to the large anterior papillary muscle. From here it passes along one of the trabeculæ connected with the sterno-costal wall of the ventricle, or in the wall itself, to reach the posterior papillary muscle or muscles. The right limb is compact and rounded and in the intact heart is usually invisible except, sometimes near the root of the moderator band or in the band itself.

The left limb of the bundle appears in the left ventricle a little below the septum membranaceum. It is a wide band immediately beneath the endocardium, which cannot usually be

Fig. 432.—Diagram of one Anterior and one Posterior Superficial Bundle of Cardiac Muscle Fibres seen from Behind. (After MacCallum.)

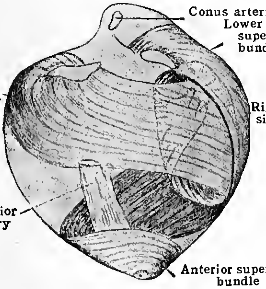


Fig. 433.—Diagram of a Deeper Bundle of Muscle Fibres. (After MacCallum.)

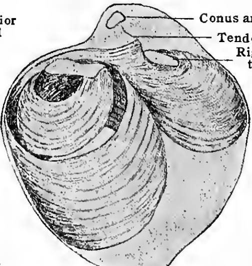


stripped off without injuring the bundle (fig. 429). It passes along the septal wall toward the apex and divides into two parts, which again subdivide to be distributed to the anterior and the posterior papillary muscles. The branches for the papillary muscles may reach them through thick trabeculæ, or they may form thin strands which, covered only by endocardium, bridge from septum to papillary muscle.

In addition to the comparatively distinct branches to the papillary muscles of both ventricles, the bundle gives off finer fibres which form a sub-endocardial plexus. This plexus, visible to the naked eye (p. 516) is made up of fibres having a structure similar to those of the ventricular portion of the bundle. The fibres were described by Purkinje as long ago as 1845,* but it was not until 1906, thirteen years after the discovery of the bundle by W. His, Jr., that Tawara† recognised their significance.

There is another node of muscle having characters similar to that of the conducting system, although not connected with it except by myocardium of the ordinary character. This is the sinus-node which is situated at the upper end of the crista terminalis of the right atrium. Unanimity is still lacking with regard to the physiological significance of this structure.

Vessels and Nerves of the Heart

The arteries.—The two coronary arteries arise from the right and left sinuses of the aorta.

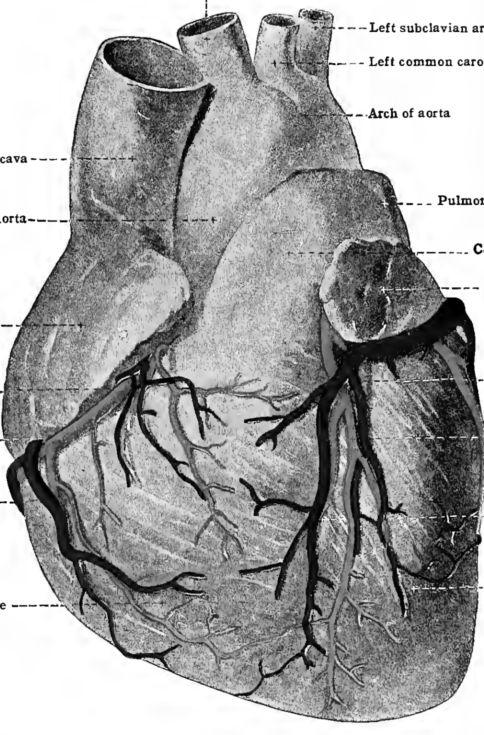
The **right coronary** artery [a. coronaria dextra] passes forward between the pulmonary artery and the right atrium, and then follows the right coronary sulcus to the diaphragmatic surface of the heart (fig. 435), to anastomose with the left coronary artery. The **posterior descending** branch [ramus descendens posterior] arises at the posterior longitudinal sulcus. It

* Arch. f. Anat., Physiol. u. wissenschaftliche Medizin.
† Das Reitungssystem des Saügertierherzens, Fischer, Jena, 1906.

passes in the furrow between the ventricles toward the apex, near which it anastomoses with branches derived from the left coronary artery. In this course the right coronary artery supplies branches to the right atrium and roots of the pulmonary artery and aorta, as well as one that descends near the margo acutus (**right marginal**), and a second (**preventricular**) to the anterior wall of the right ventricle. It supplies both ventricles and the septum.

The **left coronary artery** [a. coronarius sinistra] passes for a short distance forward, between the pulmonary artery and the left auricle, and then divides into two principal branches, one of which runs in the anterior longitudinal sulcus to the apex of the heart, the **anterior descending** branch [r. descendens anterior], around which it sends branches to anastomose with the right coronary; whilst the other, the **circumflex** [ramus circumflexus], winds to the diaphragmatic surface in the coronary groove, to anastomose with the corresponding twigs of the right artery. In this course it gives off a branch which follows the margo obtusus (**left marginal**) as well as smaller branches to the left atrium, both ventricles, and the commencement of the aorta and pulmonary vessels.

Fig. 434.—Sterno-costal Surface of the Heart, showing its Arteries and Veins. (After Spalteholz.)



The **cardiac** or **coronary veins** accompany the coronary arteries and return the blood from the walls of the heart.

The **great cardiac vein** [v. cordis magna], (fig. 434) runs in the anterior longitudinal sulcus, passing round the left side of the heart in the coronary sulcus to terminate in the commencement of the coronary sinus. Its mouth is usually guarded by two valves, and it receives in its course the posterior vein of the left ventricle, with other smaller veins from the left atrium and ventricle, all of which are guarded by valves.

The **middle cardiac** vein (v. cordis media], sometimes the larger of the two chief veins, communicates with the foregoing at its commencement above the heart's apex. It ascends in the posterior longitudinal groove, receiving blood from the ventricular walls, and joins the coronary sinus through an orifice guarded by a single valve, close to its termination.

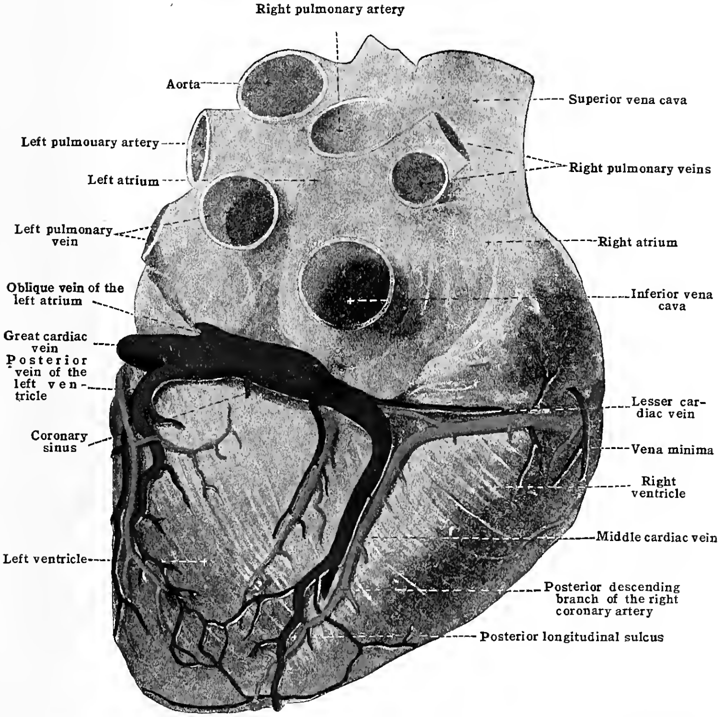
The **posterior vein of the left ventricle** [v. post. ventriculi sinistri], lies upon the posterior surface of the ventricle and, receiving branches from it, passes upward to terminate directly in the coronary sinus.

The **anterior cardiac** veins [vv. cordis anteriores] consist of several small branches from the front of the right ventricle, which vary in number and either open separately into the right atrium or join the lesser cardiac vein (fig. 434).

The **small cardiac** vein [v. cordis parva] is a small vessel which receives branches from both the right atrium and ventricle, and winds around the right side of the heart, in the coronary sulcus, to terminate in the coronary sinus.

The **coronary sinus** [sinus coronarius] (fig. 435) may be regarded as a much dilated terminal portion of the great cardiac vein. It is about 2.5 cm. (1 in.) in length, is covered by muscular fibres from the atrium, and lies in the coronary sulcus below the base of the heart. Its cardiac orifice, with the coronary (Thebesian) valve, has already been described. Besides the tributary veins already named, a small **oblique vein** [v. obliqua atrii sinistri] of the left atrium may some-

FIG. 435.—BASE AND DIAPHRAGMATIC SURFACE OF THE HEART, SHOWING ITS ARTERIES AND VEINS. (After Spalteholz.)



times be traced, on the back of the left atrium, from the ligament of the left vena cava (Marshall) to the sinus. This little vein, which is not always pervious or easy of demonstration, never possesses a valve at its orifice, and, like the coronary sinus, formed a part of the left superior vena cava of early fœtal life.

The **smallest cardiac** veins [vv. cordis minimæ] drain blood from septum and lateral walls of the atria, particularly the right; also from the conus arteriosus. They open directly into the right atrium.

Although *anastomoses* occur between the two coronary arteries, these are by no means extensive, and are not sufficient to allow of the establishment of a satisfactory collateral circulation in the case of the blocking of one coronary artery. Consequently such interference with the cardiac circulation produces rapid pathological changes in the heart musculature, provided it is sudden in occurrence. If the obliteration of the artery take place gradually, however, some relief may be afforded by the establishment of a collateral circulation through the venæ minimæ, which open out from both the atrial and ventricular cavities and communicate with the finer branches of the cardiac veins, and also with the general capillary network in the heart's walls.

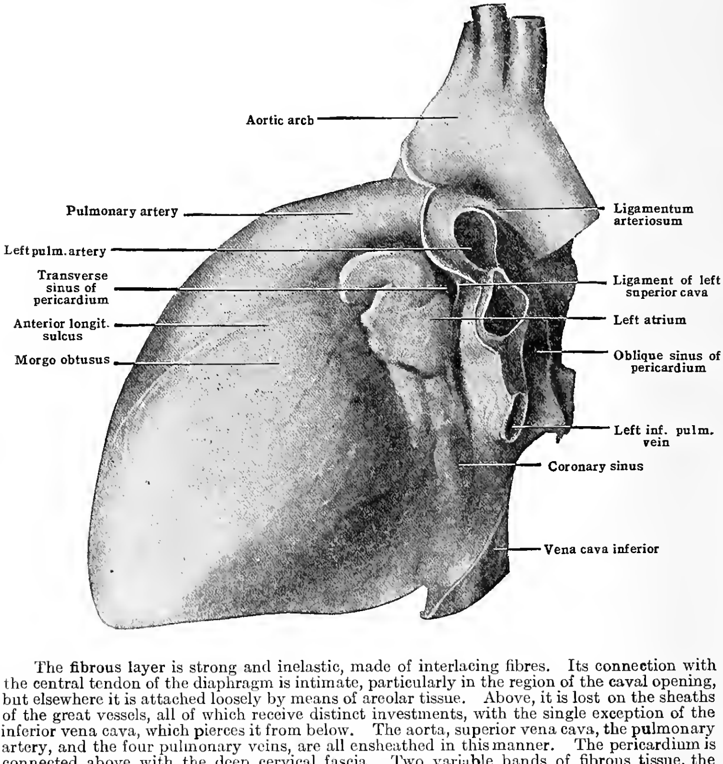
The **lymphatic** vessels of the heart pass chiefly through the anterior mediastinal lymph-nodes into the broncho-mediastinal trunk. (See Section VI.)

The **cardiac nerves**, derived from the vagus and the cervical sympathetic, descend into the superior mediastinum, passing in front of and behind the arch of the aorta; they unite in the formation of the superficial and deep cardiac plexuses. The superficial plexus lies above the right pulmonary artery as the latter passes beneath the aortic arch. The deep plexus lies between the trachea and the arch of the aorta, above the bifurcation of the pulmonary trunk. For the connections of the plexuses see section on Nervous System.

2. THE PERICARDIUM

The **pericardium** is a cone-shaped, fibro-serous sac which surrounds the heart and contains a small amount of fluid [liquor pericardii]. Its apex is above at the root of the great vessels, and its base below, adherent to the diaphragm. Its connection with the diaphragm is in part to the central tendon and in part to the muscle, especially on the left side. It consists of an outer *fibrous* layer and an inner *serous* layer. The virtual space between the serous pericardium and the epicardium is commonly called the *pericardial cavity*.

Fig. 436.—Left Posterior View of the Heart to show the Reflections of the Pericardium.



The **fibrous** layer is strong and inelastic, made of interlacing fibres. Its connection with the central tendon of the diaphragm is intimate, particularly in the region of the caval opening, but elsewhere it is attached loosely by means of areolar tissue. Above, it is lost on the sheaths of the great vessels, all of which receive distinct investments, with the single exception of the inferior vena cava, which pierces it from below. The aorta, superior vena cava, the pulmonary artery, and the four pulmonary veins, are all ensheathed in this manner. The pericardium is connected above with the deep cervical fascia. Two variable bands of fibrous tissue, the **sterno-pericardial ligaments** [ligg. sterno-pericardiaca], connect the front of the pericardium, above and below, with the posterior surface of the sternum.

The serous layer is smooth and glistening and consists of connective tissue, rich in elastic fibres, covered by endothelium. It lines the interior of the fibrous layer and is continuous with the epicardium or serous covering of the heart. The reflexion of the serous layer from the heart to the fibrous layer of the pericardium occurs at both the arterial and venous attachments of the heart. At the arterial attachment a simple tube of epicardium is reflected along the pulmonary artery and aorta. At the venous attachment the serous layer is reflected from the front of the pulmonary veins on the left, and from the front of these and from the roots of the venæ cavæ on the right. This reflexion is separated above from that around the aorta and pulmonary artery (figs. 424, 436). Around the lower margin of the left lower pulmonary vein (fig. 436) and the root of the inferior vena cava, this reflexion is continuous with an arched reflexion from the back of the atria (figs. 424, 436). The latter reflexion forms a pocket posterior to the atria which is sometimes called the *oblique sinus* of the pericardium.

Between the reflexions of the epicardium at the arterial and venous attachments of the heart there is a dorsal communication between the right and left sides of the pericardial cavity. This is the **transverse sinus** of the pericardium [s. transversus pericardii]; it passes behind the aorta and pulmonary artery and in front of the superior cava and left atrium.

During early embryonic life the sinus transversus is closed by the dorsal mesocardium (see p. 527). The primitive ventral mesocardium, which divides the right and left sides of the pericardial cavity ventrally, is lost very early.

The **ligament of the left superior cava** [lig. venæ cavæ sinistræ] (figs. 423, 436) is a doubling of the serous layer which passes between the left pulmonary artery above and the left superior pulmonary vein below. It contains, besides some fatty and areolar tissue, the shrunken remains of the left superior vena cava. It is usually connected above with the left superior intercostal vein by means of a small tributary of the latter. Passing from its lower end to the left end of the coronary sinus is the small **vena obliqua atrii sinistri** (oblique vein of Marshall). The root of the left superior intercostal (and the adjacent part of the left innominate) vein; the vein passing from the superior intercostal to the lig. venæ cavæ sinistræ; the oblique vein of the left atrium, and the coronary sinus all represent parts of the embryonic left vena cava superior.

Relations.—In front of the pericardium are found the thymus gland or its remains, areolar tissue, the sterno-pericardial ligaments, the left transversus thoracis muscle, the internal mammary vessels, the anterior margins of the pleural sac and lungs, and the sternum. Laterally, it is overlapped by the lungs with their pleural sacs, and it is in contact with the phrenic nerves and their accompanying vessels. Posteriorly, it is in relation with the œsophagus and vagus nerves, the descending aorta, the thoracic duct and vena azygos, and the roots of the lungs. Below it is separated by the diaphragm from the stomach and the left lobe of the liver.

Vessels.—The arteries of the pericardium are derived from the pericardiac, œsophageal, and bronchial branches of the thoracic aorta and from the internal mammary and phrenic arteries.

RELATIONS OF THE HEART AND PERICARDIUM TO THE THORACIC WALL

Heart (fig. 437 A and B).—The **base** of the heart corresponds *posteriorly* to the fifth, to the ninth thoracic vertebræ. *Anteriorly* the **apex** is in the fifth intercostal space, 7.5 to 8 cm. (3 to 3¼ in.) from the medan line. The **base** (above) corresponds to a line (A) drawn from a point 1 cm. (⅖ in.) below the second left chondro-costal articulation,and 3 cm (1⅕ in. from the median line, to another point (the same distance from the median line) 1 cm. above the right third chondro-sternal articulation. The **margo acutus**, or lower border corresponds to a line (B) drawn from the apex through the xiphi-sternal articulation, to a point on the sixth costal cartilage 2 cm. to the right of the median line. The **right border** of the heart may be indicated approximately by a line (slightly convex to the right) joining the right ends of A and B. The **left border** corresponds to a line (slightly convex to the left) joining the left end of A to the apex.

If a line be drawn from the upper margin of the left third chondro-sternal articulation to the right edge of the sternum in the fifth intercostal space, the upper end of the line will lie over the centre of the **pulmonary ostium,** and the lower two-thirds of it (approximately) will overlie the main axis of the **tricuspid ostium.** The **aortic ostium** is immediately to the left of the above line with its centre at the left edge of the sternum opposite the third space. The **mitral ostium** is very largely behind the third left interspace; its upper end is behind the third cartilage, its lower behind the left margin of the sternum opposite the fourth cartilage and space.

Of the ostia of the heart, the pulmonary is nearest the anterior thoracic wall, the aortic is slightly in advance of the mitral, and the tricuspid is the deepest of all.

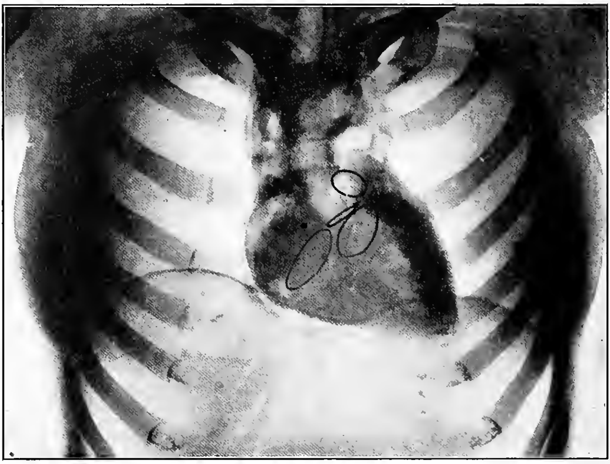
The **pericardium** follows the heart closely. The upper end (apex) in the subject used in preparing fig. 437 extended up, behind the sternum, to the lower margin of the first costal cartilage on the right and the upper margin of the second on the left.

MORPHOGENESIS OF THE HEART AND PERICARDIUM

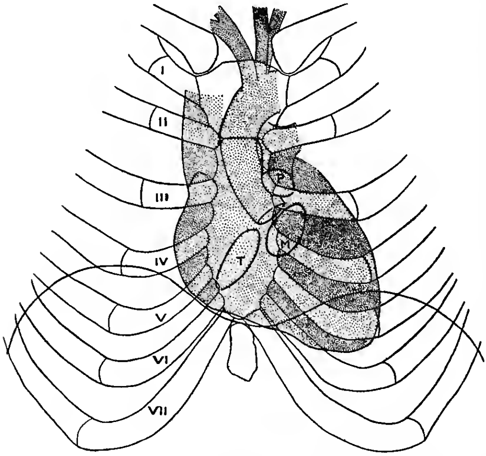
The heart is formed by the blending in the median line of two longitudinal endothelial tubes lying ventral to the fore-gut of the early embryo. Each tube is partially surrounded laterally by the splanchnic mesoderm which forms a septum between the right and left sides of

Fig. 437.—A, Teleroentgenogram of a Formalin Preparation of the Anterior Thoracic Wall with the Heart, Pericardium and Diaphragm in situ. (Le Wald, × ⅓). B, Explanatory Outline Drawing, Traced from the Negative and Controlled by Stereoscopic Views.

The ostia have been accurately fitted with wire rings. P, pulmonary ostium; *M*, mitral; *T*, tricuspid; aortic ostium is unlabelled; I–VII, right costal cartilages.



A

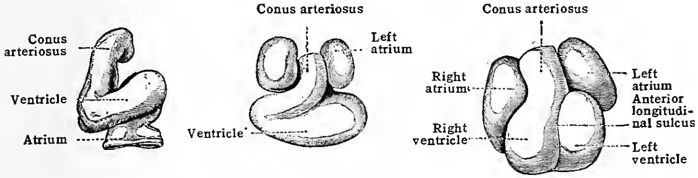


B

the cœlomic cavity. The blended endothelial tubes form the **endocardium.** The splanchnic mesoderm in relation to the endocardium becomes the **myoepicardium,** and the double layer connecting the heart dorsally and ventrally with the somatic mesoderm becomes the (temporary) dorsal and ventral mesocardia. The somatic mesoderm of the heart region becomes the **pericardium.**

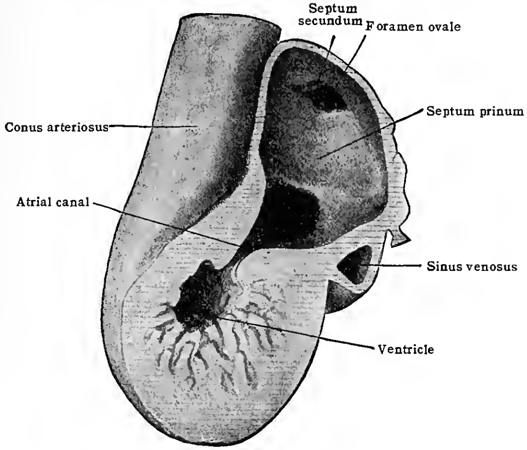
The originally straight heart-tube grows rapidly and becomes tortuous on account of its increasing length between the limits assigned by its fixed arterial and venous ends. Its arterial end is continued into the truncus arteriosus, which is later divided into the pulmonary artery and the ascending aorta. Its venous end receives the vitelline and umbilical veins, and, later on, the common cardinals also. By the formation of a series of alternate bulgings and constrictions the heart becomes differentiated into the sinus venosus, atrium, ventricle and conus arteriosus, counting from the venous to the arterial end. These parts, after going through a process of progressive differentiation and shifting (fig. 438) take up relative positions somewhat approaching those of the adult.

FIG. 438.—MODELS SHOWING THE DEVELOPMENT OF THE HEART. (After His.)



The sinus venosus lies on the dorsal wall of the atrium, and is composed of right and left horns united by a transverse portion. The sinus is separated from the atrium by a sagitally directed slit-like opening, guarded by right and left lateral valves which project into the atrium. The atrium is wide, being prolonged into a ventrally projecting pouch on either side, the future right and left auricles. The ventricle is situated caudal and somewhat ventral to the atrium. The right limb of the common ventricle, which leads into the conus arteriosus, is the future right ventricle; the left limb, connected with the atrium, is the future left ventricle. The

FIG. 439.—SAGITTAL SECTION THROUGH A RECONSTRUCTION OF THE HEART OF A 9 MM. HUMAN EMBRYO SEEN FROM THE LEFT SIDE. (Tandler, × 75.)



communication between the atrium and the ventricle, known as the atrial canal, is indicated on the exterior by a constriction; its interior consists of a transversely placed slit. The conus arteriosus is continued from the ventricle without obvious constriction and passes over into the truncus arteriosus.

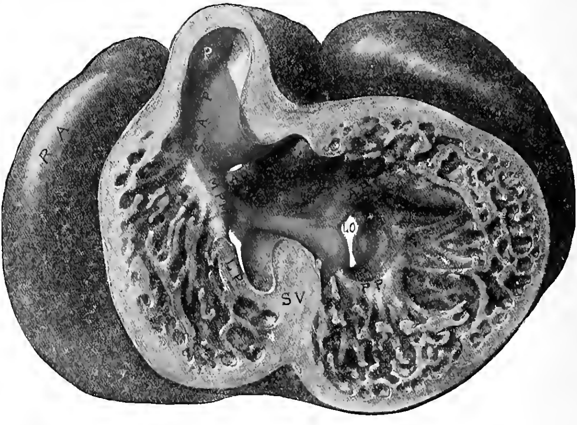
The sinus venosus early loses its bilateral symmetry owing to the rapid enlargement of the right horn. This horn soon receives, through the proximal portion of the right vitelline vein (*inferior vena cava*), all the blood coming from the left vitelline and both umbilical veins. The right common cardinal also gains ascendency over the left and becomes the *superior vena cava.*

The left horn and transverse part, now only draining the dwindling left common cardinal, (*left superior cava*) and the coronary veins, become the *coronary sinus*. The right horn gradually becomes absorbed into the right end of the atrial cavity until the superior and inferior cavæ and the coronary sinus acquire separate openings into that chamber. Between the opening of the coronary sinus and that of the inferior cava there is a ridge, the sinus-septum (between the right horn and transverse parts of the sinus), which becomes attached to the lower part of the right sinus valve.

In the **atrium** a septum begins early to grow from the ventro-cephalic wall of the atrium, toward the atrial canal. As the interatrial communication around the edge of the septum (ostium primum) is becoming narrow, a perforation occurs near the attached margin of the septum (ostium secundum). This first septum (septum primum) is incomplete because when its edge reaches the atrial canal the atria still communicate through ostium secundum. To the right of the septum primum another septum (s. secundum) is formed later; this never stretches completely across the atrium and is rather a crescentic ridge than a true septum. Until the free edges of the two septa overlap one another there is a direct passage leading from one side of the atrium to the other; eventually they do overlap and the communication becomes oblique but persists until birth. (For adult relations of septa, see p. 511.) The cavities resulting from the division of the common atrium are the *right and left atria* of the adult. The oblique channel connecting the atria (foramen ovale) is bounded on the right side by the s. secundum the free edge of which forms the **limbus fossæ ovalis.** The channel is bounded on the left by the s. primum which slants into the left atrium. The free edge of the s. primum becomes the **valvula foraminis ovalis;** the remainder, the membranous atrial septum of the adult.

FIG. 440.—RECONSTRUCTION OF THE HEART OF AN 11 MM. HUMAN EMBRYO VIEWED FROM BELOW. (Mall, 50.)

The lower part of the ventricular portion has been cut off. Connective tissue septa colored yellow. *Ao*, aorta; *Ap*, anterior papillary muscle; *La*, left atrium; *Lo*, left venous ostium; *Lp*, large (anterior) papillary muscle of right ventricle; *Mpm*, medial papillary muscle; *PP*, posterior papillary muscle; *P*, pulmonary artery; *RA*, right atrium.



The portion of the dorsal wall of the right atrium immediately adjoining the septa is derived from the sinus venosus. This part of the atrium (the *sinus venarum*) receives the great venous openings. The left side of the left sinus-valve is attached to both septa and assists the septum secundum in the formation of the *limbus foraminis ovalis*. The cephalic part of the right sinus-valve disappears along the line of the (adult) *crista terminalis*, which therefore limits the right portion of the right atrium derived from the sinus venosus. The caudal portion of this valve persists as the *inferior caval and coronary valves*. These are drawn out of their original alignment by the adhesion between the caudal part of the right sinus-valve and the sinus-septum.

The left atrium receives, through the dorsal mesocardium, the originally single pulmonary vein. This common stem is absorbed into the atrial wall; later, the primitive right and left tributaries are absorbed in a similar way, leaving the four pulmonary veins of the adult opening separately into the left atrium. The area of the left atrium adjacent to the pulmonary veins, therefore, is not part of the original atrial wall.

The **ventricles** are divided by a septum (*s. musculare ventriculorum*) growing from the caudal wall of the common ventricular cavity toward the atrial canal. The canal moves to the right, and the dorsal part of the septum blends with the dorsal lip of the canal. The free ventral edge of the interventricular septum helps to bound the foramen through which blood from the left ventricle must enter the right on its way to the conus arteriosus. The foramen persists until (the free margin of the interventricular septum having been joined by the aortic septum) it becomes the circumference of the *aortic ostium*.

The **aortic septum** is a composite structure formed partly by a septum growing between the fourth and sixth pairs of aortic arches, and partly by swellings growing in the interior of the conus and truncus arteriosus. When fully formed it extends spirally along the truncus and conus, and enters the right half of the common ventricular cavity, where it joins the right side of the free edge of the interventricular septum. The septum is arranged in such a way that the blood from the left ventricle passes no longer through the right ventricle but along its own channel (*the aorta*) through the conus and truncus to the first four pairs of aortic arches. The blood from the right ventricle passes through *the pulmonary* division of the conus and truncus arteriosus, anterior and to the left of the aorta, into the sixth arches. Further differentiation brings about the external separation of the aorta from the pulmonary artery, but their common covering of epicardium persists as such in the adult. The lower end of the aortic septum persists in the adult as the *septum membranaceum ventriculorum* and the *crista supraventricularis*, the relations of which to the septum musculare are well shown in fig. 428. During the formation of the aortic septum four endocardial swellings appear at the distal part of the interior of the conus. These are arranged as smaller and larger opposite pairs; the smaller and larger swellings, therefore, alternating around the lumen. The larger pair of swellings assists (by partial blending) in the formation of the aortic septum. When the septum is complete, half of each of the larger swellings is contained in the aorta and half of each in the pulmonary artery. One of the smaller swellings remains in the aorta and one in the pulmonary artery, so that there are now three swellings in each vessel. Each of the six swellings becomes undermined to form a *semilunar valve* of the adult.

The atrio-ventricular valves.—The interior of the ventricular cavity, which is at first smooth, becomes undermined in an irregular way, to form a system of myocardial trabeculæ. The lips of the transversely directed atrial canal become thickened into prominent anterior and posterior endocardial cushions; these project into the ventricular cavity and become involved in its myocardial trabecular system. The atrial canal, which has now moved to the right, becomes divided sagittally, into *right and left venous ostia*, by the septum primum. The interventricular septum joins the ventricular side of the posterior endocardial cushion. The anterior and posterior endocardial cushions, where they blend with one another and with the septum primum on the medial side of each venous ostium, form an atrio-ventricular valve-cusp on either side, viz., the anterior cusp of the mitral in the left ostium, and the medial cusp of the tricuspid in the right. The posterior cusp of the mitral and the anterior and posterior of the tricuspid are formed later, partly, by lateral tubercles developing in either ostium, and partly by undermining of the ostia from the ventricular side. The atrial musculature extends into the atrio-ventricular valves and, until a late stage, is continuous with the trabecular system of the ventricles. Gradually, however, this connection between atrial and ventricular musculature is lost, leaving only the chordæ tendineæ connecting the papillary muscles with the valves Muscle is found at the basal region of the valve-cusps in the adult, and occasionally persists in the chordæ tendineæ.

The connection between the atrial and ventricular musculature is not confined to that occurring by means of the valves and trabecular system. The original myocardial connection between the atrial and ventricular portions of the heart remains complete until the embryo has reached the length of about 11 mm. From that time on the epicardium begins to blend with the fibrous annuli of the venous ostia. Meanwhile the atrial musculature rapidly loses its connection with that of the ventricles until they are connected in one place only, i. e., the site of the *atrio-ventricular bundle*.

The **pericardial cavity** is the original cephalic end of the intraembryonic cœlom. The somatic mesoderm of the pericardial region forms the adult *pericardium*. The splanchnic mesoderm persists only in the part which furnishes the *myo-epicardium*. The ventral and dorsal mesocardia, both of which are formed by the splanchnic mesoderm, are, in the main, transitory. The early disappearance of the ventral mesocardium unites the right and left sides of the pericardial cœlom ventral to the heart. The dorsal mesocardium persists at the arterial and venous ends of the heart only. The loss of the dorsal mesocardium between the latter points gives rise to the *sinus transversus pericardii* of the adult.

During development, the heart and pericardium migrate from a point opposite the cephalic end of the pharynx to one opposite the caudal end of the œsophagus; in fact, from the neck well into the thorax. In the adult, instead of being at the cephalic end of the cœlom, the heart and pericardium are contained between the right and left layers of the ventral mesentery of the œsophagus; the pericardial pleura of the adult.

The cranio-caudal migration is evidenced in the adult by the course of the recurrent and of the cardiac nerves, and also by the apparent migration of the vessels derived from some of the dorsal segmental arteries.

B. THE ARTERIES AND VEINS

The **arteries** [arteriæ], proportionately to their size, have much thicker walls than the veins. After death they retain their natural form, but are contracted and contain usually a small amount of pale clot. In a very general way the thickness of wall is proportional to calibre. Some arteries, however, are constantly thicker or thinner than could be predicted from size alone.

The larger arteries usually take a direct course and branch dichotomously. In descriptive anatomy if dichotomous branches are of nearly equal size it is common for each to take another name; if one branch preponderates in size, it is apt to retain the name of the parent trunk while the smaller is regarded as a collateral branch [vas collaterale]. There are numerous exceptions to dichotomous branching; branches may run perpendicularly or recurrently to the vessel from which they arise; or several branches may arise simultaneously.

There is less tendency to anastomosis between large or medium sized arteries than in veins of corresponding magnitude. Anastomoses do occur, however, particularly in the form of arches, such as the palpebral, plantar and volar arches, or the arches between the intestinal arteries. This form of anastomosis is sometimes called inosculation. Between smaller arteries anastomosis is usually free as in the case, for instance, of the articular retia. In some organs anastomosis (excepting capillary) between neighbouring arteries can scarcely be said to exist at all; the a. centralis retinæ affords a good example of this, as do the arteries of the brain, spleen, and kidney; such arteries are called terminal.

The larger arteries are supplied by *vasa vasorum*, frequently arising from their own recurrent branches.

The **veins** [venæ] have thin walls, and after death are either collapsed or filled with clot or stained serum. They are characterized by the presence of valves and frequent anastomoses.

Frequent anastomoses occur between veins of all sizes; plexuses are common, such, for instance, those of the pelvis. *Venæ comitantes* are veins which, usually in pairs, accompany many arteries; they communicate with one another, around the artery, very freely. Veins do not primitively accompany arteries. In the case of the extremities the primitive veins are superficial. The deep veins of the limbs are of later formation and to them the superficial veins subsequently become tributary.

The veins from the stomach, spleen, pancreas and intestine are collected into a large trunk, the **portal vein.** This does not open into the inferior vena cava directly, but breaks up into numerous smaller vessels in the liver. From these the blood is returned, through the hepatic veins, to the inferior cava.

Many veins are provided with **valves,** the free borders of which are directed toward the heart. In the small veins the valves are single; in the larger veins they are usually double, rarely treble. Valves are much more numerous in the veins of infants than those of the adult, they seem to disappear progressively with advancing age. The venous valves are most numerous in the superficial veins, and in the deep veins of the extremities; in many veins of the head and neck they occur only at their point of termination in a larger trunk.

The cranial *venous sinuses* are modified veins, consisting of intima only which lines channels in the fibrous dura mater. The venous spaces in cavernous tissue, such as the corpora cavernosa, may be looked upon as specially modified veins.

The larger veins, like the arteries, have vasa vasorum.

The arteries and veins will be considered in the following order: 1, pulmonary artery and veins; 2, the systemic arteries; and, 3, the systemic veins. At the ends of the second and third divisions, the development and variations are considered.

1. THE PULMONARY ARTERY AND VEINS

The **pulmonary artery** [a. pulmonalis] (fig. 441) passes from the right ventricle to the lungs. It differs from all other arteries in the body in that it contains venous blood. It arises as a short, thick trunk from the **conus arteriosus** of the right ventricle, and, after a course of about 5 cm. (2 in.) within the pericardium, divides into a right and a left branch. These branches pass to the right and the left lung respectively.

The **trunk of the pulmonary artery** at its origin is on a plane anterior to the ascending aorta, and slightly overlaps that vessel. Thence it passes upward, backward, and to the left, forming a slight curve around the front and left side of the ascending portion of the aorta; and, having reached the concavity of the aortic arch, on a plane posterior to the ascending aorta, it divides into its right and left branches, which diverge from each other at an angle of about 130°. The division of the pulmonary artery occurs immediately to the left of the second left chondrosternal articulation.

In the fœtus, the pulmonary artery continues its course upward, backward, and to the left under the name of the **ductus arteriosus (Botalli),** and opens into the descending aorta just below the origin of the left subclavian artery. After birth, that portion of the pulmonary artery which extends to the aorta becomes obliterated, and remains merely as a fibrous cord, the **ligamentum arteriosum** (fig. 436).

Relations.—In front, the trunk of the pulmonary artery is covered by the remains of the thymus gland, and the pericardium. The artery lies, at its commencement, behind the upper margin of the third left chondro-sternal articulation. The right margin of the artery is behind the second piece of sternum but the greater part of the vessel is behind the medial end of the second intercostal space.

Behind, it lies successively upon the ascending aorta and the left atrium.

To the **right** are the ascending aorta, the right atrium, the right coronary artery, and the cardiac nerves.

To the **left** are the pericardium, the left pleura and lung, the left auricle, the left coronary artery, and the cardiac nerves.

The **right pulmonary artery** [ramus dexter] longer than the left, passes almost horizontally under the arch of the aorta to the root of the right lung, where it divides, either directly or after repeated division, into three branches, one for each lobe. These branches follow the course of the bronchi, dividing and subdividing for the supply of the lobules of the lung. The terminal branches do not anastomose with each other.

Relations.—In its course to the lung it has **in front** of it the ascending aorta, the superior vena cava, the phrenic nerve, the anterior pulmonary plexus, and the reflexion of the pleura. **Behind** are the right bronchus and the termination of the azygos vein. **Above** is the arch of the aorta, and **below** are the left atrium and the upper right pulmonary vein.

At the root of the lung it has the right bronchus **above** and **behind** it; the pulmonary veins **below** and **in front.** Crossing in front of it and the other structures forming the root of the lung are the phrenic nerve and the anterior pulmonary plexus; behind are the azygos vein, the vagus nerve, and the posterior pulmonary plexus.

The **left pulmonary artery,** shorter and slightly smaller than the right, passes in front of the descending aorta to the root of the left lung, where it divides into two branches for the supply of the upper and lower lobes respectively. These divide and subdivide as on the right side.

Relations.—At the root of the lung it has the left bronchus **behind** and also **below** it, in consequence of the more vertical direction taken by the left bronchus than by the right. **Below** and **in front** are the pulmonary veins, while passing from the artery and the upper left pulmonary vein is the ligament of the left superior cava. Crossing in front of it and the other structures forming the root of the lung are the phrenic nerve, the anterior pulmonary plexus, and the reflexion of the left pleura; crossing behind, are the descending aorta, the left vagus nerve, and the posterior pulmonary plexus.

The **pulmonary veins** [vv. pulmonales] (figs. 424, 441) return the aërated blood from the lungs to the heart. They are usually four in number, superior and inferior, of the right and left sides. Occasionally, however, there are three pulmonary veins on the right side, the result of the vein from the middle lobe of the right lung opening separately into the left atrium instead of joining as usual the upper of the two right pulmonary veins. The relations of the pulmonary veins to the pulmonary arteries and bronchi in the lungs are given with the anatomy of the lungs (Section X).

The pulmonary veins are about 15 mm. in length. In the pericardium the **right pulmonary veins** [vv. pulmonales dextræ] both pass behind the superior vena cava. The superior vein receives the vein from the right middle lobe and runs below and in front of the right pulmonary artery.

The **left pulmonary veins** [vv. pulmonales sinistræ] enter the left atrium about 3 cm. in front of the veins of the right side. The superior vein is below the left pulmonary artery.

2. THE SYSTEMIC ARTERIES

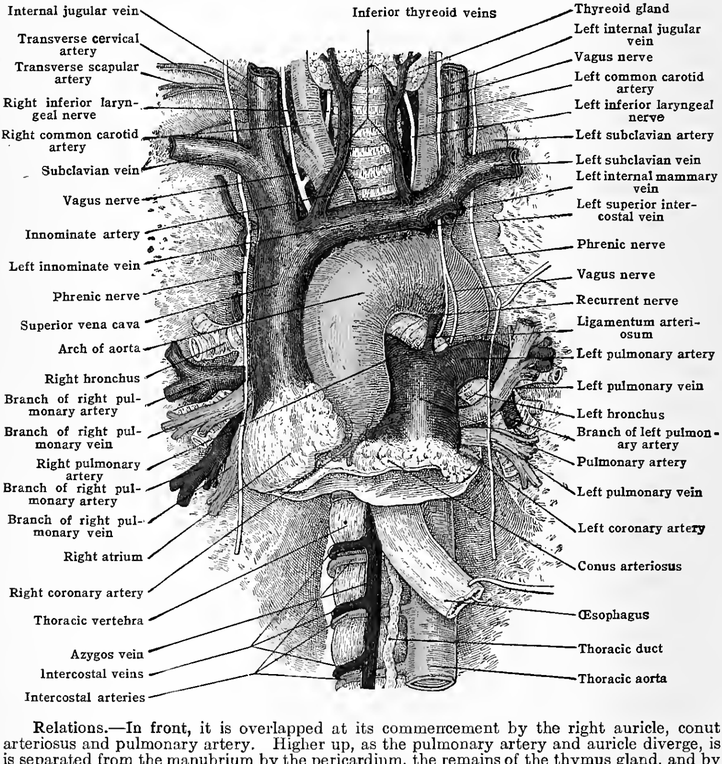
THE AORTA

The **aorta** (fig. 442) is the main systemic arterial trunk, and from it all the systemic arteries are derived. It begins at the left ventricle of the heart, and ascends near the anterior thoracic wall as high as the second right chondro-sternal articulation [**aorta ascendens**]. It then turns backward and to the left forming an arch [**arcus aortæ**] which reaches the posterior thoracic wall at the left side of the fourth thoracic vertebra. From here it runs downward along the vertebral column [**aorta descendens**] through the thorax and abdomen and ends by dividing, opposite the fourth lumbar vertebra, into the right and left common iliac arteries. From the point of bifurcation a small vessel, the middle sacral, is continued down the middle line in front of the sacrum and coccyx. The middle sacral represents the sacral and coccygeal aorta.

The Ascending Aorta

The **ascending aorta** [aorta ascendens] (fig. 442) begins at the upper part of the left ventricle, on a level with the third intercostal space, and ascends behind the sternum to the upper border of the right second chondrosternal articulation. It measures about 5 to 5.5 cm. (2 to $2\frac{1}{4}$ in.), forming, as it ascends, a gentle curve with its convexity to the right. It is enclosed for the greater part of its length in the pericardium, being invested, together with the pulmonary artery, in a common sheath formed by the serous layer of that membrane. A dilatation known as the **bulbus aortæ** occurs immediately above the heart upon which are three localized bulgings, known as the **aortic sinuses** (sinuses of Valsalva); they are placed, one to the right, one to the left, and one posteriorly. From the right and eft are derived the coronary arteries of the heart. (See HEART.)

FIG. 441.—THE GREAT VESSELS OF THE THORAX.
(Modified from a dissection in St. Bartholomew's Hospital Museum.)



Relations.—In **front,** it is overlapped at its commencement by the right auricle, conut arteriosus and pulmonary artery. Higher up, as the pulmonary artery and auricle diverge, is is separated from the manubrium by the pericardium, the remains of the thymus gland, and by the loose tissue and fat in the superior mediastinum, and is here slightly overlapped by the right pleura and by the edge of the right lung in full inspiration. The root of the right coronary artery is also in front.

Behind are the left atrium of the heart, the right pulmonary artery, the right bronchus, and the anterior right deep cardiac nerves.

On the right side it is in contact, below with the right atrium, and above with the superior vena cava.

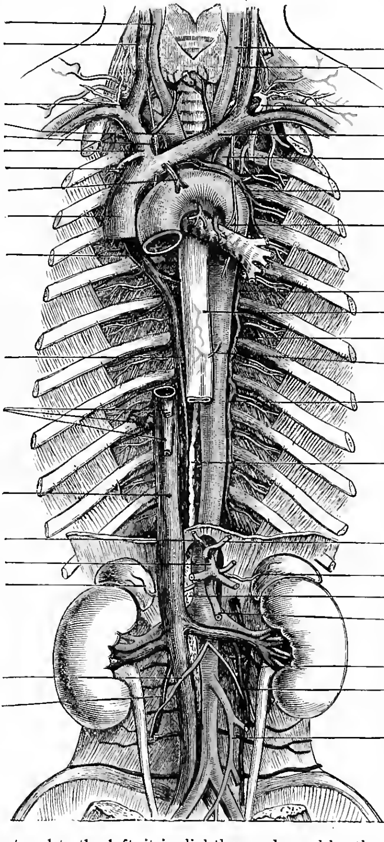
On the left side are the pulmonary artery and the branches of the right superficial cardiac nerves.

Branches.—The right and left coronary arteries have already been described (p. 519).

The Arch of the Aorta

The **arch of the aorta** [arcus aortæ] (figs. 441, 442), extends in a gentle curve upward, backward, and to the left, from the level of the upper border of the second right costal cartilage to the lower border of the fourth thoracic vertebra. Attached to the concavity of the arch, just beyond the origin of the left subclavian artery, is the **ligamentum arteriosum** (vestige of the dorsal part of the left sixth arch). Between the left subclavian artery and the ligamentum arteriosum there is sometimes a definite constriction of the arch (**isthmus aortæ**) situated opposite the third thoracic vertebra. When the isthmus is well marked, it is succeeded by a dilatation (**aortic spindle**) which begins in the neighbourhood of the ligamentum arteriosum and passes over into the descending aorta. Passing under the arch are the left bronchus, the right pulmonary artery, and the left recurrent (inferior laryngeal) nerve. It measures about 4.5 cm. ($1\frac{4}{5}$ in.).

Fig. 442.—The Thoracic and Abdominal Aorta.



Relations.—**In front and to the left**, it is slightly overlapped by the right pleura and lung, and to a greater extent by the left pleura and lung. It is crossed in the following order from right to left, by the left phrenic nerve, by the cardiac branches of the vagus nerve, the cardiac branches of the sympathetic nerve, by the left vagus nerve, and by the left superior intercostal vein as it passes up to the left innominate vein.

Behind and to the right are the trachea, the œsophagus, the thoracic duct, the deep cardiac plexus which is situated on the trachea just above its bifurcation, and the left recurrent (inferior laryngeal) nerve.

Above it are the three chief branches for the head, neck, and upper extremities, namely, the innominate, the left carotid, and the left subclavian arteries, and the left innominate vein.

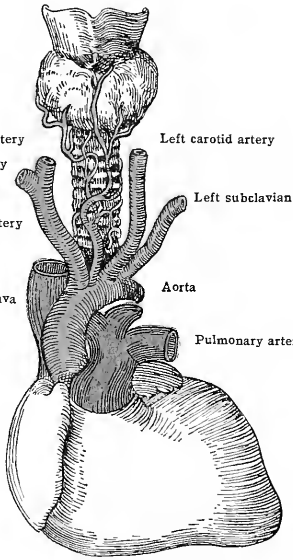
Below it—that is, in its concavity—are the bifurcation of the pulmonary artery, the left bronchus, the left recurrent (inferior laryngeal) nerve, the ligamentum arteriosum, the superficial cardiac plexus, two or more bronchial lymphatic glands, and the reflexion of the pericardium.

The **branches of the aortic arch** are:—the innominate, the left common carotid, and the left subclavian arteries. The innominate and left carotid arise close together—indeed, so close that, when seen from the interior of the aorta, the orifices appear merely separated by a thin septum. The left subclavian arises a little less close to the left carotid.

THE INNOMINATE ARTERY

The **innominate** [a. anonyma] or brachio-cephalic artery (fig. 441), the largest branch of the arch of the aorta, extends from near its commencement upward and a little forward and to the right, as high as the upper limit of the right sterno-clavicular joint where it bifurcates into the right common carotid and right subclavian arteries. It lies obliquely in front of the trachea, and measures from 3.7 to 5 cm. ($1\frac{1}{2}$ to 2 in.).

Fig. 443.—The Thyreoidea Ima. (After Henle.)



Relations.—In front of the artery are the manubrium, the origins of the sterno-hyoid and sterno-thyreoid muscles, the right sterno-clavicular joint, and the remains of the thymus gland. The left innominate vein crosses the root of the vessel, and the inferior thyreoid and thyreoidea ima veins descend obliquely over it to end in the left innominate vein. The inferior cervical cardiac branches of the right vagus nerve pass in front of it on their way to the deep cardiac plexus.

Behind, it lies on the trachea, crossing that tube obliquely from left to right, and coming into contact above with the right pleura.

To the **right side** are the right innominate vein, the right vagus, and the pleura.

To the **left side** are the left common carotid, the remains of the thymus gland, the right inferior thyreoid vein; and, higher, the trachea.

The **branches of the innominate artery** are:—(1) The right common carotid; and (2) the right subclavian. These are terminal branches. There are usually no collateral branches from this vessel, but at times the thyreoidea ima may arise from it.

The **thyreoida ima** artery, which occurs in about 10 per cent. of subjects, ascends on the front of the trachea to the thyreoid gland. It may be large in which case it might complicate the low operation of tracheotomy. It does not always arise from the innominate, but occasionally from the arch of the aorta (fig. 443) or from the right common carotid.

THE COMMON CAROTID ARTERIES

The **common carotid** arteries [aa. carotides communes] pass up deeply from the thorax on either side of the neck to about the level of the upper border of the thyreoid cartilage, where they divide into the external and internal carotid arteries. The **external carotid** supplies the structures at the upper part of the front and side of the neck, the larynx, pharynx, tongue, face, the upper part of the back of the neck, the structures in the pterygoid region, the scalp, and in chief part the membranes of the brain. The **internal carotid** gives off no branch in the neck, but enters the cranium and supplies the greater part of the brain, the structures contained in the orbit, and portions of the membranes of the brain.

The common carotid artery on the right side arises from the bifurcation of the innominate at the upper limit of the sterno-clavicular joint; on the left side from the arch of the aorta a little to the left of the innominate artery, and on a plane somewhat posterior to that vessel (fig. 441). The portion of the left common carotid artery which extends from the arch of the aorta to the upper limit of the sterno-clavicular articulation lies deeply in the chest, and requires a separate description; but above the level of the sterno-clavicular joint the relations of the right and left carotids are practically the same, and are given under the account of the right common carotid.

THORACIC PORTION OF THE LEFT COMMON CAROTID ARTERY

Within the thorax the left common carotid is deeply placed behind the manubrium of the sternum, and is overlapped by the left lung and pleura. It arises from the middle of the aortic arch, close to the left side of the innominate artery, and a little posterior to that vessel, and ascends obliquely in front of the trachea to the left sterno-clavicular articulation, above which its relations are similar to those of the right common carotid (fig. 442).

Relations.—**In front,** but at some little distance, are the manubrium and the origins of the left sterno-hyoid and sterno-thyreoid muscles, whilst in contact with it are the remains of the thymus gland, and the loose connective tissue and fat of the superior mediastinum. Crossing its root is the left innominate vein.

Behind, it lies successively upon the trachea the left recurrent (inferior laryngeal) nerve, the œsophagus (which here inclines a little to the left), and the thoracic duct.

To its **right side** is the root of the innominate artery, and higher up are the trachea and the inferior thyreoid veins.

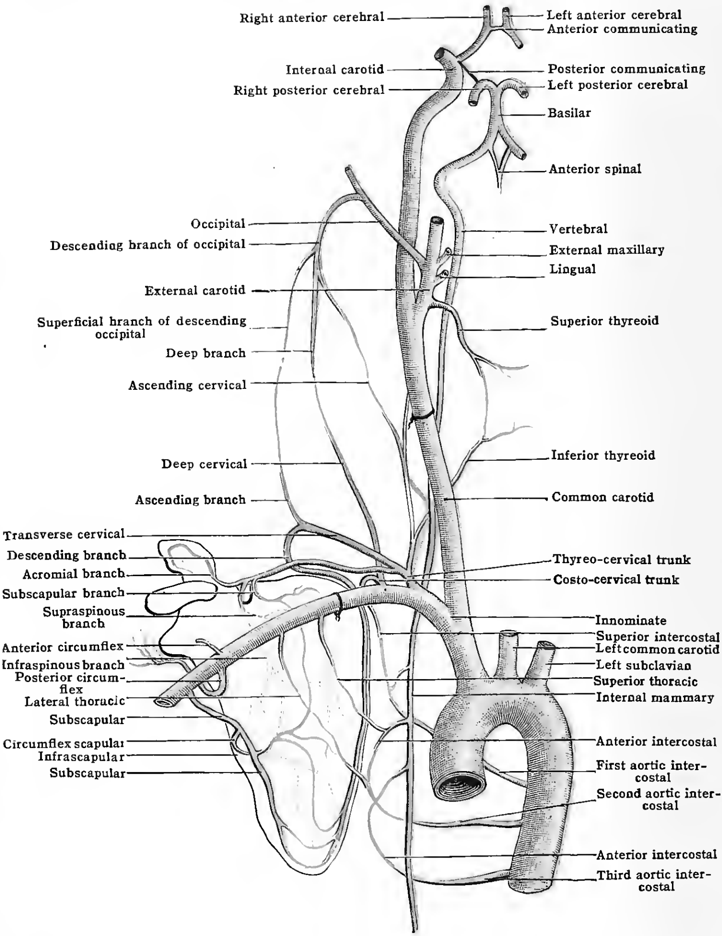
To its **left side,** but on a posterior plane, are the left subclavian artery and the left vagus nerve; and, slightly overlapping it, the edge of the left pleura and lung.

THE COMMON CAROTID ARTERY IN THE NECK

The **common carotid artery in the neck** extends from the sterno-clavicular articulation to the upper border of the thyreoid cartilage on a level with the fourth cervical vertebra, where it divides into the external and internal carotid arteries. A line drawn from the sterno-clavicular joint to the interval between the mastoid process and the angle of the jaw would indicate its course. The artery is at first deeply placed beneath the sterno-mastoid, sterno-hyoid, and sterno-thyreoid muscles, and at the level of the top of the sternum is only 2 cm. ($\frac{3}{4}$ in.) distant from its fellow of the opposite side, and merely separated from it by the trachea. As the carotid arteries run up the neck, however, they diverge in the form of a **V** and become more superficial, though on a plane posterior to that in which they lie at the root of the neck, and are separated from each other by the larynx and pharynx. At their bifurcation they are about 6 cm. ($2\frac{1}{4}$ in.) apart. The common carotid is contained in a sheath of fascia common to it and the internal jugular vein and vagus nerve. The artery, vein, and nerve, however, are not in contact, but separated from one another by fibrous septa, which divide the common sheath into three compartments: one for the artery, one for the vein, and one for the nerve. The vein, which is larger than the artery, lies to the lateral side, and somewhat overlaps it. The vagus nerve lies behind and between the two vessels. The artery on the right side measures about 9.5 cm. ($3\frac{3}{4}$ in.); on the left side, about 12 cm. ($4\frac{3}{4}$ in.) in length.

FIG. 444.—THE COLLATERAL CIRCULATION AFTER LIGATURE OF THE COMMON CAROTID AND SUBCLAVIAN ARTERIES.

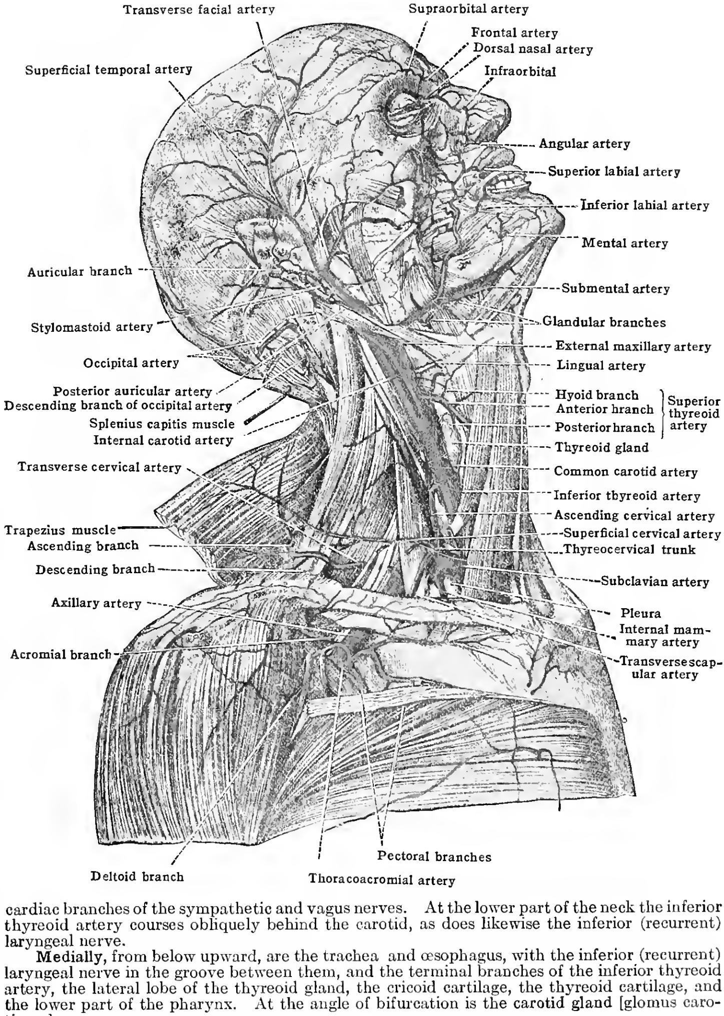
(A ligature is placed on the common carotid and on the third portion of the subclavian artery.)



Relations.—In front the artery is covered by the skin, superficial fascia, platysma, and deep fascia, and is more or less overlapped by the sterno-mastoid muscle. At the lower part of the neck it is covered in addition by the sterno-hyoid and sterno-thyreoid muscles, and is crossed by the anterior jugular vein, and is often overlapped by the thyreoid gland. Opposite the cricoid cartilage it is crossed obliquely by the omo-hyoid muscle, and, above this spot, by the superior thyreoid vein, and the sterno-mastoid artery. Along the anterior border of the sterno-mastoid there is a communicating vein between the facial and anterior jugular veins, which, as it crosses the line of the carotid artery, is in danger of being wounded in the operation of tying the carotid. The ramus descendens n. hypoglossi generally descends in front of the carotid sheath, being there joined by one or two communicating branches from the second and third cervical nerves. At times this nerve runs within the sheath. There are usually two lymphatic glands about the bifurcation of the artery. These are often found enlarged and infiltrated in cancer of the lip and tongue.

Behind, the common carotid lies on the longus colli and scalenus anterior below, and longus capitis (rectus capitis anterior major) above. Posterior to the artery, but in the same sheath, is the vagus nerve; and posterior to the sheath, the cervical sympathetic and the cervical

FIG. 445.—ARTERIES OF THE HEAD AND NECK. (After Toldt, "Atlas of Human Auatomy," Rebman, London and New York.)



cardiac branches of the sympathetic and vagus nerves. At the lower part of the neck the inferior thyreoid artery courses obliquely behind the carotid, as does likewise the inferior (recurrent) laryngeal nerve.

Medially, from below upward, are the trachea and œsophagus, with the inferior (recurrent) laryngeal nerve in the groove between them, and the terminal branches of the inferior thyreoid artery, the lateral lobe of the thyreoid gland, the cricoid cartilage, the thyreoid cartilage, and the lower part of the pharynx. At the angle of bifurcation is the carotid gland [glomus caroticum].

Laterally are the internal jugular vein and the vagus nerve. On the right side, at the root of the neck, the vein diverges somewhat from the artery, leaving a space in which the vagus nerve and vertebral artery are exposed. On the left side the vein approaches and somewhat overlaps the artery, thus leaving no interval corresponding to that on the right side.

The cricoid cartilage is, as a rule, taken as the centre of the incision in the operation for ligature of the common carotid artery. The incision is made in the line of the vessel parallel to the anterior margin of the sterno-mastoid muscle. The omo-hyoid forms one of the chief rallying points in the course of the operation for ligature of the artery above that muscle, the usual situation. The artery is found beating at the angle formed by the omo-hyoid with the sterno-mastoid.

Branches.—(1) External and (2) internal carotid arteries. The common carotid gives off no lateral branch, and consequently does not diminish in size as it runs up the neck. It is often a little swollen just below its bifurcation, a condition that should not be mistaken for an aneurismal dilation.

The **collateral circulation** (fig. 444), after ligature of the common carotid, is carried on chiefly by the anastomosis of the internal carotid with the internal carotid of the opposite side through the circle of Willis; by the vertebral with the opposite vertebral; by the inferior thyreoid with the superior thyreoid; by the deep cervical branch of the costo-cervical trunk (superior intercostal) with the descending branch of the occipital; by the superior thyreoid, lingual, external maxillary (facial), occipital, and temporal, with the corresponding arteries of the opposite side, and by the ophthalmic with the angular. The anastomosis between the deep cervical branch of the costo-cervical trunk with the descending branch of the occipital is an important one; it is situated deeply at the back of the neck, and is to be found lying between the semispinalis capitis (complexus) and cervicis muscles.

THE EXTERNAL CAROTID ARTERY

The **external carotid** artery [a. carotis externa] (fig. 445), the smaller of the two branches into which the common carotid divides at the upper border of the thyreoid cartilage, is distributed to the anterior part of the neck, the face, and the cranial region, including the skin, the bones, and the dura mater. It is at first situated medial to the internal carotid; but as it ascends in the neck it forms a gentle curve, with its convexity forward, and, running slightly backward as well as upward, terminates opposite the neck of the mandible just below the condyle, by dividing into the internal maxillary and superficial temporal arteries. It here lies superficial to the internal carotid, from which it is separated by a portion of the parotid gland. At its origin it is overlapped by the anterior margin of the sterno-mastoid, and is covered by the superficial fascia, platysma, and deep fascia. Higher up the neck it is deeply placed, passing beneath the stylo-hyoid muscle, the posterior belly of the digastric muscle, and the hypoglossal nerve; and finally becomes embedded in the parotid gland, where it divides into its terminal branches. It is separated from the internal carotid artery posteriorly by the stylo-pharyngeus and stylo-glossus muscles, the glosso-pharyngeal nerve, the pharyngeal branch of the vagus nerve, a portion of the parotid gland, and the stylo-hyoid ligament; or, if the styloid process is abnormally long, by that process itself. It measures about 6.5 cm. ($2\frac{3}{5}$ in.).

Relations.—In front, in addition to the skin, superficial fascia, platysma, and deep fascia, it has the hypoglossal nerve, the lingual, common facial and posterior facial veins, the posterior belly of the digastric and stylo-hyoid muscles, the superior cervical lymphatic glands, branches of the facial nerve, and the parotid gland. The sterno-mastoid also overlaps it in the natural state of the parts.

Behind, it is in relation with the internal carotid, from which it is separated by the stylo-glossus and stylo-pharyngeus muscles, the glosso-pharyngeal nerve, the pharyngeal branch of the vagus nerve, the stylo-hyoid ligament, and the parotid gland. The superior laryngeal nerve crosses behind both the external and internal carotid arteries.

Medially, it is in relation with the hyoid bone, the pharyngeal wall, the ramus of the mandible, the stylo-mandibular ligament which separates it from the submaxillary gland, and the parotid gland.

Laterally, in the first part of its course, it is in contact with the internal carotid artery.

The **branches of the external carotid** are usually given off in the following order, from below upward:—

1. Ascending pharyngeal.
2. Superior thyreoid.
3. Lingual.
4. External maxillary (facial).
5. Sternocleidomastoid.
6. Occipital.
7. Posterior auricular.
8. Superficial temporal.
9. Internal maxillary.

1. THE ASCENDING PHARYNGEAL ARTERY

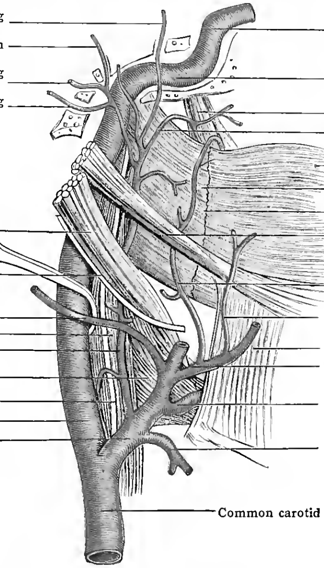
The **ascending pharyngeal** artery [a. pharyngea ascendens] (fig. 446) is usually the first or second branch of the external carotid. Occasionally it comes off at the bifurcation of the common carotid from the common carotid itself. It is a long slender vessel which runs deeply seated up the neck to the base of the skull, having the walls of the pharynx and the tonsil **medially,** the internal carotid artery **laterally,** and the vertebral column, the longus capitis (rectus capitis anterior major), and the sympathetic nerve **posteriorly. In front** it is crossed by the stylo-glossus (fig. 446) and the stylo-pharyngeus muscles and the glosso-pharyngeal nerve.

Branches of the Ascending Pharyngeal Artery

The branches of the ascending pharyngeal artery are small and variable. They supply the longus and rectus capitis muscles, the upper cervical sympathetic ganglion and adjacent lymph-nodes, as well as the pharynx, soft palate, ear, cranial nerves, and meninges.

The **pharyngeal** branches [rami pharyngei] supply the superior and middle constrictor muscles and the mucous membrane lining them. These vessels anastomose with branches

Fig. 446.—Scheme of Right Ascending Pharyngeal Artery. (Walsham.) The internal carotid artery is hooked aside.



of the superior thyreoid. One branch (the **palatine**) passes over the upper edge of the superior constrictor to the soft palate and its muscles. This branch follows a course similar to that taken by the ascending palatine artery, and when the latter is small may take its place. It generally gives off small twigs to the Eustachian tube and tonsil. The **inferior tympanic** artery [a. tympanica inferior] accompanies the tympanic branch of the glosso-pharyngeal nerve through the tympanic canaliculus into the tympanum, and anastomoses with the other tympanic arteries. The **posterior meningeal** artery [a. meningea posterior] is distributed to the membranes of the brain. Some twigs pass with the jugular vein through the jugular foramen into the cranium, and supply the dura mater in the posterior fossa of the skull. Others occasionally reach the same fossa through the hypoglossal (anterior condyloid) canal in company with the hypoglossal nerve; while others pass through the cartilage of the lacerated foramen and supply the middle fossa of the skull.

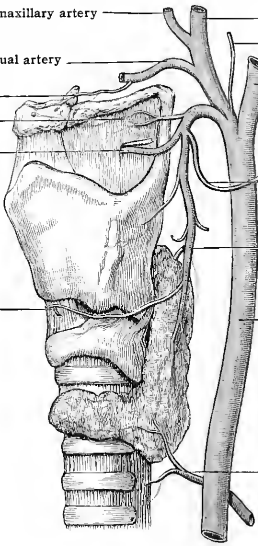
2. THE SUPERIOR THYREOID ARTERY

The **superior thyreoid** artery [a. thyreoidea superior] (figs. 445, 447) arises from the front of the external carotid a little above the origin of that vessel, and, coursing forward, medially, and then downward, in a tortuous manner, supplies the depressor muscles of the hyoid bone, the larynx, the thyreoid gland, and the lower part of the pharynx. The artery at first runs forward and a little upward, just beneath the greater cornu of the hyoid bone. In this part of its course it lies in the superior carotid triangle, and is quite superficial, being covered only with the integument, fascia, and platysma. It next turns downward, and passes beneath the omo-hyoid, sterno-hyoid, and sterno-thyreoid muscles, and ends at the upper part of the thyreoid gland by breaking up into terminal glandular brauches. The superior thyreoid vein passes beneath the artery on its way to the internal jugular vein. The superior thyreoid is the artery most commonly divided in cases of suicidal wounds of the throat.

Branches of the Superior Thyreoid Artery

The named **branches of the superior thyreoid artery** are:—(1) The hyoid; (2) the sterno-mastoid; (3) the superior laryngeal; (4) the crico-thyreoid; (5) anterior; (6) posterior; and (7) glandular.

Fig. 447.—Scheme of Left Superior Thyreoid Artery. (Walsham.)



(1) The **hyoid** [ramus hyoideus] is usually a small twig which passes along the lower border of the hyoid bone, lying on the thyreo-hyoid membrane under cover of the thyreo-hyoid and sterno-hyoid muscles. It supplies the infra-hyoid bursa and the thyreo-hyoid muscle, and anastomoses with its fellow of the opposite side, and with the hyoid branch of the lingual. When the latter artery is small, the hyoid branch of the superior thyreoid is usually comparatively large, and *vice versa*.

(2) The **sterno-mastoid** [ramus sternocleidomastoideus] (fig. 447) courses downward and backward across the carotid sheath, and entering the sterno-mastoid supplies the middle portion of that muscle. It gives off slender twigs to the thyreo-hyoid, sterno-hyoid, and omo-hyoid muscles, and the platysma and integuments covering it. At times the vessel arises directly from the external carotid. It lies usually somewhere in the upper part of the incision for tying the common carotid above the omo-hyoid muscle.

(3) The **superior laryngeal** [a. laryngea superior] (fig. 447) passes medially beneath the

thyreo-hyoid muscle, and, perforating the thyreo-hyoid membrane along with the internal branch of the superior laryngeal nerve, supplies the intrinsic muscles and mucous lining of the larynx. Its further distribution within the larynx is given with the description of that organ. This branch sometimes arises from the external carotid direct. It may enter the larynx by passing through a foramen in the thyreoid cartilage.

(4) The **crico-thyreoid** [ramus cricothyreoideus] passes across the crico-thyreoid membrane immediately beneath the lower border of the thyreoid cartilage. It anastomoses with its fellow of the opposite side, and usually sends a small branch through the membrane into the interior of the larynx. Occasionally a considerable twig descends over the cricoid cartilage to enter the isthmus of the thyreoid gland. The crico-thyreoid has, however, frequently been seen of comparatively large size—once as large as the radial, and crossing the membrane obliquely. In order to avoid injuring the crico-thyreoid artery in the operation of laryngotomy, it is usual, if the operation has to be done in a hurry, to make the incision through the crico-thyreoid membrane in a transverse direction, and as near to the cricoid cartilage as possible.

(5) The **anterior** branch [ramus anterior] is the terminal branch supplying the isthmus and the neighbouring part of the lateral lobe of the thyreoid gland.

(6) The **posterior** branch [ramus posterior], the other terminal, supplies the posterior part of the lateral lobe, and sends branches to the inferior constrictor of the pharynx and to the œsophagus. It anastomoses with the ascending branches of the inferior thyreoid artery.

(7) The **glandular** branches [rami glandulares] are the ultimate twigs, arising from the anterior and posterior terminal branches, for the supply of the thyreoid gland.

3. THE LINGUAL ARTERY

The **lingual** artery [a. lingualis] (fig. 448) arises from the front of the external carotid, between the superior thyreoid and external maxillary (facial) arteries, often as a common trunk with the latter vessel, and nearly opposite or a little below the greater cornu of the hyoid bone. It may, for purposes of description, be divided into three portions: the **first, or oblique,** extends from its origin to the posterior edge of the hyo-glossus muscle; the **second, or horizontal,** lies beneath the hyo-glossus; the **third,** or **ascending**, beneath the tongue. The **first** or **oblique portion** is situated in the superior carotid triangle, and is superficial, being covered merely by the integument, platysma, and deep fascia. Here it lies on the middle constrictor muscle and superior laryngeal nerve. After ascending a short distance, it curves downward and forward beneath the hypoglossal nerve, and, in the **second part of its course,** runs horizontally along the upper border of the hyoid bone, beneath the hyo-glossus, by which it is separated from the hypoglossal nerve and its vena comitans, and the posterior belly of the digastric and the stylo-hyoid muscles. In this part of its course it lies successively on the middle constrictor of the pharynx and the genio-glossus muscle, and crosses a small triangular space known as 'Lesser's triangle,' the sides of which are formed by the tendons of the digastric, the base by the hypoglossal nerve, and the floor by the hyo-glossus muscle, in which situation it is usually tied. In the **third part of its course** it ascends tortuously, usually beneath the anterior margin of the hyo-glossus, to the under surface of the tongue, and is thence continued to the tip of that structure lying between the lingualis and the genio-glossus muscles. From the anterior edge of the hyo-glossus to its termination it is only covered by the mucous membrane of the under surface of the tongue. This part of the vessel is sometimes called the ranine artery. The lingual artery is accompanied by small venæ comitantes.

Branches of the Lingual Artery

The named **branches of the lingual artery** are:—(1) The hyoid; (2) the dorsal lingual; (3) the sublingual; and (4) the deep lingual (ranine).

(1) The **hyoid** branch [ramus hyoideus] (fig. 448) is a small vessel which arises from the first part of the lingual, and courses along the upper border of the hyoid bone, superficial to the hyo-glossus, but beneath the insertion of the posterior belly of the digastric and the stylo-hyoid. It anastomoses with its fellow of the opposite side, and with the hyoid branch of the superior thyreoid artery, and supplies the contiguous muscles.

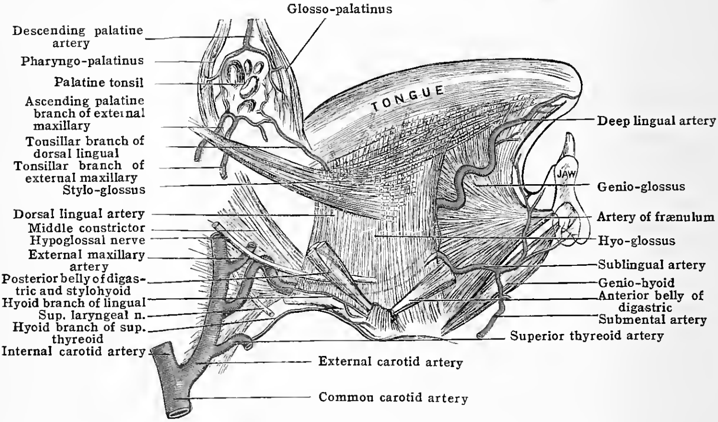
(2) The **dorsalis linguæ** (fig. 448) arises from the second portion of the lingual artery, usually under cover of the posterior edge of the hyo-glossus muscle. It ascends to the back of the dorsum of the tongue, and, dividing into branches, supplies the mucous membrane on each side of the **V** formed by the vallate papillæ. It also supplies the pillars of the fauces and the tonsil, where it anastomoses with the other faucial and tonsillar arteries. Instead of a single artery, as above described, there may be several small vessels running directly to the parts mentioned. The artery anastomoses in the mucous membrane by very small branches with the

vessel of the opposite side; but the anastomosis is so minute that when one lingual artery is injected the injection merely passes across to the opposite side at the tip of the tongue; and when the tongue is divided accurately in the middle line, as in the removal of one-half of that organ, practically no hæmorrhage occurs.

(3) The **sublingual artery** [a. sublingualis] (fig. 448) usually comes off from the lingual at the anterior margin of the hyo-glossus. It passes beneath the mylo-hyoid to the sublingual gland, which it supplies, and finally it usually anastomoses with the submental artery, a branch of the external maxillary (facial). It also supplies branches to the side of the tongue, and gives off a terminal twig, which anastomoses beneath the mucous membrane of the floor of the mouth (to which it also gives twigs) with the artery of the opposite side. The **artery of the frænum** is usually derived from this vessel (fig. 448).

(4) The **deep lingual** [a. profunda linguæ], the termination of the lingual, courses forward beneath the mucous membrane, on the under surface of the tongue, to the tip. It lies lateral to the genio-glossus, between that muscle and the inferior lingualis, and is accompanied by the lingual vein and terminal branch of the lingual nerve. It follows a very tortuous course, so that it is not stretched when the tongue is protruded. Branches are given off from it to the contiguous muscles and mucous membrane. Near the tip of the tongue it communicates with its fellow of the opposite side, as shown by the fact that when the lingual artery of one side is injected, the injection fluid passes into the branches of the artery of the other side.

Fig. 448.—Scheme of the Right Lingual Artery. (Walsham.)



4. THE EXTERNAL MAXILLARY (FACIAL) ARTERY

The **external maxillary** or **facial** artery [a. maxillaris externa] (fig. 449) arises immediately above the lingual from the fore part of the external carotid, at times as a common trunk with the lingual. It courses forward and upward in a tortuous manner to the mandible, and, passing over the body of this bone at the anterior edge of the masseter muscle, winds obliquely upward and forward over the face to the medial angle of the eye, where it anastomoses, under the name of the **angular artery**, with the dorsal nasal branch of the ophthalmic. It is usually divided into two portions—the cervical and the facial.

The **cervical portion** (fig. 449) ascends tortuously from its origin from the external carotid upward and forward beneath the posterior belly of the digastric and stylo-hyoid muscles, and usually also beneath the hypoglossal nerve, and then, making a turn, runs horizontally forward for a short way beneath the jaw, either imbedded in or lying under the submaxillary gland. It has here the mylo-hyoid and stylo-glossus beneath it. On leaving the cover of the gland it forms a loop passing first downward and then upward over the lower border of the jaw immediately in front of the masseter muscle, where it is superficial, being merely covered by the integument and platysma. Here it can be felt beating, and can be readily compressed. In the above course it lies in the posterior part of the submaxillary triangle, and, in addition to the structures already mentioned as crossing it, is covered by the skin, superficial fascia, and platysma, and by one or two submaxillary lymphatic nodes. The vein is separated from the artery by the submaxillary gland, the posterior belly of the diagastric muscle, the stylo-hyoid muscle, and the hypoglossal nerve.

The **facial portion** (fig. 449) of the external maxillary artery ascends tortuously forward toward the angle of the mouth, passing under the platysma (risorius), the zygomatic muscle, the zygomatic head of the quadratus labii superioris (zygomaticus minor), and the zygomatic and buccal branches of the facial nerve. It here lies upon the jaw and the buccinator muscle. Thence it courses upward by the side of the nose toward the medial angle of the eye, passing over or under the infraorbital and angular heads of the quadratus labii superioris, and under the infraorbital branches of the facial nerve. It lies on the caninus (levator anguli oris) and the infraorbital branches of the fifth nerve. The anterior facial vein takes a straighter course than the external maxillary artery, is separated from it by the zygomatic muscle, and lies lateral to it.

Branches of the External Maxillary Artery of the Neck

The **branches of the external maxillary artery in the neck** are:—(1) The ascending palatine; (2) the tonsillar; (3) the glandular; (4) the submental.

(1) The **ascending palatine** [a. palatina ascendens] (figs. 448, 449)—the first branch of the external maxillary, but often a distinct branch of the external carotid—ascends between the internal and external carotids, and then between the stylo-glossus and stylo-pharyngeus muscles, and on reaching the wall of the pharynx is continued upward between the superior constrictor and internal pterygoid muscles toward the base of the skull as high as the levator veli palatini, where it divides into two branches, a palatine and a tonsillar. One of these branches, the **palatine**, passes with the levator veli palatini over the curved upper margin of the superior constrictor to the soft palate, where it is distributed to the tissues constituting that structure, and anastomoses with its fellow of the opposite side and with the descending palatine branch of the internal maxillary, and the ascending pharyngeal, which vessel often to a great extent supplies the place of this artery. The other branch, the **tonsillar**, supplies the tonsil and the Eustachian tube, anastomosing with the tonsillar branch of the external maxillary (facial) and ascending pharyngeal arteries. The ascending palatine artery supplies the muscles between which it runs on its way to the palate.

(2) The **tonsillar** branch [ramus tonsillaris] (fig. 449) ascends between the stylo-glossus and internal pterygoid muscles to the level of the tonsil, where it perforates the superior constrictor muscle of the pharynx, and ends in the tonsil, anastomosing with the tonsillar branch of the ascending palatine and with the other tonsillar arteries (fig. 448). It gives branches also to the root of the tongue.

(3) The **glandular** branches [rami glandulares] are distributed to the submaxillary gland as the artery is passing through or beneath that structure. A small twig from one of these branches usually supplies the submaxillary (Wharton's) duct.

(4) The **submental** artery [a. submentalis] (fig. 449) comes off from the external maxillary as the latter vessel lies under cover of the submaxillary gland, and, passing forward on the mylo-hyoid muscle between the base of the jaw and the anterior belly of the digastricus, supplies these structures and the overlying platysma and integuments. It anastomoses with the sublingual artery. The external maxillary also supplies the adjacent muscles of the neck.

Branches of the External Maxillary Artery on the Face

From the **lateral** or **concave** side of the artery are given off branches which supply the masseter muscle and anastomose with the masseteric and buccinator branches of the internal maxillary artery, the transverse facial artery, and the infraorbital arteries.

From the **medial** or **convex** side the following larger and named vessels are given off:—(1) The inferior labial; (2) the superior labial; and (3) the angular.

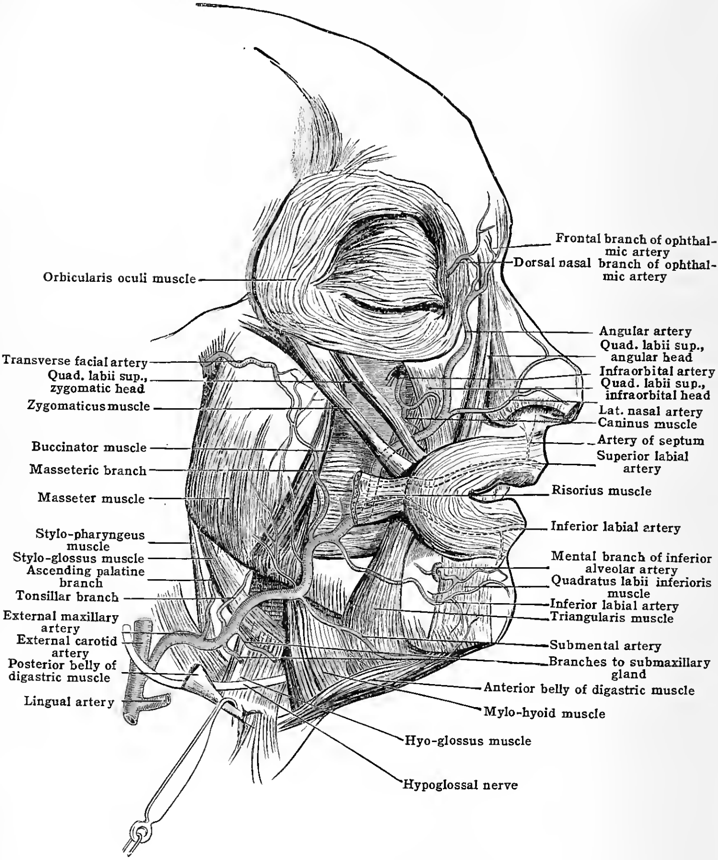
(1) The **inferior labial** artery [a labialis inferior] arises at the angle of the mouth and runs in the under lip within the substance of the orbicularis oris, close to the mucous membrane. It anastomoses with the artery of the other side. Frequently an additional branch passes from the external maxillary to the lower lip.

(2) The **superior labial** artery [a. labialis superior] arising from the facial a little higher than the inferior, passes forward beneath the zygomaticus, and then, like the inferior labial, courses tortuously along the lower margin of the upper lip between the orbicularis oris and the mucous membrane, about 1.2 cm. ($\frac{1}{2}$ in.) from the junction of the mucous membrane and the skin. It is usually larger than the inferior labial. It anastomoses with its fellow of the opposite side, and gives off a small artery to the septum—**arteria septi nasi.** Compression of this vessel will sometimes control hæmorrhage from the nose.

(3) The **angular** artery [a. angularis] (fig. 449) is the terminal branch of the external maxillary. It supplies the nose and anastomoses at the medial angle of the eye with the dorsal nasal branch of the ophthalmic. It is accompanied by the anterior descending vein from the scalp.

It lies to the medial side of the lacrimal sac and supplies that structure and the lower part of the orbicularis oculi, beneath which a branch anastomoses with the infraorbital artery. The situation of the artery to the medial side of the lacrimal sac should be borne in mind in opening a lacrimal abscess.

Fig. 449.—Scheme of the Right External Maxillary Artery. (Walsham.)



5. THE STERNOCLEIDOMASTOID

The **sternocleidomastoid** artery [a. sternocleidomastoidea] arises from the posterior side of the external carotid at the point where the carotid is crossed by the digastric muscle. It is distributed to the sternocleidomastoid muscle, and is frequently represented by one of the muscular branches of the occipital artery.

6. THE OCCIPITAL ARTERY

The **occipital** artery [a. occipitalis] (fig. 450) is usually a vessel of considerable size. It comes off from the posterior part of the external carotid opposite the external maxillary (facial), or else a little higher than that vessel. It then winds upward and backward to the interval between the mastoid process of the temporal bone and transverse process of the atlas, and, after running horizontally backward in a groove on the mastoid portion of the temporal bone, again turns upward, and ends by ramifying in the scalp over the back of the skull, extending as far forward as the vertex.

The vessel may be divided into three parts—viz., that anterior to the sterno-mastoid muscle; that beneath the sterno-mastoid; and that posterior to the sterno-mastoid.

In the **first part of its course** the occipital artery is covered by the integuments and fascia, and is more or less overlapped by the posterior belly of the digastric muscle, the parotid gland, and posterior facial (temporo-maxillary) vein. It is crossed by the hypoglossal nerve as the latter winds forward over the carotid vessels to reach the tongue. It successively crosses in front of the internal carotid artery, the hypoglossal nerve, the vagus nerve, the internal jugular vein, and the spinal accessory nerve.

In the **second part of its course** it sinks deeply beneath the digastric muscle into the interval between the mastoid process of the temporal bone and the transverse process of the atlas. It is here covered by the sterno-mastoid, splenius capitis, and longissimus capitis muscles and by the origin of the digastric; and lies, first on the rectus capitis lateralis, which separates it from the vertebral artery, then in a groove, the occipital groove, on the mastoid portion of the temporal bone, and then on the insertion of the superior oblique muscle.

In the **third part of its course** it enters the triangular interval formed by the diverging borders of the splenius capitis and the superior nuchal line of the occipital bone. Here it lies beneath the integuments and the aponeurosis uniting the occipital attachments of the sterno-mastoid and trapezius, and rests upon the semi-spinalis capitis (complexus) just before the insertion of that muscle into the occipital bone. In company with the greater occipital nerve, it perforates either this aponeurosis, or less often the posterior belly of the epicranius (occipito-frontalis), and follows roughly, but in a tortuous course, the line of the lamboid suture, lying between the integument and the cranial aponeurosis. In the scalp it divides into several large branches, which ramify over the back of the skull and reach as far forward as the vertex. They anastomose with the corresponding branches of the opposite side, and with the posterior auricular and the superficial temporal arteries.

Branches of the Occipital Artery (Fig. 450)

The **branches of the occipital artery** are:—(1) The muscular; (2) the meningeal; (3) the auricular; (4) the mastoid; (5) the descending; (6) the occipital.

(1) The **muscular** branches [rami musculares] (fig. 450) supply the sternocleidomastoid and adjacent muscles. One of these branches may take the place of the sterno-mastoid branch of the external carotid. The hypoglossal nerve then, as a rule, loops round it instead of round the occipital.

(2) The **meningeal** branches [rami meningei] (fig. 450), one or more in number, are long slender vessels which leave the occipital artery as it crosses the internal jugular vein and, ascending along the vessel, pass with it through the jugular or hypoglossal foramen, and are distributed to the dura mater lining the posterior fossa of the skull.

(3) The **auricular** branch [ramus auricularis] ascends over the mastoid process to the back of the ear, and supplies the pinna and concha. It sometimes takes the place of the posterior auricular artery (fig. 450).

(4) The **mastoid** branch [ramus mastoideus] is a small twig that passes into the skull through the mastoid foramen, supplying the dura mater, the diploë, the walls of the transverse sinus, and the mastoid cells.

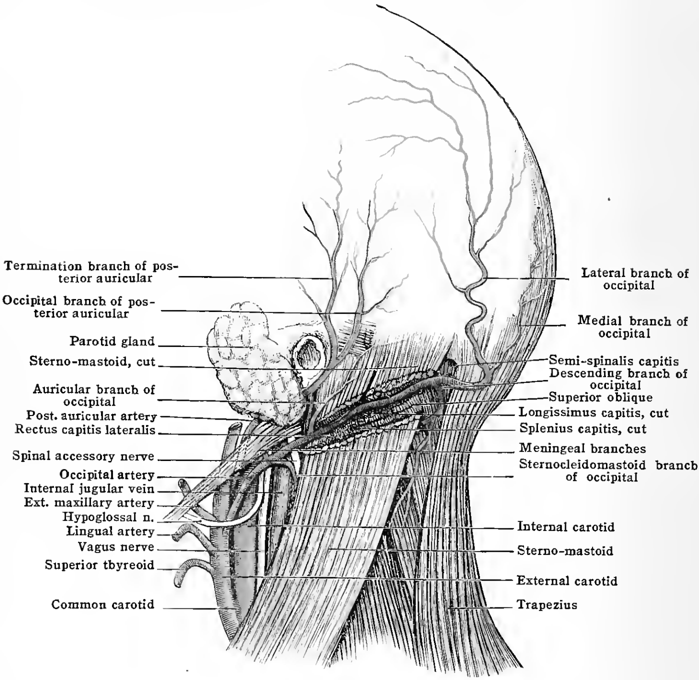
(5) The **descending** or **princeps cervicis** [ramus descendens] (fig. 450), the largest of the branches of the occipital, arises from that artery just before it emerges from beneath the splenius, and, descending for a short distance between the splenius and semi-spinalis capitis (complexus), divides into a superficial and a deep branch. The **superficial branch** perforates the splenius, supplies branches to the trapezius, and anastomoses with the ascending branch of the transverse cervical artery. The **deep branch** passes downward between the semi-spinalis capitis (complexus) and colli, and anastomoses with the deep cervical branch of the costo-cervical trunk and with branches of the vertebral. The anastomoses between the above-mentioned arteries form important collateral channels after ligature of the common carotid and subclavian arteries (fig. 444).

(6) The **occipital** or **terminal** branches [rami occipitales] (fig. 450), usually two in number, named from their position medial and lateral, ramify over the scalp, and have already been described. The medial branch generally gives off a twig which enters the parietal foramen (parietal artery) and is distributed to the dura mater. The occipital artery may also give off the stylo-mastoid, the posterior auricular, or the ascending pharyngeal arteries.

7. THE POSTERIOR AURICULAR ARTERY

The **posterior auricular** artery [a. auricularis posterior] (fig. 450) arises from the posterior part of the external carotid artery, usually immediately above the posterior belly of the digastric, about the level of the tip of the styloid process. Occasionally it arises under cover of the digastric, quite close to, or as a common trunk with, or as a branch of, the occipital. It courses upward and backward in the parotid gland to the notch between the margin of the external auditory meatus and the mastoid process, where it divides into branches. In this course it rests on the styloid process, crosses the spinal accessory nerve, and is crossed by the facial nerve.

Fig. 450.—Scheme of Left Occipital and Posterior Auricular Arteries. (Walsham.)



Branches of the Posterior Auricular Artery

The **branches of the posterior auricular artery** are:—(1) the stylo-mastoid; (2) the auricular; (3) the occipital (fig. 450).

The posterior auricular also gives branches to the parotid gland and the adjacent muscles, namely, the posterior belly of the digastric, the stylo-hyoid, and auricularis posterior (retrahens aurem).

(1) The **stylo-mastoid** artery [a. stylomastoidea] comes off from the posterior auricular artery just before it reaches the notch between the margin of the external auditory meatus and the mastoid process, and, following the facial nerve upward, enters the stylo-mastoid foramen in the temporal bone. In the facial canal (aqueduct of Fallopius) it gives off the following named twigs:—(*a*) meatal, to the external auditory meatus; (*b*) **mastoid** [rami mastoidei], to the mastoid cells and tympanic antrum; (*c*) **stapedic** [ramus stapedius], which runs forward to the stapedius muscle; (*d*) **posterior tympanic** [a. tympanica posterior], which anastomoses with the anterior tympanic branch of the internal maxillary, forming with it in the fœtus a vascular circle around the membrana tympani; (*e*) **vestibular**, to the vestibule and semicircular canals; and (*f*) **terminal**, a small twig which leaves the facial canal (by the hiatus) with the great superficial petrosal nerve, and anastomoses with the superior petrosal branch of the middle meningeal artery.

(2) The **auricular** branch [ramus auricularis] passes upward behind the ear and beneath the auricularis posterior (retrahens aurem), supplying the medial surface of the pinna and adjacent

skin. It anastomoses with the posterior branch of the superficial temporal artery. The branches to the pinna not only supply the back of that structure, but some perforate the cartilage, and others turn over its free margin to supply the lateral surface; there they anastomose with the anterior auricular branches from the temporal.

(3) The **occipital** branch [ramus occipitalis] passes upward and backward, crossing the aponeurotic insertion of the sterno-mastoid muscle. It gives a branch to the posterior belly of the epicranius (occipito-frontalis), and anastomoses with the occipital artery.

8. THE SUPERFICIAL TEMPORAL ARTERY

The **superficial temporal** artery [a. temporalis superficialis] (fig. 445), is the smaller of the two terminal divisions of the external carotid, though apparently the direct continuation of that vessel. It arises opposite the neck of the mandible and, under cover of the parotid gland, passes upward in the interval between the condyle and the external auditory meatus to the zygoma, lying on the capsule of the temporo-mandibular joint. Thence it ascends over the posterior zygomatic root and the temporal aponeurosis for about 4 or 5 cm. ($1\frac{1}{2}$ or 2 in.), and there divides into frontal and parietal branches. It is surrounded by a dense plexus of sympathetic nerves, and is accompanied by the auriculo-temporal nerve, which lies beneath and generally a little behind it. It is crossed by the temporal and zygomatic branches of the facial nerve, and by the auricularis anterior (attrahens aurem) muscle. As it crosses the zygoma it can be readily felt pulsating immediately in front of the ear, and in this situation can be compressed against the bone. It is here quite superficial, being merely covered by the integuments and a delicate prolongation from the cervical fascia (fig. 445).

Branches of the Superficial Temporal Artery

The **branches of the superficial temporal** artery are:—(1) The parotid; (2) the transverse facial; (3) the anterior auricular; (4) the zygomatico-orbital; (5) the middle temporal; (6) the frontal; (7) the parietal.

(1) The **parotid** branches [rami parotidei] are small twigs given off in the substance of the parotid gland.

(2) The **transverse facial** [a. transversa faciei] is the largest branch of the temporal. It sometimes arises from the external carotid as a common trunk with the temporal. It is at first deeply seated in the substance of the parotid gland, but soon emerging from the upper part of the anterior border of the gland known, courses transversely across the masseter muscle about a finger's breadth below the zygoma. The parotid duct runs below it, and the zygomatic (infraorbital) branches of the facial nerve above it. It supplies the parotid gland, the masseter muscle, and the skin of the face, and anastomoses with the infraorbital, the buccal, and the external maxillary (facial) arteries.

(3) The **anterior auricular** branches [rami auriculares anteriores] are three or four in number and supply the tragus, the pinna, and the lobule of the ear, and to some extent the external auditory meatus.

(4) The **zygomatico-orbital** artery [a. zygomaticoorbitalis] (fig. 445), at times a branch of the deep temporal, passes forward along the upper border of the zygoma in the fat between the superficial and deep layers of the temporal aponeurosis, and, after giving branches to the orbicularis oculi, sends one or more twigs into the orbit through foramina in the zygomatic (malar) bone to anastomose with the lacrimal and palpebral branches of the ophthalmic.

(5) The **middle temporal** artery [a. temporalis media] (fig. 453), arises just above the zygoma, and, perforating the temporal aponeurosis and temporal muscle, ascends on the squamous portion of the temporal bone, and anastomoses with the posterior deep temporal artery.

(6) The **frontal** or **anterior terminal** branch [ramus frontalis] ramifies tortuously in an upward and forward direction over the front part of the skull. It lies first between the skin and temporal fascia and then between the skin and epicranial aponeurosis. It supplies the anterior belly of the epicranius (occipito-frontalis) and the orbicularis oculi muscles, and anastomoses with the supraorbital and frontal branches of the ophthalmic, and with the corresponding artery of the opposite side. The secondary branches given off from this vessel to the scalp run from before backward.

(7) The **parietal** or **posterior terminal** branch [ramus parietalis] ramifies on the side of the head between the skin and temporal fascia. Its branches anastomose, in front with the anterior terminal branch; behind, with the posterior auricular and occipital arteries; and above, across the vertex of the skull, with the corresponding artery of the opposite side.

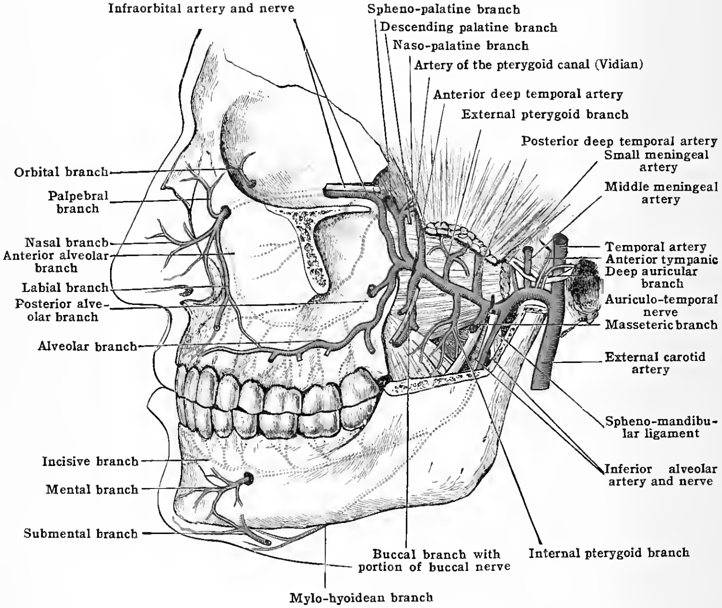
9. THE INTERNAL MAXILLARY ARTERY

The **internal maxillary** artery [a. maxillaris interna] (fig. 451) is the larger of the two terminal divisions of the external carotid. It arises opposite the neck of the mandible in the substance of the parotid gland, and, passing first between the mandible and the spheno-mandibular ligament and then between the external and internal pterygoid muscles, sinks deeply into the pterygo-palatine (spheno-maxillary) fossa, and there breaks up into its terminal branches. It is divided into three portions: a mandibular, a pterygoid, and a pterygo-palatine.

(1) In the **first part of its course** (the **mandibular portion**) the artery lies between the neck of the mandible and the spheno-mandibular ligament, taking a horizontal course forward, nearly parallel to and a little below the auriculo-temporal nerve and the external pterygoid muscle. It is here embedded in the parotid gland, and usually crosses in front of the inferior alveolar (dental) nerve.

(2) In the **second part of its course** (the **pterygoid portion**) the artery may be placed superficial or deep to the external pterygoid muscle. In the first case it passes between the two pterygoid muscles and the ramus of the jaw, and then turns upward over the lateral surface of the external pterygoid, medial to the temporal muscle to gain the two heads of the external pterygoid, between which it

Fig. 451.—Scheme of Left Internal Maxillary. (Walsham.)



sinks into the pterygo-palatine fossa. In the second case it passes medial to the external pterygoid, and is covered by that muscle till it reaches the interval between its two heads, where it then often forms a projecting loop as it turns into the pterygo-palatine fossa.

(3) In the **third part of its course** (the **pterygo-palatine portion**) the artery lies in the pterygo-palatine fossa beneath the maxillary division of the fifth nerve and in close relationship with the spheno-palatine (Meckel's) ganglion, and there breaks up into its terminal branches.

Branches of the Internal Maxillary Artery

The **branches of the internal maxillary artery** are:—

(A) **From the first part**:—(1) The deep auricular; (2) the anterior tympanic; (3) the middle meningeal; (4) the inferior alveolar (dental); (5) the accessory meningeal (sometimes). All these vessels pass through bony or cartilaginous canals.

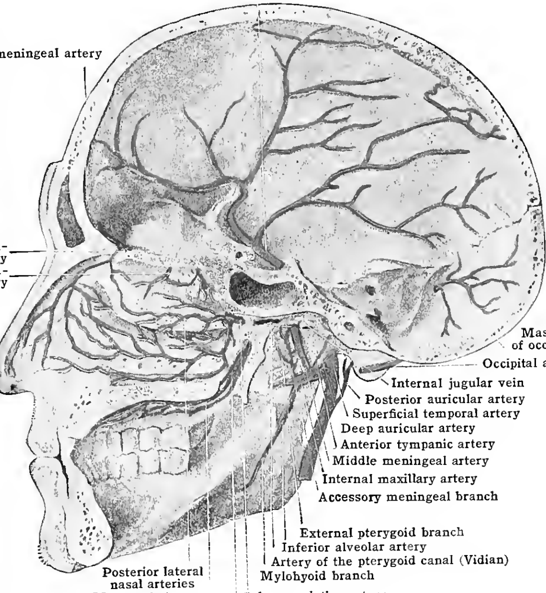
(B) **From the second part:**—(1) The masseteric; (2) the posterior deep temporal; (3) the pterygoid; (4) the buccal; and (5) the anterior deep temporal. All these branches supply muscles.

(C) **From the third part:**—(1) The posterior superior alveolar (dental); (2) the infra-orbital; (3) the descending palatine; (4) the a. canalis pterygoidei or Vidian; and (5) the spheno-palatine. All these branches pass through bony canals.

Branches of the First Part of the Internal Maxillary Artery

(1) The **deep auricular** artery [a. auricularis profunda] (fig. 451) passes upward in the substance of the parotid gland behind the capsule of the temporo-mandibular joint, and, perforating the bony or cartilaginous wall of the external auditory meatus, supplies the skin of that passage and the membrana tympani. It at times gives a branch to the joint as it passes behind the temporo-mandibular articular capsule.

Fig. 452.—The Middle Meningeal Artery within the Skull. (After Spalteholtz.)



(2) The **anterior tympanic** artery [a. tympanica anterior] is a long slender vessel, which runs upward behind the condyle of the jaw to the petro-tympanic (Glaserian) fissure, through which it passes to the interior of the tympanum. Here it supplies the lining membrane of that cavity and anastomoses with the other tympanic arteries, forming with the posterior tympanic branch of the stylo-mastoid artery a vascular circle around the membrana tympani. This circle is more distinct in the fœtus than in the adult.

(3) The **middle meningeal** artery [a. meningea media] is the largest branch of the internal maxillary artery. It comes off from the vessel as it lies between the spheno-mandibular ligament and the ramus of the jaw, and under cover of the external pterygoid passes directly upward to the foramen spinosum, through which it enters the interior of the cranium. In this part of its course it is crossed by the chorda tympani nerve; and just before it enters the foramen is embraced by the two heads of origin of the auriculo-temporal nerve (fig. 451).

The trunk of the mandibular division of the fifth nerve, as it emerges from the foramen ovale, lies in front of the artery. As the artery passes upward it is surrounded by filaments of the sympathetic nerve, and is accompanied by two veins. On entering the skull it ramifies between the bone and dura mater, supplying both structures. It at first ascends for a short distance in a groove on the greater wing of the sphenoid, and then divides into two branches, an anterior and a posterior.

The **anterior branch** passes upward, in the groove on the greater wing of the sphenoid, on to the parietal bone at its anterior and inferior angle; at this spot the groove becomes deepened and often bridged over by a thin plate of bone, being converted for 6 to 12 mm. ($\frac{1}{4}$ to $\frac{1}{2}$ in.) or more into a distinct canal. The situation of the artery is here indicated on the exterior of the skull by a spot 3.7 cm. ($1\frac{1}{2}$ in.) behind, and about 2.5 cm. (1 in.) above, the zygomatic process of the frontal bone. The anterior branch is continued along the anterior border of the parietal bone nearly as far as the superior sagittal sinus, and gives off in its course, but especially posteriorly, large branches which ramify in an upward and backward direction in grooves on the parietal bone (fig. 452).

The **posterior branch** passes backward over the squamous portion of the temporal bone; and thence on to the parietal bone, behind the anterior branch. This branch and its collaterals extend upward as far as the sagittal sinus, and backward as far as the transverse (lateral) sinus.

In addition to its terminal anterior, and terminal posterior branches, the middle meningeal gives off:—(*a*) **Ganglionic** branhecs to the semilunar (Gasserian) ganglion and its sheath of dura mater. (*b*) A **superficial petrosal** branch [ramus petrosus superficialis], which enters the hiatus of the facial canal in company with the large superficial petrosal nerve and anastomoses with the terminal branch of the stylo-mastoid artery. (*c*) A **superior tympanic** artery [a. tympanica superior], which enters the canal for the tensor tympani, and supplies that muscle. (*d*) An **orbital or lacrimal** branch, which enters the orbit at the outermost part of the superior orbital (sphenoidal) fissure, or sometimes through a minute foramen, just lateral to that fissure, and anastomoses with the lacrimal branch of the ophthalmic. (*e*) **Anastomotic or perforating** branches which pierce the greater wing of the sphenoid bone, and anastomose with the deep temporal arteries.

(4) The **inferior alveolar** artery [a. alveolaris inferior] (fig. 451), arising from the internal maxillary as it lies between the spheno-mandibular ligament and neck of the jaw, courses downward to the mandibular foramen, which it enters in company with, and a little behind and lateral to, the inferior alveolar nerve. It then passes along the canal in the interior of the bone, giving off branches to the molar, premolar, and canine teeth. On reaching the mental foramen it divides into two branches, the incisive and the mental. The **incisive** continues its course in the bone, supplies branches to the incisor teeth, and anastomoses with the artery of the opposite side. The **mental** branch [ramus mentalis] passes through the mental foramen in company with the mental branch of the inferior alveolar (dental) nerve, and emerges on the chin under cover of the quadratus labii inferioris. It anastomoses above with the inferior labial (coronary), and below with the submental, and also with the inferior labial. Near its origin the artery gives off (*a*) a **lingual** or **gustatory** branch, which accompanies and supplies the lingual nerve, and ends in the mucous membrane of the mouth; and, just before it enters the mandibular (dental) foramen in the lower jaw, (*b*) a **mylo-hyoidean** branch [ramus mylohyoideus], which accompanies the nerve of that name along the groove in the lower jaw, and, after supplying the mylo-hyoid muscle, anastomoses with the sublingual and submental arteries.

(5) The **accessory or small meningeal branch** [ramus meningeus accessoria] arises either from the internal maxillary a little in front of the middle meningeal, or as a branch of the latter vessel. It passes upward along the course of the mandibular division of the fifth nerve, and, entering the skull through the foramen ovale, is distributed to the semilunar (Gasserian) ganglion, and to the walls of the cavernous sinus and the dura mater in the neighbourhood.

Branches of the Second Part of the Internal Maxillary Artery

The branches of the second portion of the internal maxillary all supply muscles. They are:—(1) The masseteric; (2) the posterior deep temporal; (3) the pterygoid; (4) the buccal; and (5) the anterior deep temporal.

(1) The **masseteric** artery [a. masseterica] comes off from the internal maxillary as the latter is passing from between the neck of the jaw and the spheno-mandibular ligament. It passes, with the masseteric nerve through the mandibular (sigmoid) notch in the mandible and supplies the masseter muscle. Some filaments perforate the muscle and anastomose with the transverse facial and with the masseteric branches of the external maxillary (facial).

(2) The **posterior deep temporal** artery [a. temporalis profunda posterior] arises, as a rule, from the internal maxillary in common with the masseteric for a little beyond that branch. It passes upward beneath the temporal muscle in a slight groove on the anterior margin of the squamous portion of the temporal bone, supplying the temporal muscle, the pericranium and the external layer of the bone. It anastomoses with the other temporal arteries.

(3) The **pterygoid** branches [rami pterygoidei] are short trunks which pass into and supply the internal and external pterygoid muscles.

(4) The **buccal** artery [a. buccinatoria] (fig. 451) courses forward and downward with the buccal nerve to the buccinator muscle, lying in close contact with the medial side and anterior margin of the tendon of the temporal muscle and coronoid process of the lower jaw. It supplies the buccinator muscle and mucous membrane of the mouth, and anastomoses with the external maxillary (facial), transverse facial, and infraorbital arteries.

(5) The **anterior deep temporal** artery [a. temporalis profunda anterior] ascends beneath the temporal muscle in a slight groove on the greater wing of the sphenoid bone. It supplies the muscle, pericranium, and subjacent bone, and gives off small branches which pass through minute foramina in the zygomatic (malar) bone. Some of these last branches enter the orbit and anastomose with the lacrimal artery; others emerge on the face and anastomose with the transverse facial artery.

Branches of the Third Part of the Internal Maxillary Artery

The branches of the third part of the internal maxillary artery, like those of the first part, all pass through bony canals. They are the following:—(1) The posterior superior alveolar (dental); (2) the infraorbital; (3) the descending palatine; (4) the artery of the pterygoid canal (Vidian); and (5) the sphenopalatine.

(1) The **posterior superior alveolar (dental)** artery [a. alveolaris superior posterior] arises from the internal maxillary as the latter is passing into the pterygo-palatine (spheno-maxillary) fossa, and descends in a tortuous manner in a groove on the back of the body of the maxilla. It gives off branches to the maxillary sinus, to the molar and premolar teeth, the gums, and to the buccinator muscle.

(2) The **infraorbital** artery [a. infraorbitalis] arises from the internal maxillary, generally as a common trunk with the posterior alveolar (dental). It passes forward and a little upward through the pterygo-palatine (spheno-maxillary) fossa; then forward in company with the infraorbital branch of the fifth nerve, first along the groove, and then through the canal in the orbital plate of the maxilla; and finally, emerging on the face at the infraorbital foramen, under cover of the quadratus labii superioris, is distributed to the structures forming the upper lip, the lower eyelid, the lacrimal sac, and the side of the nose. It anastomoses with the superior labial (coronary) and angular branches of the external maxillary (facial), with the nasal and lacrimal branches of the ophthalmic, and with the transverse facial. It gives off small branches supplying the fat of the orbit and the inferior rectus and inferior oblique muscles. The **anterior superior alveolar** branch [a. alveolaris superior anterior] passes downward through a groove in the anterior wall of the maxilla, together with the anterior alveolar branch of the infraorbital nerve, and supplies branches to the incisor and canine teeth and the mucous membrane of the maxillary sinus. It has also **nasal** branches which pass through the foramina in the nasal process of the maxilla.

(3) The **descending palatine** artery [a. palatina descendens] descends in the pterygo-palatine canal with the anterior palatine branch of the spheno-palatine ganglion. On emerging on the palate at the greater (posterior) palatine foramen, it divides into the following branches:—(*a*) The **major palatine** artery [a. palatina major], which courses forward in the muco-periosteum at the junction of the hard palate with the alveolar process as far as the incisive (anterior palatine) foramen, where it anastomoses with the spheno-palatine artery; and (*b*) **minor palatine** arteries [aa. palatinæ minores], which pass backward and downward into the soft palate, contributing to the supply of that structure, and anastomosing with the ascending palatine artery. After the operation for cleft palate, serious hæmorrhage occasionally occurs from the descending palatine artery. The foramen is situated a little behind, and medial to, the last molar tooth, and almost immediately in front of the hamular process (fig. 452).

(4) The **arteria canalis pterygoidei or Vidian** artery is a long slender branch which passes backward through the pterygoid (Vidian) canal in company with the nerve of the same name into the cartilage of the lacerated foramen. It gives off branches which supply the roof of the pharynx, and anastomose with the ascending pharyngeal and spheno-palatine arteries; also a branch which is distributed to the Eustachian tube; and one which enters the tympanum, and anatomoses with the other tympanic arteries.

(5) The **spheno-palatine** [a. sphenopalatina], the terminal branch of the internal maxillary, passes with the naso-palatine branch of the spheno-palatine ganglion from the pterygo-palatine (spheno-maxillary) fossa into the nose through the spheno-palatine foramen. Crossing the roof of the nose in the muco-periosteum, it passes on to the septum, and then runs forward and downward in a groove on the vomer toward the incisive (anterior palatine) foramen, where it anastomoses with the anterior palatine artery, which enters the nose through the lateral compartment of that foramen (the canal of Stenson). In this course it gives off branches to the roof and contiguous portions of the pharynx, and to the sphenoidal cells. It has also **posterior lateral nasal** branches [aa. nasales post. laterales], which ramify over the nasal conchæ (turbinate bones) and lateral walls of the nose, and give twigs to the ethmoidal and frontal sinuses and the lining membrane of the maxillary sinus; and **posterior septal** branches [aa. nasales post. septi], which run upward and forward, giving small twigs to the mucous membrane covering the upper part of the septum, and which pass through the cribriform plate of the ethmoid, and anastomose with the ethmoidal arteries (perforating or meningeal branches).

THE INTERNAL CAROTID ARTERY

The **internal carotid** artery [a. carotis interna] (figs. 453 and 454) arises with the external carotid at the bifurcation of the common carotid, opposite the upper border of the thyreoid cartilage, on a level with the fourth cervical vertebra. It is at first placed a little lateral to the external carotid, but as it ascends in the neck the external carotid becomes more superficial and in front of the internal. The internal carotid passes up the neck, in front of the transverse processes of the upper cervical vertebræ, lying upon the longus capitis (rectus capitis ant. major), to the carotid foramen, thence through the carotid canal in the petrous portion of the temporal bone, making at first a forward and medial turn and then a second turn upward, and enters the cranium through the foramen lacerum. It makes a sigmoid curve on the side of the body of the sphenoid bone, and terminates, after perforating the dura mater, by dividing opposite the anterior clinoid processes in the lateral fissure (fissure of Sylvius), into the anterior and middle cerebral arteries.

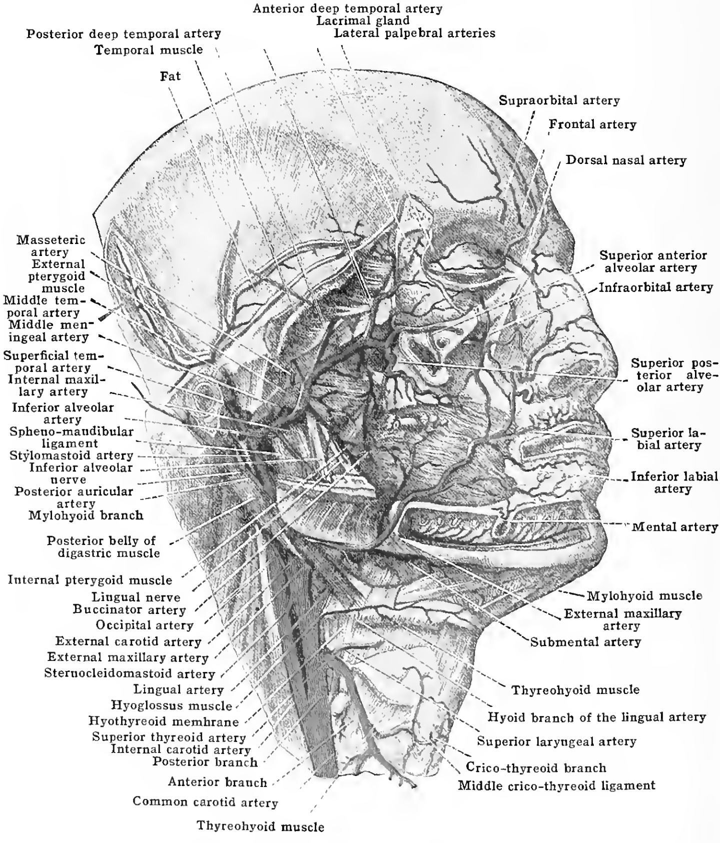
In its course up the neck it often forms one or more curves, especially in old people. Between the internal and the external carotids, at their angle of divergence, is situated the carotid body or gland [glomus caroticum].

The internal carotid is the continuation upward of the primitive dorsal aorta, and supplies the greater part of the brain, the contents of the orbit, and parts of the internal ear, forehead, and nose. It is divided into three portions:—(1) a cervical; (2) a petrosal; and (3) an intracranial.

1. The Cervical Portion

Relations.—In the neck (fig. 453) the artery is at first comparatively superficial, having in front of it, as it lies in the superior carotid triangle, the skin, superficial fascia, platysma and

Fig. 453.—The Carotid Arteries. (After Toldt, "Atlas of Human Anatomy," Rebman London and New York.)



deep fascia, and the overlapping edge of the sterno-mastoid muscle. Higher up, as it sinks beneath the parotid gland, it becomes deeply placed, and is crossed by the posterior belly of the digastric and stylo-hyoid muscles, the hypoglossal nerve, and the occipital and posterior auricular arteries; whilst still higher it is separated from the external carotid artery, which here gets in front of it, by the stylo-glossus and stylo-pharyngeus muscles, the glosso-pharyngeal nerve, the pharyngeal branch of the vagus nerve, and by the stylo-hyoid ligament.

Behind, it lies upon the longus capitis (rectus capitis anticus major), which separates it from the transverse processes of the three upper cervical vertebræ, on the superior cervical ganglion of the sympathetic nerve, and on the vagus nerve. Near the base of the skull, the hypoglossal, vagus, glosso-pharyngeal, and spinal accessory nerves cross obliquely behind it, separating it here from the internal jugular vein, which, as the artery is about to enter the carotid canal, also forms one of its posterior relations.

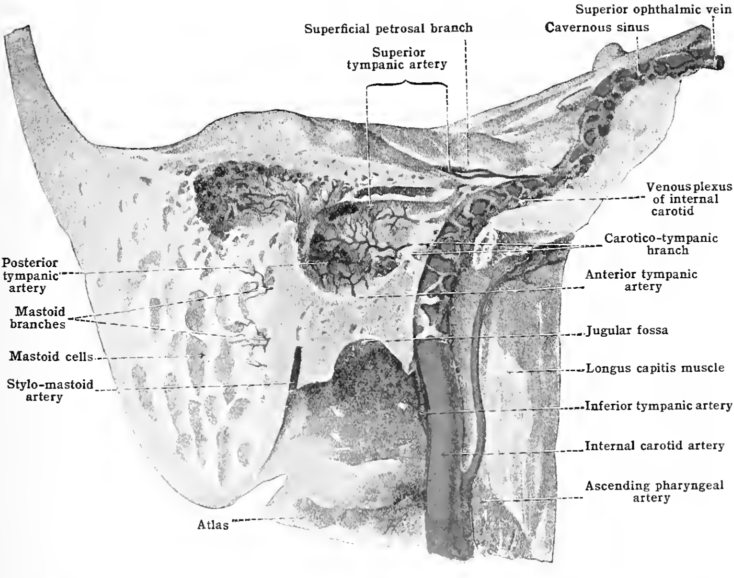
On its lateral side are the internal jugular vein and vagus nerve.

On its medial side it is in relation with the pharynx, the superior constrictor muscle separating it from the tonsil. The ascending pharyngeal and ascending palatine arteries, and at the base of the skull the Eustachian tube and levator palati muscles, are also medial to it.

2. Thf Petrosal Portion

The **petrosal portion** (fig. 454) is situated in the carotid canal in the petrous portion of the temporal bone. It is here separated from the walls of the canal by a prolongation downward of the dura mater. In this part of its course it first ascends in front of the tympanum and cochlea of the internal ear; it then turns forward and medially, lying a little medial to and behind the Eustachian tube, and enters the cranial cavity by turning upward through the foramen lacerum, lying upon the lingula of the sphenoid bone. In this part of its course it is accompanied by the ascending branches from the superior cervical ganglion of the sympathetic. These form a plexus about the artery, but are situated chiefly on its lateral side. It is also surrounded by a number of small veins, which receive tributaries from the tympanum and open into the cavernous sinus and internal jugular vein.

Fig. 454.—The Internal Carotid Artery in the Canal. (After Spalteholz.)



3. The Intracranial Portion

On entering the cranium through the foramen lacerum, the internal carotid first ascends to reach the lateral part of the body of the sphenoid medial to the lingula. It then follows the carotid sulcus forward and slightly downward along the medial wall of the cavernous sinus (fig. 454). Here it has the sixth nerve immediately lateral to it, and is covered by the lining membrane of the sinus. Again turning upward, it pierces the dura mater on the medial side of the anterior clinoid process, and, passes between the second and third nerves to the anterior perforated substance. At the medial end of the lateral (Sylvian) fissure it pierces the arachnoid and divides into its two terminal branches, the anterior and middle cerebral. As it lies in the foramen lacerum the artery is crossed on its lateral side by the great superficial petrosal nerve as the latter goes to join the great deep petrosal from the carotid plexus to form the nerve of the pterygoid canal (Vidian).

Branches of the Internal Carotid Artery

The **cervical portion** gives off no branch. The **petrosal portion** gives off the caroticotympanic. The **branches of the intracranial portion** are:—(2) ophthalmic; (3) posterior communicating; (4) chorioid; (5) anterior cerebral; (6) middle erebral.

As the internal carotid artery lies on the medial side of the cavernois sinus, it also gives off the following small branches—branches to the walls of the cavernous inus; to the pituitary body; to the semilunar (Gasserian) ganglion; to the dura mater. These anastomose with anterior branches of the middle meningeal.

1. THE CAROTICOTYMPANIC ARTERY

The **caroticotympanic** enters the tympanum through a small foramen in the posterior wall of the carotid canal, and contributes its quota to the blood-supply of that cavity. It anastomoses with the tympanic branches of the stylo-mastoid, internal maxillary, and middle meningeal arteries.

2. THE OPHTHALMIC ARTERY

The **ophthalmic** artery (fig. 455) comes off from the internal carotid immediately below the anterior clinoid process just as the latter vessel is passing through the dura matter. Entering the orbit through the optic foramen below and lateral to theo ptic nerve, it at once perforates the sheath of dura mater which is prolonged through the optic foramen on both artery and nerve. It then runs in a gentle curve with a lateral convexity below the optic nerve and lateral rectus, being here crossed by the naso-ciliary (nasal) nerve. Turning forward and upward, it passes over the optic nerve, to its medial side. Thence it runs obliquely beneath the superior rectus in front of the naso-ciliary (nasal) nerve under the lower border of the superior oblique, but above the medial rectus, and continues its course under the pulley for the superior oblique and reflected tendon of that muscle to the medial palpebral region, where it divides into the frontal and nasal branches.

Branches of the Ophthalmic Artery

The **branches of the ophthalmic artery** are:—(1) the lacrimal; (2) the supraorbital; (3) the central artery of the retina; (4) the muscular; (5) the ciliary; (6) the posterior ethmoidal; (7) the anterior ethmoidal; (8) the medial palpebral; (9) the frontal; and (10) the dorsal nasal.

(1) The **lacrimal** artery [a. lacrimalis], is usually the first and often the largest branch of the ophthalmic. It arises between the superior and lateral rectus on the lateral side of the optic nerve from the ophthalmic, soon after that vessel has entered the orbit. At times it is given off from the ophthalmic outside the orbit, and then usually passes into that cavity through the superior orbital (sphenoidal) fissure. It runs forward along the lateral wall of the orbit with the lacrimal nerve, above the upper border of the lateral rectus, to the lacrimal gland, which it supplies. In this course it furnishes the following branches:—(*a*) **Recurrent,** one or more branches which pass backward through the superior orbital (sphenoidal) fissure, and anastomose with the lacrimal branch of the middle meningeal artery. The anastomosis is sometimes of large size, and then takes the chief share in the formation of the lacrimal artery. (*b*) **Muscular** branches, distributed chiefly to the lateral rectus. (*c*) **Zygomatic** branches—small twigs, which pass through the zygomatico-orbital (malar) canals, and anastomose with the orbital branch of the middle temporal, and with the transverse facial on the cheek. (*d*) **Lateral palpebral** arteries [aa. palpebrales laterales] which are distributed to the upper and lower eyelids and to the conjunctiva. (*e*) **Ciliary.** See Ciliary Arteries, page 553.

(2) The **supraorbital** artery [a. supraorbitalis] usually arises from the ophthalmic as the latter vessel is about to cross over the optic nerve. Passing upward to the medial side of the superior rectus and levator palpebræ, it runs along the upper surface of the latter muscle with the frontal nerve in the orbital fat, but beneath the periosteum, to the supraorbital notch. On emerging on the forehead beneath the orbicularis oculi, it divides into a superficial and deep branch, the former ramifies between the skin and epicranius (occipito-frontalis), the latter

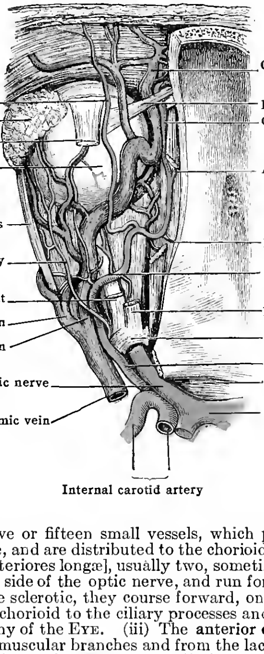
between the epicranius and the pericranium. Both branches anastomose with the anterior branches of the superficial temporal, the angular branch of the external maxillary (facial), and the transverse facial artery. The branches of the supraorbital are:—(*a*) **periosteal,** to the periosteum of the roof of the orbit; (*b*) **muscular,** to the levator palpebræ and superior rectus; (*c*) **diploic,** given off as the artery is passing through the supraorbital notch and, entering a minute foramen at the bottom of the notch, is distributed to the diploë and frontal sinuses; (*d*) **trochlear,** to the pulley of the superior oblique; (*e*) **palpebral,** to the upper eyelid.

(3) The **arteria centralis retinæ,** a small but constant branch, comes off from the ophthalmic close to the optic foramen, and, perforating the optic nerve about 6 mm. ($\frac{1}{4}$ in.) behind the globe, runs forward in (the substance of the nerve) to the eyeball, supplying the retina. Its further description is given in the section on the EYE.

(4) The **muscular** branches [rami musculares] are very variable in their origin and distribution. They may be roughly divided into superior and inferior sets. The superior or smaller set supply the superior oblique, the levator palpebræ, and superior rectus. The inferior pass forward, between the optic nerve and the inferior rectus, supplying that muscle, the medial rectus, and the inferior oblique. From the muscular branches are given off the anterior ciliary arteries. (See CILIARY ARTERIES.)

(5) The **ciliary** arteries are divided into three sets:—The **short posterior,** the **long posterior,** and the **anterior.** (i) The **short posterior** [aa. ciliares posteriores breves], five or six in number, come off chiefly from the ophthalmic as it is crossing the optic nerve. They run forward about

FIG. 455.—THE LEFT OPHTHALMIC ARTERY AND VEIN.



the nerve, dividing into twelve or fifteen small vessels, which perforate the sclerotic around the entrance of the optic nerve, and are distributed to the chorioid coat. (ii) The **long posterior** ciliary arteries [aa. ciliares posteriores longæ], usually two, sometimes three, in number, come off from the ophthalmic on either side of the optic nerve, and run forward with the short ciliary to the sclerotic. On piercing the sclerotic, they course forward, one on either side of the eyeball between the sclerotic and the chorioid to the ciliary processes and iris. Their further distribution is given under the anatomy of the EYE. (iii) The **anterior ciliary** arteries [aa. ciliares anteriores] are derived from the muscular branches and from the lacrimal. They run to the globe along the tendons of the recti, forming a zone of radiating vessels beneath the conjunctiva. Some of them, the **episcleral arteries** [aa. episclerales], perforate the sclerotic about 6 mm. ($\frac{1}{4}$ in.) behind the cornea, and supply the iris and ciliary processes. It is these vessels that are enlarged and congested in iritis, forming the circumcorneal zone of redness so characteristic of that disease. They then differ from the tortuous vessels of the conjunctiva in that they are straight and parallel. The remainder constitute the **anterior conjunctival** arteries [aa. conjunctivales anteriores].

(6) The **posterior ethmoidal** artery [a. ethmoidalis posterior] (fig. 455) runs medially between the superior oblique and medial rectus, and, leaving the orbit by the posterior ethmoidal canal, together with the posterior ethmoidal branch of the naso-ciliary (nasal) nerve, enters the posterior ethmoidal cells, whence it passes through a transverse slit-like aperture between the sphenoid bone and cribriform plate of the ethmoid bone into the cranium. It gives off (*a*) **ethmoidal** branches to the posterior ethmoidal cells; (*b*) **meningeal** branches to the dura mater lining the cribriform plate; and (*c*) **nasal** branches, which pass through the cribriform plate to

the superior meatus and upper spongy bones of the nose, and anastomose with the nasal branches of the spheno-palatine artery (fig. 452).

(7) The **anterior ethmoidal** artery [a. ethmoidalis anterior] (fig. 452), a larger branch than the posterior ethmoidal, arises in front of the latter, passes medially between the superior oblique and medial rectus, and, leaving the orbit through the anterior ethmoidal canal, in company with the anterior ethmoidal nerve, enters the cranial cavity. After running a short distance beneath the dura mater on the cribriform plate of the ethmoidal bone, it passes into the nose through the horizontal slit-like aperture by the side of the crista galli. Its terminal branch passes along the groove on the under surface of the nasal bone, and emerges on the nose between the bone and lateral cartilage, terminating in the skin of that organ. It gives off the following branches in its course:—(i) **Ethmoidal,** to the anterior ethmoidal cells; (ii) **anterior meningeal** artery, [a. meningea anterior] to the dura mater of the anterior fossa; (iii) **nasal,** to the middle meatus and anterior part of the nose; (iv) **frontal,** to the frontal sinuses; (v) **cutaneous,** or **terminal,** to the skin of the nose.

(8) The **medial palpebral** arteries [aa. palpebrales mediales] arise either separately or by a common trunk from the ophthalmic artery opposite the pulley for the superior oblique, just as the latter vessel is about to divide into its terminal branches. They pass, one above and one below, the medial palpebral ligament and then skirt along the upper and lower eyelids respectively, near the free margin between the palpebral tarsi and the orbicularis muscle, and form a **superior** and an **inferior tarsal arch** [arcus tarsus superior et inferior] by anastomosing with the lateral palpebral branches of the lacrimal. The upper also anastomoses with the supraorbital artery and orbital branch of the temporal artery; the lower with the infraorbital, the angular branch of the external maxillary (facial), and the transverse facial arteries. A branch from the lower palpebral passes with the ductus nasolacrimalis as far as the inferior meatus. Small twigs, the **posterior conjunctival** arteries [aa. conjunctivales posteriores], are also given to the caruncula lacrimalis and conjunctiva.

(9) The **frontal** artery [a. frontalis], the upper of the terminal branches of the ophthalmic, pierces the superior tarsus at the medial angle of the orbit, passes upward over the frontal bone beneath the orbicularis oculi, supplies the structures in its neighbourhood, and anastomoses with its fellow of the opposite side, with the supraorbital, and with the anterior division of the superficial temporal artery.

(10) The **dorsal nasal** [a. dorsalis nasi], the lower of the terminal branches of the ophthalmic, leaves the orbit at the medial angle by perforating the tarsus above the medial palpebral ligament. It then descends along the dorsum of the nose, beneath the integuments, and anastomoses with the angular and lateral nasal branches of the external maxillary (facial). It gives off a **lacrimal branch** as it crosses the lacrimal sac, and a **transverse nasal branch** as it crosses the root of the nose; the latter vessel anastomoses with its fellow of the opposite side.

3. THE POSTERIOR COMMUNICATING ARTERY

The **posterior communicating** artery [a. communicans posterior] (fig. 456) is given off from the internal carotid just before the division of that vessel into the anterior and middle cerebral arteries; occasionally it arises from the middle cerebral itself.

It is as a rule a slender vessel which runs backward over the optic tract and pedunculus cerebri along the side of the hippocampal gyrus to join the posterior cerebral. At times, however, it is of considerable size, and contributes chiefly to form the posterior cerebral, the portion of the latter vessel between the basilar and posterior communicating being then as a rule reduced to a mere rudiment. It gives off the following branches:—(*a*) the **hippocampal,** to the gyrus of that name; and (*b*) the **middle thalamic,** to the optic thalamus.

4. THE CHORIOID ARTERY

The **chorioid** artery [a. chorioidea] is a small but constant vessel which arises as a rule from the back part of the internal carotid just lateral to the origin of the posterior communicating.

It passes backward on the optic tract and the pedunculus cerebri, at first lying parallel and lateral to the posterior communicating artery. It then dips under the edge of the uncinate gyrus and, entering the chorioid fissure at the lower end of the inferior cornu of the lateral ventricle, ends in the chorioid plexus and supplies the hippocampus and fimbria.

5. THE ANTERIOR CEREBRAL ARTERY

The **anterior cerebral** artery [a. cerebri anterior] (figs. 456, 459), one of the terminal branches into which the internal carotid divides in the lateral fissure (fissure of Sylvius), supplies a part of the cortex of the frontal and parietal lobes of the brain and a small part of the basal ganglia. It passes at first anteriorly and medially across the anterior perforated substance between the olfactory and optic nerves to the longitudinal fissure where it approaches its fellow of the opposite side and communicates with it by a short transverse trunk, about five mm. long, known as the **anterior communicating** artery [a. communicans anterior] (fig. 456). Onward from this point it runs side by side with its fellow in the longitudinal fissure round the genu of the corpus callosum; then, turning backward, it continues along the upper surface of that commissure, and, after giving off large branches to the frontal and parietal lobules, anastomoses with the posterior cerebral artery.

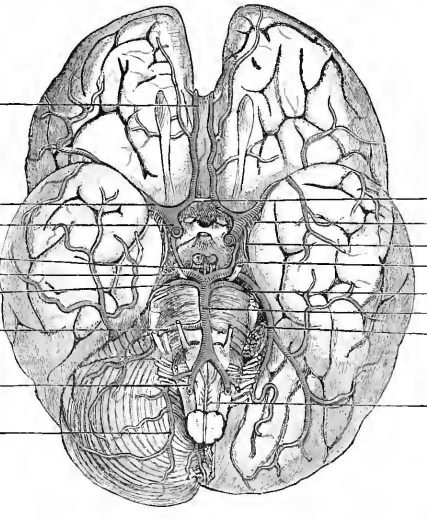
6. THE MIDDLE CEREBRAL ARTERY

The **middle cerebral** artery [a. cerebri media] (figs. 456, 460), the larger of the terminal divisions of the internal carotid, supplies the basal ganglia and a part of the cortex of the frontal and parietal lobes. It passes obliquely upward and lateralward into the lateral (Sylviau) fissure, and opposite the insula divides into cortical branches.

Circulus Arteriosus

The four arteries which supply the brain, namely, the two internal carotid arteries and the two vertebrals (which unite to form the basilar), form a remark-

Fig. 456.—The Arteries of the Brain.
(The cerebellum has been cut away on the left side to show the posterior part of the cerebrum. From a preparation in the Museum of St. Bartholomew's Hospital.)



able anastomosis at the base of the brain known as the circle of Willis [circulus arteriosus (Willisi)]. This so-called circle, which has really the form of a heptagon, is formed, **in front,** by the anterior communicating artery uniting the anterior cerebral arteries of opposite sides; **laterally,** by the internal carotids and the posterior communicating arteries stretching between these and the posterior cerebrals; **behind,** by the two posterior cerebrals diverging from the bifurcation of the basilar artery (fig. 456).

This free anastomosis between the two internal carotid and the two vertebral arteries serves to equalise the flow of blood to the various portions of the brain; and, should one or more of the arteries entering into the formation of the circle be temporarily or permanently obstructed, it ensures a flow of blood to the otherwise deprived part through some of the collateral arteries. Thus, if one carotid or one vertebral is obstructed, the parts supplied by that vessel receive their blood through the circle from the remaining pervious vessels. Indeed, one vertebral artery alone has been found equal to the task of carrying sufficient blood for the supply of the brain after ligature of both the carotids and the other vertebral artery. Further, the circle of Willis is the only medium of communication between the ganglionic or central and the peripheral or cortical branches of the cerebral arteries, and between the various ganglionic branches themselves. The ganglionic and the cortical branches form separate and distinct systems, and do not anastomose with each other; and the ganglionic, moreover, are so-called end-vessels, and do not anastomose with the neighbouring ganglionic branches. The three cerebral arteries, anterior, middle, and posterior may be regarded as branches of the circle of Willis. (For details concerning the distribution of the cerebral arteries see p. 562.)

THE SUBCLAVIAN ARTERY

The **subclavian artery** on the right side [a. subclavia dextra] arises at the bifurcation of the innominate opposite the upper limit of the right sterno-clavicular articulation. On the left side it arises from the arch of the aorta, and, as far as the medial border of the scalenus anterior, is situated deeply in the chest. The first portion of the left subclavian artery is described separately.

Beyond the medial border of the scalenus anterior the artery has the same relations on both sides. It courses from this point beneath the clavicle in a slight curve across the root of the neck to the lateral border of the first rib, there to end in the axillary artery. Thus the course of the artery in the neck will be indicated by a line drawn from the sterno-clavicular joint in a curve with its convexity upward to the middle of the clavicle. The height to which the artery rises in the neck varies. It is perhaps most commonly about 1.2 cm. ($\frac{1}{2}$ in.) above the clavicle. If the curved line above mentioned is drawn to represent part of the circumference of a circle having its center at a point on the lower margin of the clavicle 3.7 cm. ($1\frac{1}{2}$ in.) from the sternal end of that bone, the line of the artery will be sufficiently well indicated for all practical purposes. In its course the artery arches over the dome of the pleura and gains the groove on the upper surface of the first rib by passing between the scalenus anterior and medius muscles. The artery is accompanied by the subclavian vein, the latter vessel lying in front of the scalenus anterior, anterior to the artery, and on a slightly lower plane.

The subclavian artery is divided into three portions—as it lies medial to, posterior to, or lateral to, the scalenus anterior muscle.

THE FIRST OR THORACIC PORTION OF THE LEFT SUBCLAVIAN ARTERY

The **left subclavian** artery [a. subclavia sinistra] (fig. 457) arises from the left end of the arch of the aorta. The first part of the left subclavian is consequently longer than the first part of the right, which arises at the bifurcation of the innominate artery. The artery at its origin is situated deeply in the thorax, and as it arises from the aorta is on a plane posterior to and a little to the left of the thoracic portion of the left common carotid. It first ascends almost vertically out of the chest, and at the root of the neck curves laterally over the apex of the left pleura and lung to the interval between the anterior and middle scalene muscles. Beyond the medial border of the scalenus anterior—that is, in the second and third portions of its course—its relations are similar to those of the right subclavian artery.

Relations.—**In front** it is covered by the left pleura and lung, whilst more superficial are the sterno-thyreoid, sterno-hyoid, and sterno-mastoid muscles. It is crossed a little above its origin by the left innominate vein, and higher in the neck near the scalenus anterior by the internal jugular, vertebral, and subclavian veins. The phrenic nerve crosses the artery immediately medial to the scalenus anterior, and then descends parallel to it, but on an anterior plane, to cross the arch of the aorta. The vagus nerve descends parallel to the artery between it and the left common carotid, coming into contact with its anterior surface just before crossing the arch of the aorta. The left cervical cardiac nerves of the sympathetic also descend in front of it on their way to the cardiac plexus. The left *ansa subclavia* also loops in front of the subclavian artery. The left common carotid is situated anteriorly and to its right. The thoracic duct arches over the artery just medial to the scalenus anterior, to empty its contents into the confluence of the internal jugular and subclavian veins (fig. 442).

Behind and somewhat medial to it are the œsophagus, thoracic duct, inferior cervical ganglion of the sympathetic, longus colli muscle, and vertebral column. To some extent it is overlapped posteriorly by the left pleura and lung.

On its **right side** are the trachea and the inferior laryngeal nerve, and, higher up, the œsophagus and thoracic duct.

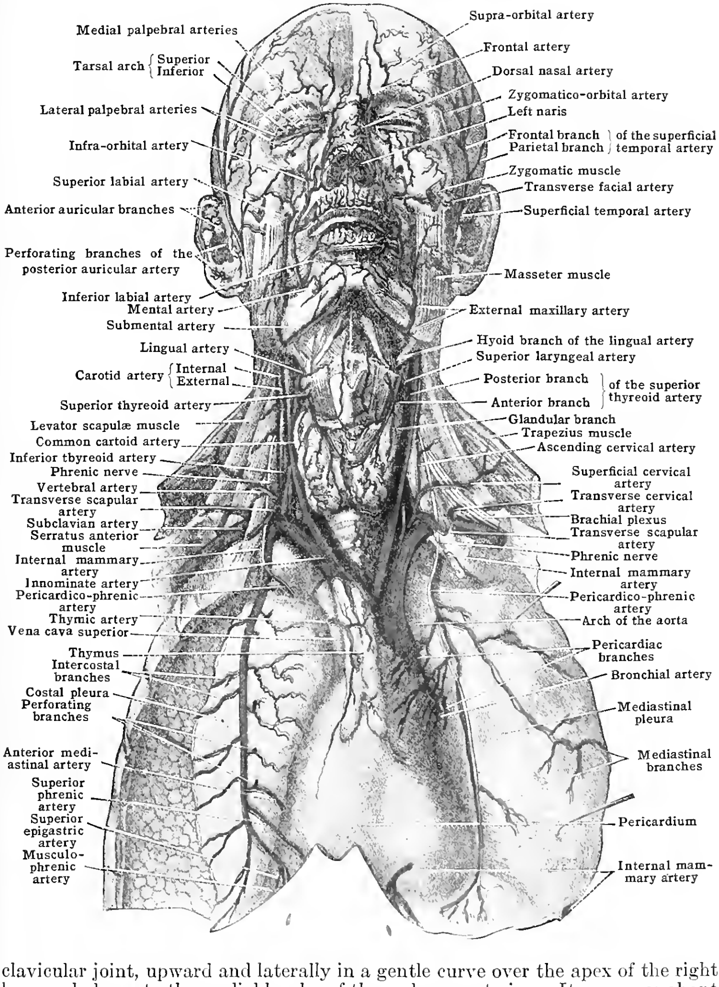
On its **left side** are the left pleura and lung.

Branches.—The vertebral, internal mammary, and thyreo-cervical trunk (thyreoid axis) usually arise from the first portion on the left side. (See p. 559.)

THE FIRST PORTION OF THE RIGHT SUBCLAVIAN ARTERY

The **first portion of the right subclavian artery** (fig. 457) extends from its origin at the bifurcation of the innominate, behind the upper margin of the right sterno-

Fig. 457.—The Subclavian Artery. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



clavicular joint, upward and laterally in a gentle curve over the apex of the right lung and pleura to the medial border of the scalenus anterior. It measures about 3 cm. ($1\frac{1}{4}$ in.). In this course it ascends in the neck a variable distance above the clavicle, but is so deeply placed, so surrounded by important structures, and gives off so many large branches, that it is now seldom or never selected for the application of a ligature.

Relations.—In front it is covered by the integuments, the superficial fascia, the platysma, the anterior layer of the deep fascia, the clavicular origin of the sterno-mastoid, the sterno-hyoid and sterno-thyreoid muscles, and the deep cervical fascia. It is crossed by the commencement of the innominate, by the internal jugular, and by the vertebral veins; and, in a medio-lateral direction, by the vagus and phrenic nerves, and the superior cardiac branches of the sympathetic nerve. A loop of the sympathetic nerve itself also crosses the artery, and forms with the trunk of the sympathetic a ring around the vessel known as the **ansa subclavia** (annulus of Vieussens).

Behind, but separated from the artery by a cellular interval, are the longus colli muscle, the transverse process of the seventh cervical or first thoracic vertebra, the main chain of the sympathetic nerve, the inferior cardiac nerves, the recurrent laryngeal nerve, and the apex of the right lung and pleura.

Below, it is in contact with the pleura and lung and the loop of the recurrent laryngeal nerve, which winds round the artery from the vagus and ascends behind it to the larynx. The subclavian vein is below the artery and on an anterior plane.

Branches.—The vertebral, internal mammary, superficial cervical, and thyreo-cervical trunk (thyreoid axis) arise from this part of the vessel on the right side. (See p. 559.) Not uncommonly a small aberrant artery also takes origin from this portion of the artery and descends to the left behind the œsophagus to join a branch of the aorta opposite the third or fourth thoracic vertebra. This vessel is probably the remains of the right dorsal aorta.

THE SECOND PORTION OF THE SUBCLAVIAN ARTERY

The **second portion of the subclavian artery** lies behind the scalenus anterior muscle. It measures about 2 cm. ($\frac{3}{4}$ in.) in length and here reaches highest in the neck. The subclavian vein is separated from the artery by the scalenus anterior, and lies on a lower and anterior plane (fig. 463).

Relations.—**In front** it is covered by the skin, superficial fascia, platysma, anterior layer of deep fascia, the clavicular origin of the sterno-mastoid, posterior layer of deep fascia, and by the scalenus anterior. The phrenic nerve—which, in consequence of its oblique course medially downward, crosses a portion of both the first and second part of the subclavian—is separated from the second portion by the scalenus anterior muscle, as is also the subclavian vein which courses on a somewhat lower plane.

Behind the artery are the apex of the pleura and lung, and a portion of the scalenus medius; also the scalenus minimus (partially or entirely fibrous, known as Sibson's fascia, see p. 355).

Above is the brachial plexus.

Below are the pleura and lung.

One **branch** only—the costo-cervical trunk (superior intercostal)—is, as a rule, given off from this portion of the subclavian; occasionally the transverse cervical or the descending branch of the transverse cervical (posterior scapular artery) arises from it.

THE THIRD PORTION OF THE SUBCLAVIAN ARTERY

The **third portion of the subclavian artery** extends from the lateral margin of the scalenus anterior muscle to the lateral border of the first rib. It is more superficial than either the first or second portions; it is in relation with less important structures, and as a rule gives off no branch, and for these reasons is the part selected when practicable for the application of a ligature. It is the longest of the three portions of the subclavian artery, and lies in a triangle—the subclavian triangle—bounded by the sterno-mastoid, the omo-hyoid, and the clavicle (fig. 445).

Relations.—**In front** it is covered by skin, superficial fascia, platysma, supra-clavicular nerves (descending superficial branches) of the cervical plexus; the anterior layer of deep fascia which descends from the omo-hyoid to the clavicle; and the posterior layer of deep fascia which descends from the omo-hyoid to the first rib and passes over the scalenus anterior and phrenic nerve. Between the two layers of fascia is a variable amount of cellular tissue and fat, and running in this is the transverse scapular (supra-scapular) artery. The subclavian is crossed by this artery unless the arm is drawn well downward. Close to the lateral margin of the sterno-mastoid, the external jugular vein pierces the fascia, and crosses the subclavian artery to open into the subclavian vein. As this vein lies between the two layers of fascia, it receives on its lateral side the transverse scapular (supra-scapular), transverse cervical, and other veins of the neck, which together form a plexus of large veins in front of the artery. The nerve to the subclavius, and, when present, the accessory branch from this nerve to the phrenic, also here cross in front of the artery. In very muscular subjects the clavicular head of the sterno-mastoid may be larger than usual, and in such a case will form one of the coverings of the artery.

Behind, the artery is in contact with the scalenus medius, and with the lower trunk of the brachial plexus.

Below, the artery rests in the posterior of the two grooves on the upper surface of the first rib.

Above is the brachial plexus of nerves and the posterior belly of the omo-hyoid muscle. The trunk formed by the fifth and sixth cervical nerves is also above the artery, but on a somewhat anterior plane. It is close to the vessel, and has been mistaken for the artery in the application of a ligature.

As a rule there is no branch given off from the third portion of the subclavian. At times, however, the transverse cervical or the descending branch of the transverse cervical (posterior scapular artery) may arise from the third portion of the subclavian instead of from the thyreo-cervical trunk (thyreoid axis) and from the transverse cervical respectively, as here described.

There is considerable variation in the branches of the subclavian artery and Bean (Am. Jour. Anat., Vol. 4, p. 303) has shown that the branches are arranged in a different way on the two sides of the body. The usual form on the right side is for the vertebral, internal mammary, the superficial cervical and the common trunk of the inferior thyreoid and transverse scapular arteries to arise from the first part of the subclavian. In this case the ascending cervical is a branch of the inferior thyreoid, while the transverse cervical and costo-cervical arise from the second portion. There are no branches from the third portion. On the left side the usual form is for the vertebral and internal mammary, and thyreo-cervical trunk, to arise from the first part. The thyreo-cervical trunk divides into inferior thyreoid, transverse scapular, and transverse cervical arteries; the superficial cervical is absent, and the costo-cervical trunk arises from the first part.

There are three more types of origin of the branches; in one, the vertebral, internal mammary, costo-cervical, and inferior thyreoid come from the first part, while the transverse cervical arises from the second part, and the transverse scapular comes either from the third part or the axillary artery; in the second, the inferior thyreoid, transverse scapular and transverse cervical arise in a common stem from the first part; while in the third, which is the rarest form, the inferior thyreoid and superficial cervical arteries come by a common trunk from the first part, while the transverse scapular artery arises from the internal mammary.

1. THE VERTEBRAL ARTERY

The **vertebral** artery [a. vertebralis] (fig. 458) the first, largest, and most constant branch, arises from the upper and posterior part of the first portion of the subclavian, on the right side, about 2 cm. ($\frac{3}{4}$ in.) from the origin of the latter vessel from the innominate, on the left side, from the most prominent part of the arch of the subclavian, close to the medial edge of the scalenus anterior muscle. It first ascends vertically to the foramen transversarium of the sixth cervical vertebra, and, having passed through that foramen and those of the next succeeding cervical vertebræ as high as the epistropheus (axis), it turns laterally and then ascends to reach the foramen in the transverse process of the atlas; after passing through that foramen it turns backward behind the articular process, lying in the groove on the posterior arch of the atlas. It next pierces the posterior occipito-atlantoid membrane and the dura mater, and enters the cranium through the foramen magnum. Here it passes upward, at first lying by the side of the medulla, then in front of that structure, and terminates at the lower portion of the pons by anastomosing with the vertebral of the opposite side to form the basilar.

The vertebral artery may be divided for purposes of description into four parts: the **first,** or **cervical,** extending from its origin to the transverse process of the sixth cervical vertebra; the **second,** or **vertebral,** situated in the foramina transversaria; the **third,** or **occipital,** contained in the suboccipital triangle; and the **fourth,** or **intracranial,** within the cranium.

The first or cervical portion.—The artery here lies between the scalenus anterior and longus colli muscles. **In front** it is covered by the vertebral and internal jugular veins, and is crossed by the inferior thyreoid artery, and on the left side, in addition, by the thoracic duct, which runs over it medio-laterally. **Behind,** the artery lies on the transverse process of the seventh cervical vertebra and the sympathetic nerve. To its **medial side** is the longus colli. To its **lateral**

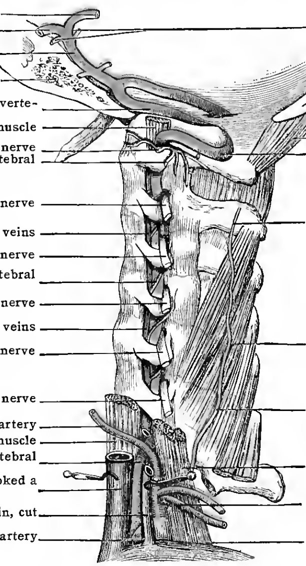
side is the scalenus anterior. It gives off as a rule no branch in this part of its course. Occasionally, however, a small branch passes into the foramen tranversarium of the seventh cervical vertebra.

The second or vertebral portion.—As the artery passes through the foramina transversaria, it is surriunded by a plexus of veins and by branches of the sympathetic nerve. The cervical nerves lie behind it. Between the transverse processes it is in contact with the intertransverse muscles.

The third or occipital portion.—The artery here lies in the suboccipital triangle, bounded by the superior oblique, inferior oblique, and rectus capitis posterior major muscles. As it winds round the groove on the atlas, it has the rectus capitis lateralis, the articular process, and the posterior occipito-atlantoid membrane **in front** of it; the superior oblique, the rectus capitis posterior major, and the semispinalis capitis (complexus) **behind** it. Separating it from the arch of the atlas, is the first cervical or suboccipital nerve.

The **fourth** or **intracranial portion** extends from the aperture in the dura mater to the lower border of the pons, where it pierces the arachnoid and unites with its fellow to form the basilar artery. It here winds round from the side to the front of the medulla, lying in the

Fig. 458.—Scheme of the Left Vertebral Artery. (Walsham.)
The internal jugular and vertebral veins are hooked aside to expose the artery.



vertebral groove on the basilar part of the occipital bone. In this course it passes beneath the first process of the ligamentum denticulatum, and between the hypoglossal nerve in front, and the anterior roots of the suboccipital nerve behind.

Branches of the Vertebral Artery

The first part of the vertebral artery gives no branches. The second and third parts give off *muscular* branches to the semispinalis and posterior recti and oblique muscles. The second part also gives off five or six, (1) Spinal branches. The fourth part gives off the following: (2) Posterior meningeal; (3) posterior spinal; (4) anterior spinal; and (5) posterior inferior cerebellar.

(1) The spinal branches [rami spinales] run through the intervertebral foramina into the vertebral canal, and there divide into two branches: one of which ramifies on the backs of the bodies of the cervical vertebræ; while the other runs along the spinal nerves, supplies the cord and its membranes, and anastomoses with the arteries above and below.

(2) The meningeal [ramus meningeus] is a small branch given off as the vertebral artery pierces the dura mater to enter the cranium. It supplies the bone and dura mater of the posterior fossa of the skull, and anastomoses with the posterior meningeal branches derived from the occipital and ascending pharyngeal arteries. It gives branches to the falx cerebelli.

(3) The **posterior spinal** artery [a. spinalis posterior] runs downward obliquely along the side of the medulla to the back of the cord, down which it passes behind the roots of the spinal nerves, being reinforced by spinal branches accompanying these nerves, in the neck, the thoracic, and in the lumbar region. It can be traced as low as the end of the spinal cord.

(4) The **anterior** spinal artery [a. spinalis anterior] comes off from the vertebral a little below its termination in the basilar artery. Descending with a medial slant in front of the medulla, it unites on a level with the foramen magnum with its fellow of the opposite side. The single vessel thus formed runs downward in front of the spinal cord beneath the pia mater as far as the termination of the cord, being reinforced by the spinal branches on the way down. The spinal arteries are described in detail with the anatomy of the spinal cord.

(5) The **posterior inferior cerebellar** [a. cerebelli inferior posterior] (fig. 456)—the largest branch of the vertebral—arises from that vessel just before it joins its fellow to form the basilar artery. At times it may come off from the basilar itself. It runs, at first laterally across the restiform body between the origin of the vagus and hypoglossal nerves, and, descending toward the vallecula, there divides into two branches, medial and lateral. (*a*) The *medial branch* runs backward between the vermis and the lateral hemisphere of the cerebellum. It supplies the vermis, and anastomoses with the artery of the opposite side, and with the superior vermian of the superior cerebellar. (*b*) The *lateral branch* runs laterally and, ramifying over the under surface of the cerebellar hemisphere, supplies its cortex and anastomoses along its lateral margin with the superior cerebellar arteries.

From the undivided trunk of the posterior inferior cerebellar artery branches are given to the medulla oblongata, supplying the chorioid plexus and the fourth ventricle.

THE BASILAR ARTERY

The **basilar** artery [a. basilaris] is formed by the confluence of the right and left vertebral arteries, which meet at an acute angle at the lower border of the pons. It runs forward and upward in a slight groove in the middle line of the pons, and divides at the upper border of that structure at the level of the tentorial notch into the two posterior cerebral arteries, which take part in the formation of the circle of Willis (fig. 456).

Branches of the Basilar Artery

The **branches of the basilar artery** are:—1. Pontine; 2. internal auditory; 3. anterior inferior cerebellar; 4. superior cerebellar; 5. posterior cerebral.

(1) The **pontine** branches [rami ad pontem] are numerous small vessels which come off at right angles on either side of the basilar artery, and, passing laterally over the pons, supply that structure and adjacent parts of the brain.

(2) The **internal auditory** artery [a. auditiva interna], a long slender vessel, accompanies the auditory nerve into the internal auditory meatus (fig 514). It here lies between the facial and auditory nerves, and at the bottom of the meatus passes into the internal ear, and anastomoses with the other auditory arteries. (See Internal Ear.)

(3) The **anterior inferior cerebellar** [a. cerebelli inferior anterior] arises from the basilar soon after its origin, passes laterally and backward across the pons, and then over the brachium pontis to the front part of the under surface of the cerebellum. It anastomoses with the posterior inferior cerebellar artery (fig. 456).

(4) The **superior cerebellar** [a. cerebelli superior] comes off from the basilar immediately behind its bifurcation into the posterior cerebral arteries. It courses laterally and backward over the pons, in a curve roughly corresponding to that of the posterior cerebral artery, from which it is separated by the third cranial nerve; but, soon sinking into the groove between the pons and the pedunculus cerebri, it curves round the latter onto the upper surface of the cerebellum, lying nearly parallel to the fourth nerve. Here it divides into two branches medial and lateral. (*a*) The *medial branch* courses backward along the superior vermis, anastomosing with its fellow of the opposite side, and, at the posterior notch of the cerebellum, with the inferior vermian branch of the posterior inferior cerebellar artery. (*b*) The *lateral* runs to the circumference of the cerebellum, anastomosing with the lateral branch of the inferior posterior cerebellar artery.

Branches are given off from the main trunk of the superior cerebellar artery, or from its medial branch to the anterior velum (valve of Vieussens), the corpora quadrigemina, the pineal body, and the chorioid plexus.

(5). The **posterior cerebral** arteries [aa. cerebri posteriores] are the two terminal branches into which the basilar bifurcates at the upper border of the pons, immediately behind the posterior perforated substance. Each artery runs at first laterally and a little forward across the pedunculus cerebri immediately in front of the third nerve, which separates it from the superior cerebellar artery. After receiving the posterior communicating artery, which runs backward from the internal carotid, the posterior cerebral turns backward onto the under surface of the cerebral hemisphre, where it breaks up into branches for the supply of the temporal and occipital lobes.

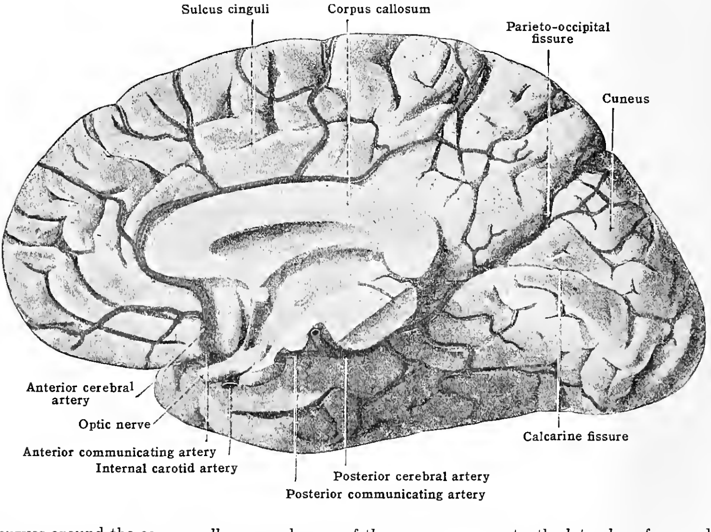
The **branches of the posterior cerebral artery** are described below in connection with those of the other cerebral arteries.

Distribution of the Cerebral Arteries

Although the brain receives its blood supply from two distinct sources, namely, from the internal carotids and from the vertebrals, it is convenient to consider together the distribution of the various cerebral branches derived from these stems. The formation of the circulus arteriosus (circle of Willis) and the origin of the anterior, middle and posterior cerebral arteries has already been described (pp. 554, 561). The detailed distribution of these vessels will now be considered. In general, their branches may be divided into *central* or *ganglionic* and *peripheral* or *cortical.*

The **anterior cerebral artery** has but a limited **central** distribution. It gives off a few inconstant branches which enter the anterior perforated substance and supply the anterior end of the caudate nucleus. One or two of these run to the corpus callosum and septum pellucidum. The **anterior communicating** branch is a transverse trunk which connects the two arteries and thereby completes the circulus arteriosus in front. It lies in front of the optic chiasm, and varies considerably in length and size. It may give off some of the branches to the anterior perforated substance. The **cortical branches** supply the gyrus rectus, the olfactory lobe and a part of the orbital gyri on the ventral surface. On the medial surface branches supply the cortex as far back as the parieto-occipital fissure. These branches are given off as the artery

Fig. 459.—The Arteries of the Mesial Surface of the Brain. (After Spalteholz.)



curves around the corpus callosum and some of them curve over onto the lateral surface and supply the superior and middle temporal convolutions. Branches from the anterior cerebral artery also supply the corpus callosum (fig. 459).

The **middle cerebral artery** gives off most of the branches to the basal ganglia and supplies the greater part of the lateral surface of the brain. It runs through the lateral fissure (fissure of Sylvius) (fig. 460). The *branches* of the middle cerebral include the following:

The **central branches** are:—(i) The **caudate,** two or three small branches, which arise from the medial aspect of the artery and pass through the medial part of the floor of the lateral fissure (fissure of Sylvius) to the head of the caudate nucleus. (ii) The **antero-lateral** are numerous small arteries which pass through the anterior perforated substance and supply the caudate nucleus (except its head), the internal capsule, and part of the optic thalamus. (iii) The **lenticulostriate,** a larger branch of the antero-lateral set, passes through a separate aperture in the lateral part of the anterior perforated substance, runs upward between the lenticular nucleus, which it supplies, and the external capsule, perforates the internal capsule, and terminates in the caudate nucleus. It has been so frequently found ruptured in apoplexy that it is called by Charcot the 'artery of cerebral hæmorrhages.' (iv) Sometimes a more or less distinct branch, called **lenticulo-optic,** is distributed to the lateral and hinder portion of the lenticular nucleus and the lateral portion of the optic thalamus.

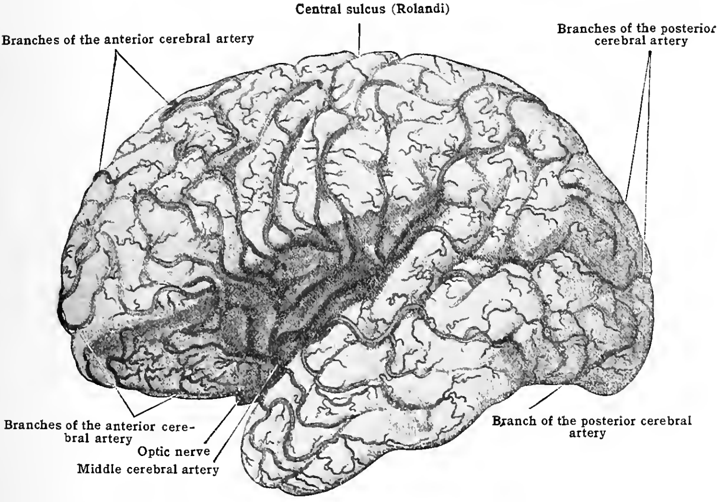
The **cortical branches** come off opposite the insula. They supply the insula, the inferior frontal gyri, the central gyri (anterior and posterior), the parietal lobules, superior and inferior, the supra-marginal, angular, and superior temporal gyri.

The **posterior cerebral** give off both central and cortical branches. The **central branches** are the postero-median, posterior chorioid, and the postero-lateral. The **postero-median** enter the posterior perforated substance and supply the medial portion of the optic thalamus, and the walls of the third ventricle; the **posterior chorioid** pass through the transverse fissure to the tela chorioidea (velum interpositum) and chorioid plexus; the **postero-lateral** run to the posterior part of the optic thalamus and give branches to the cerebral peduncles and the corpora quadrigemina.

The **cortical branches** of the posterior cerebral supply the entire occipital lobe and all of the temporal lobe except the superior temporal gyrus (fig. 459).

In regard to the cerebral arteries in general it may be said that there is no anastomosis between the cortical and central branches, the two forming distinct and separate systems. The cortical may or may not anastomose with each other, but the communication between the neighbouring cortical branches is seldom sufficient to maintain the nutrition of an area when the vessel that normally supplies it is obstructed. The central branches are so-called end-vessels and do not anastomose with each other. Hence obstruction of the middle cerebral artery leads to softening of the area supplied by its central branches, but not always to softening of the region supplied by its cortical branches. Indeed, the cortical region may escape completely, although the central area is irreparably disorganised. The gross anastomosis of the posterior cerebral with the anterior cerebral arteries through the circulus arteriosus has already been described. To sum up the distribution of the cerebral arteries, the branches of each are divided into the central, or ganglionic and the peripheral or cortical. The central branches arise at the commencement of the cerebral arteries about the circulus arteriosus whilst the cortical are derived chiefly from the termination of these vessels.

FIG. 460.—THE ARTERIES OF THE LATERAL SURFACE OF THE BRAIN. (After Toldt, "Atlas of Human Anatomy," Rebman, London and New York.)



(A) The **central branches** are divided into four sets—two median and two lateral. 1. The two **median** are—(1) The **antero-median,** which arise from the anterior cerebral and the anterior communicating, and supply the fore end of the caudate nucleus, and (2) the **postero-median,** which arise from the posterior cerebral and supply the medial part of the optic thalamus and neighbouring wall of the third ventricle. 2. The **two lateral** are:—(1) The **antero-lateral** arise from the middle cerebral, and, passing through the anterior perforated substance, supply the lenticular nucleus, the posterior part of the caudate nucleus, the internal and external capsules, and the lateral part of the optic thalamus. (2) The **postero-lateral** arise from the posterior cerebral, and supply the hinder part of the optic thalamus, the pedunculus cerebri, and the corpora quadrigemina.

(B) The **cortical branches** ramify in the pia mater, giving off branches to the cortical substance, some of which extend through it to the underlying white substance.

It will be seen that the middle cerebral supplies the somæsthetic area of the cortex. It also supplies the cortical auditory centre, and, in part, the higher visual centre. The anterior cerebral supplies only a small part of the somæsthetic area, namely, the part of the leg centre that occupies the paracentral lobule and the highest part of the anterior central gyrus. The posterior cerebral supplies the visual path from the middle of the tract backward, and the half vision centre in the occipital lobe. It supplies also the corpora quadrigemina and the sensory part of the internal capsule.

The branches which supply the cerebellum and brain stem are given in connection with the vertebrals on page 561.

2. THE THYREOCERVICAL TRUNK

The **thyreocervical trunk** [truncus thyreocervicalis] or **thyreoid axis** arises from the upper and front part of the subclavian artery, usually opposite the internal mammary, and slightly medial to the scalenus anterior. It is a short thick trunk, and divides almost immediately into three radiating branches—namely, the **inferior thyreoid,** the **transverse scapular,** and the **transverse cervical** (figs. 444, 457). This is the usual form only on the left side (see page 559). It may give off also the **ascending cervical.**

THE INFERIOR THYREOID ARTERY

The **inferior thyreoid** artery [a. thyreoidea inferior] is the largest of the three branches into which the thyreocervical trunk (thyreoid axis) divides, and may arise in a common trunk with the transverse scapular, or as a branch of the subclavian. It ascends tortuously passing medially in front of the vertebral artery, the inferior laryngeal nerve and the longus colli muscle, and behind the common carotid and the sympathetic nerve or its middle cervical ganglion, to the thyreoid gland, where it anastomoses with the superior thyreoid artery and the artery of the opposite side.

The branches of the inferior thyreoid artery are:—(1) Muscular; (2) œsophageal and pharyngeal; (3) tracheal; (4) inferior laryngeal; (5) glandular; and (6) ascending cervical.

(1) The **muscular** branches supply the scalenus anterior, longus colli, sternohyoid, sternothyreoid, and omo-hyoid muscles, and the inferior constrictor muscle of the pharynx.

(2) The **œsophageal and pharyngeal** branches [rami œsophagei et pharyngei] of the inferior thyreoid artery supply the œsophagus and pharynx and anastomose with the other arteries supplying those structures.

(3) The **tracheal** branches [rami tracheales] ramify on the trachea, where they anastomose with the tracheal branches of the superior thyreoid and bronchial arteries.

(4) The **inferior laryngeal** artery [a. laryngea inferior] passes along the trachea to the back of the cricoid cartilage in company with the inferior laryngeal nerve. It enters the larynx beneath the inferior constrictor. Its further distribution in that organ is described under Larynx.

(5) The **glandular** branches [rami glandulares] supply the thyreoid gland.

(6) The **ascending cervical** artery [a cervicalis ascendens] (figs. 444, 457) is given off from the thyreocervical trunk or from the inferior thyreoid as that vessel is passing beneath the carotid sheath. It ascends between the scalenus anterior and the longus capitis (rectus capitis anterior major), lying parallel and medial to the phrenic nerve and behind the internal jugular vein. It anastomoses with the vertebral, ascending pharyngeal, and occipital arteries, and supplies branches to the deep muscles of the neck [rami musculares], to the spinal canal [rami spinales], and to the phrenic nerve. Two veins accompany the ascending cervical artery and end in the innominate vein.

THE TRANSVERSE SCAPULAR ARTERY

The **transverse scapular** or suprascapular [a. transversa scapulæ] artery passes laterally across the root of the neck, lying first beneath the sterno-mastoid, and then in the subclavian triangle behind the clavicle and subcalvius muscle. At the lateral angle of this space it is joined by the suprascapular nerve, sinks beneath the posterior belly of the omo-hyoid, and passes over the ligament bridging the scapular notch, the nerve passing through the notch (fig. 461). It then ramifies in the supraspinous fossa of the scapula, and, winding downward round the base of the spine over the neck of the scapula, enters the infraspinous fossa, and terminates by anastomosing with the circumflex (dorsal) scapular artery, and the descending branch of the transverse cervical (posterior scapular) artery.

As it lies under cover of the sterno-mastoid muscle, it crosses the phrenic nerve and the scalenus anterior; and as it courses through the subclavian triangle, it is separated by the cervical fascia which descends from the omo-hyoid to the first rib, from the subclavian artery and brachial plexus of nerves. If this artery is seen in tying the subclavian it should not be injured, as it is one of the chief vessels by which the collateral circulation is carried on after ligature of the subclavian in the third part of its course. At the lateral part of the subclavian triangle it is covered by the trapezius, and after passing over the transverse scapular ligament it pierces the supraspinous fascia and passes beneath the supra-spinatus muscle, ramifying between it and the bone. In the infraspinous fossa it lies between the infra-spinatus and the bone. The artery is accompanied by two veins.
